17.1 INTRODUCTION

We define magnetofection as nucleic acid delivery under the influence of a magnetic field acting on nucleic acid vectors, which are associated with magnetic nanoparticles. Such methods have been developed independently by several research groups [1–14]. Since we have first introduced the term magnetofection [15], it has become widely used in the scientific literature.

Nowadays, the introduction of nucleic acids into cells is a well-established and widely used tool in research and has become a highly promising strategy for therapeutic applications. By introducing nucleic acids into cells, a wide variety of cellular processes can be influenced or exploited to some

particular purpose by having nucleic acids interact with cellular components or having genetic information encoded in nucleic acids expressed in cells. Almost 40 years of research has yielded highly efficient shuttles for nucleic acid delivery, which are genetically modified viruses and their synthetic counterparts and which are commonly known as viral and nonviral vectors. Yet, further improvements with respect to the efficiency and the specificity of nucleic acid delivery are required and can be achieved. This is mostly evident *in vivo* where the target cells not only are often refractory to transfection or transduction but also the access to the target cells is limited by multiple barriers in addition to those that are prevalent on the cellular level. The latter are relatively well

defined. Limiting steps on the cellular level include, for example, overcoming the plasma membrane, escape from internal vesicles, and suitable intracellular localization (e.g., if required, intracellular transport toward the nucleus, nuclear uptake, and suitable localization within the nucleus). Nature itself has optimized viruses in overcoming such limitations. Consequently, nonviral vectors were often designed to mimic essential viral functions that allow them to infect cells and were equipped with modules that mediate binding to cells, uptake via natural transport processes, escape from endosomes, and nuclear uptake. No matter the level of perfection to which the nature has evolved viruses or how sophisticated nonviral vector engineers have been in copying their design, vectors, in the first place, need to find their target cells. Independent of vector type, vector contact with target cells is the primary event in, and a prerequisite for, a successful transfection/transduction process. The frequency and total number of productive cell binding events are dependent on the vector concentration in the culture medium and are limited by diffusion under standard cell culture conditions. This is due to the fact that viral vectors, in general, and nonviral vectors, usually, are nanoparticles and as such can reach target cells in culture only by diffusion unless further measures are taken.* As diffusion is a slow process and many vector types are subject to time-dependent inactivation under cell culture conditions (as well as being toxic in very high concentrations), measures that accelerate vectors toward target cells and, thus, increase the vector concentration at the cell surface can improve transfection/transduction efficiency [16]. In this context, the most convenient measure in cell culture has been exploiting gravitation. For example, vectors have been associated with dense silica particles to overcome the diffusion limitation [17]. Precipitate formation with nucleic acids is, in fact, the oldest nonviral method to achieve nucleic acid delivery in cell culture [18] and also nowadays, gravitation is exploited unwittingly by most researchers performing *in vitro* transfections with commercially available reagents. Most cationic lipids and polycations form precipitates with nucleic acids in salt-containing solution. Also, centrifugal force [19–22] and convective flow of transfection medium toward target cells [23] enhance nucleic acid delivery by accelerating vectors toward the cells to be transfected. All these methods are physical means of vector targeting. For obvious reasons, some of these methods cannot be applied *in vivo*. Magnetofection is another physical means of vector targeting, which at least has the potential for efficient *in vivo* application.

17.2 MAGNETIC DRUG TARGETING AND THE PRINCIPLE OF MAGNETOFECTION

Certain medical indications of localized disease predictably will profit from methods of localized drug delivery. Typical

examples include solid tumors before systemic spread where surgical excision is not an option or where conventional means of therapy have been exhausted. Standard therapy with cytotoxic drugs involves “flooding” the patient with medication to achieve a sufficiently high drug concentration at the disease site. Not surprisingly, such treatments are frequently associated with severe side effects that compromise the patient’s quality of life, if not worse.

Already in the mid-1960s, researchers attempted the first steps of exploiting magnetic fields to localize carbonyl iron in intracranial aneurisms and in this manner produce magnetically localized thrombi [24–27]. In the 1970s, Widder and colleagues introduced the concept of magnetic drug targeting [28], designed for accumulating drugs mostly in tumors upon administration into the circulation. Active agents are associated with magnetically responsive materials in the nano- to micrometer size range and are accumulated at the site of disease by a suitable magnetic field (Figure 17.1). The magnetic carrier materials are mostly iron oxides of various compositions, which can be of natural or synthetic origin [16,29–31]. In a first step, Widder and coworkers prepared albumin microspheres with entrapped iron oxide and adriamycin, infused them into the caudal artery of rat tails, and demonstrated magnetic retention in a tail segment exposed to a permanent magnet. In another study, they applied magnetic albumin microspheres with entrapped doxorubicin in a Yoshida sarcoma rat model. A 100-fold higher dose of free doxorubicin was required to achieve the same drug level in the tumor as with the magnetically targeted drug [32]. The treatment was therapeutically effective in that it resulted in total tumor remission in a high percentage of experimental animals. In contrast, animals treated with free doxorubicin, placebo microspheres, or nonlocalized doxorubicin microspheres exhibited a significant increase in tumor size with metastases and subsequent death in 90%–100% of the animals [33,34]. Other researchers obtained similar results [35–41]. After extensive preclinical examinations, Lübke et al. were the first to apply magnetic drug targeting in a phase I clinical trial with 14 cancer patients where other therapeutic options had been exhausted [42–45]. The treatment was well tolerated and retardation of tumor growth and even local remissions were observed [45]. Nevertheless, one conclusion of the study was that improvements of magnetic drug targeting were required to make it more effective, at least in cancer therapy. Alexiou et al. tried to improve the efficacy in a tumor-bearing rabbit model by using the strongest magnetic field (generated through an electromagnet) ever applied in magnetic drug targeting [46,47]. The results were quite favorable. On the other hand, an independent clinical phase II/III trial for the treatment of hepatocellular carcinoma with a magnetic carrier composed of elementary iron [48–50] had to be discontinued as the clinical endpoints could not be met with statistical significance. In summary, at least in animal models it has been clearly demonstrated that (1) magnetic drug targeting is feasible even if the drug administration site is remote from the target site under magnetic field influence [43,51], (2) that magnetic particles can extravasate under the

* For lipoplexes and polyplexes, this holds true with the limitation that they often tend to aggregate, depending on their surface characteristics and on the ionic strength of the medium. For their aggregated forms, gravitation is of course the driving force that lets them sediment on cells.

FIGURE 17.1 (See color insert following blank page 206.) Magnetic drug targeting. An anticancer drug (e.g., mitoxantrone) bound to magnetic particles is injected into a blood vessel (here tumor-feeding blood vessel) of the patient and is concentrated in the target tissue (e.g., tumor) by an external magnetic field. (From Siemens AG, Pictures of the Future 01/2007, page 64, www.siemens.com/pof. With permission.)

influence of the magnetic field [37,52,53], and (3) that the magnetic carriers are well tolerated.

Similar motivations that inspire the development of magnetic drug targeting apply to developing nucleic acid or gene therapies. The objective is to achieve therapeutic benefit for patients with ever improved specificity and less side effects, particularly in cases where conventional treatments fail. However, achieving and maintaining therapeutic drug levels at target sites is an even bigger challenge with nucleic acids or vectors than it is with conventional drugs. Therefore, we and others have considered magnetic targeting of nucleic acids or gene vectors to be a promising concept.

The principle of magnetofection, as we and others have reported, is quite simple; although several technical hurdles had to be overcome to make it work efficiently. Naked nucleic acids or gene vectors are bound to magnetic nanoparticles, and in analogy to magnetic drug targeting, a magnetic field is used to accumulate nucleic acids or vectors at target cells (Figure 17.2). *In vitro*, this is straightforward, *in vivo*, several challenges remain as are discussed later.

The first to pursue this idea were Kuehnle and Kuehnle in a patent application filed in 1994 (U.S. patent 5516670 issued in 1996) where they describe torpedo-like magnetic particles

FIGURE 17.2 Magnetofection in cell culture. Nonviral or viral vectors associated with magnetic nanoparticles (magnetofectins) are accelerated onto a cell layer in a culture dish through magnetic force. The result is rapid and efficient transfection, even at lower vector doses. (Modified from Plank, C., Schillinger, U., Scherer, F., Bergemann, C., and Remy, J.S., *Biol. Chem.*, 384, 737, 2003. With permission.)

that may be suitable to deliver DNA as well as an apparatus generating a magnetic field for delivery. Chan describes the use of pulsating magnetic fields for introducing nucleic acids that are associated with magnetic nanoparticles into cells in a patent application filed in 1996 (U.S. patent 5753477 issued in 1998). These patents contain interesting ideas and instructive experimental setups. But unfortunately, significant experimental results are missing. Only in the year 2000, Mah et al. presented the first scientific abstract on associating AAV vectors reversibly with magnetic microspheres of varying diameters, which led to increased vector transduction efficiencies [54]. We have first reported on magnetofection and publicly used this term at a scientific conference in the year 2000 [15]. The work of Hughes and coworkers on magnetically enhanced retroviral nucleic acid delivery was the first to be published in a peer-reviewed journal [1] followed briefly later by our own work [2,55] and Mah's paper on magnetically enhanced AAV vector-mediated gene delivery [3]. In the same year, Pandori and coworkers reported about adenovirus-magnetic microbead conjugates [4] and adenoviral transduction enhanced and guided by a magnetic field. Since then, numerous papers have been published about magnetofection method development or that involve the use of magnetofection methods as research tools (see also Tables 17.1 and 17.2). Also, magnetofection reagents have become commercially available in the meantime. Promising more recent developments include the use of a special type of alternating magnetic fields to enhance gene delivery [56] and a method called nanotube spearing where DNA is immobilized on nickel-embedded nanotubes, which are speared by magnetic force into cells *in vitro* [57].

17.3 WHAT IS NEEDED TO PRACTICE MAGNETOFECTION?

17.3.1 NUCLEIC ACIDS AND/OR GENE VECTORS

It has turned out that cellular uptake during magnetofection involves the same mechanisms that also govern conventional transfection/transduction processes [22]. Therefore, the chemical, physical, and biological characteristics of nucleic acids and vectors are as essential in magnetofection as they are in conventional nucleic acid delivery. For example, we have found that endosomolytic agents like the influenza peptide INF7 promote transfection efficiency in magnetofection as they do in conventional transfection [2]. Important characteristics of vectors and their components when to be assembled with magnetic nanoparticles are predominantly charge, size, and the possibility of chemical coupling reactions. Accordingly, strategies of assembling vectors with magnetic particles can be developed and magnetic particle synthesis can be adjusted to the needs of the assembly process.

17.3.2 MAGNETIC PARTICLES

To be useful in magnetofection, magnetic particles need to fulfill some essential features (text with modifications from Ref. [58]):

1. They need to comprise functionality which allows them to be associated with nucleic acids, gene vectors, and, if necessary, third components (e.g., a polycationic or lipidic transfection reagent).
2. The association with nucleic acids, gene vectors, or third components must not impair their functionality in delivery and intracellular processing.
3. Their magnetic properties need to be such that they or at least their formulations with nucleic acids, vectors, or further components can be attracted toward target cells using "reasonable" magnetic force. Reasonable in this context means that the device generating the magnetic force must be affordable enough and must have dimensions compatible with handling in a research laboratory. Reasonable magnetic force also means that the magnetic field itself does not unduly impair cellular functions.
4. They must be physically and chemically stable enough to be stored over several months in a pharmaceutically acceptable suspension medium.
5. Their magnetic core and their surface coatings have to be biocompatible, so that they can be applied in living cells and organisms.

Magnetic particles that meet these requirements and that have been used in magnetofection consist of a magnetic iron oxide core (e.g., magnetite [Fe₃O₄] or maghemite [Fe₂O₃]) and are coated with different, usually charged polymers (Figure 17.3). Although magnetic nanoparticle synthesis is textbook knowledge [59,60], it is still a science and an art in its own rights [61]. Among the many different synthetic procedures that yield magnetic nanomaterials, essentially two types can be discriminated: one involving high temperature, usually carried out in organic solvent and often starting from organometallic precursor compounds. These procedures yield extraordinarily uniform magnetic nanomaterials whose particle size reportedly can be tuned by adjusting the reaction conditions [62]. The resulting magnetic nanoparticles are usually coated with hydrophobic compounds such as oleic acid and are dispersed in organic solvent. Their use in biological applications requires special procedures to transfer them into aqueous environment while avoiding agglomeration (for example, providing them with a second, amphipathic coating layer). The other type of synthetic procedure is less sophisticated and involves relatively mild aqueous reaction conditions throughout the synthesis. Magnetic particles derived with this latter synthetic procedure have been mostly used in magnetofection applications [63] (a detailed protocol is provided in Ref. [58]). The synthesis starts from aqueous, sterile filtered, and degassed solutions of iron(II) and iron(III) salts. A primary precipitate is formed by the addition of a base such as aqueous ammonia in the presence of a compound intended to serve as a stabilizing layer on the newly formed particle surface. The material is then heated to 90°C and magnetic material forms. After cooling to room temperature, various sonication, dialysis, or washing steps are carried out in order to remove excess stabilizing compound. A large variety of particles can

FIGURE 17.3 Magnetic particles. (A) Brown iron oxide nanoparticles suspended in water are attracted by an applied permanent magnet. (B) Transmission electron micrographs of magnetic particles coated with PEI. No stain was used and therefore only the electron-dense iron oxide crystals but no PEI molecules are visible. The magnetic particles are organized in multidomain structures of irregular shape. (From Plank, C., Schillinger, U., Scherer, F., Bergemann, C., and Remy, J.S., *Biol. Chem.*, 384, 737, 2003.)

be generated using this basic protocol with different stabilizers such as derivatized dextrans or starch or polycations such as polyethylenimine or polylysine or protamine sulfate, or polyanions such as citrate, polyaspartic acid, phosphorylated starch, polyacrylic acid, arabinic acid, and many other compounds. The hydrodynamic diameters of such particles can range from 20 nm to the micrometer-range [60,64,65]. Recently, Chorny and coworkers have reported on a novel way of preparing polylactide magnetic particles [66]. Their procedure involves an emulsification-solvent evaporation method in the presence of PEI and polylactide applied to oleate-coated magnetic nanoparticles (synthesized similarly as described above). Also, this magnetic carrier for plasmid DNA turned out to be highly useful in magnetically driven gene delivery.

The “responsiveness” of magnetic particles to magnetic fields is dependent, on the one hand, on their material properties and, on the other hand, on the characteristics of the magnetic field. The important material properties are the magnetic susceptibility and the saturation magnetization that determine the magnetic moment. The magnetic force acting on magnetic nanoparticles is dependent on their size, the magnetic field gradient, and the magnetic flux density (below the limit of magnetic saturation of the particles). To our knowledge, so far only iron oxide magnetic nano- and microparticles have been used in magnetofection applications. Compared with elementary iron, iron-cobalt, iron-platinum, or other magnetic nanomaterials, the iron oxides have relatively low saturation magnetization. Nevertheless, their magnetic properties are entirely sufficient at least for magnetofection in cell culture where the target cells can be brought in closest proximity to

the source of a magnetic gradient field. Maximum magnetic responsiveness is of course desirable for intravascular applications *in vivo*. However, in this case, the major material characteristics in favor of iron oxides are their proven biocompatibility [67]. These materials have been in clinical use as contrast agents in magnetic resonance imaging (MRI) for many years. Iron oxide magnetic nanoparticles are biodegradable and their iron sooner or later is fed into the iron storage pool, which, for example, is of several grams in the human body. In this context, it is interesting to note that chemists were not the first to design iron oxide particles. Magnetite crystals are found in living organisms such as magnetotactic bacteria, in the central nervous systems of fish, and even in the human brain [68–71]. At least for fish, magnetite has been defined as a magnetoreceptor essential for orientation along the earth’s magnetic field [70], and there is experimental evidence that similar mechanisms apply in migratory birds [72].

Finally, a few remarks on the term magnetic and on particle size: the literature in magnetic drug targeting and MRI often refers to superparamagnetic iron oxide nanoparticles (SPION). In very simplified terms, superparamagnetic behavior means that particles are magnetized only when they are in an external magnetic field and show no residual magnetization once the external magnetic field is removed [29]. This is due to the so-called Brownian relaxation. With very small particles, magnetization of the particles is immediately destroyed by thermal motion once the external field has been turned off. True superparamagnetism is very difficult to achieve at room temperature and is dependent both on

magnetic core size and shell properties (for example, aggregation phenomena can destroy superparamagnetic behavior) [73,74]. Concerning the purpose of magnetofection in cell culture, properties like superparamagnetism are not required. It is even such that there appear to be no special requirements on magnetic particle core size for magnetofection above a certain lower limit and below an unknown upper limit. The lower limit is dictated by basic laws of physics and chemistry and reasonable magnetic force as defined above. We have found that particles with a magnetite crystallite size of 9–11 nm are superior to smaller particles with 3–4 nm crystallite size as components of the magnetic transfection vectors for magnetofection. Concerning the unknown upper size limit, it is remarkable that, for example, in Hughes's work, magnetic microparticles linked by the extremely stable biotin–streptavidin interaction to retroviral vectors were fully compatible with viral infectivity [1]. In summary, for magnetic targeting, particularly *in vivo*, it is certainly desirable to have magnetic particles with maximum magnetic susceptibility, as long as they are biocompatible. However, so far there is no indication that magnetofection in cell culture would benefit from maximizing magnetic force acting on magnetic nucleic acid vectors (passages of the above text are from Ref. [58]).

17.3.3 ASSOCIATING NUCLEIC ACIDS OR VECTORS WITH MAGNETIC PARTICLES

In general, possible ways of association are biological (e.g., receptor–ligand), physical (e.g., electrostatic, hydrophilic, hydrophobic), and chemical (covalent) conjugation.

A very straightforward possibility of linkage is to mix preassembled nucleic acid vectors (e.g., polyplexes, lipoplexes, or viruses) with charged magnetic nanoparticles and to incubate them for several minutes in physiological salt-solution until they associate through physical self-assembly (Figure 17.4A). This strategy is based on the natural tendency of polyelectrolyte nanoparticles to aggregate at elevated ionic strength, also known as salt-induced colloid aggregation [75]. As nucleic acid vectors and the magnetic particles described above are usually charged nanoparticles, they are amenable to this phenomenon. In this way, even similarly charged particles will associate because their repulsive Coulomb forces can be overcome by the attractive van der Waals forces when the particles approach each other closely enough. At elevated ionic strength (e.g., physiological salt concentration), such an approach is possible because the extension of the so-called diffuse layer of counterions surrounding charged particle surfaces is greatly reduced compared with salt-free conditions. Thus, for binding a charged nucleic acid vector, it does not play an important role if the magnetic nanoparticles used are positively or negatively charged. Interestingly, binding via salt-induced aggregation works not only when preassembled vectors are mixed with charged magnetic particles but also when vector components and magnetic particles are mixed step by step. In our experience, the mixing order can play a role, but not a major one. More important are the ratios of the various components (magnetic particles, nucleic acid, or

preassembled vector, third components such as polycations or cationic lipids). In binary systems (for example, polycation-coated magnetic nanoparticles plus viral vector particles), the association behavior is usually simple. At a certain ratio of the components, magnetic particles and vectors will be quantitatively associated with one another [2] (Figure 17.4B and C). When either component is in excess, either free magnetic particles or free vector particles will coexist with magnetic particle–vector complexes. In ternary systems, for example, PEI-coated magnetic particles plus nucleic acid plus free PEI, there may be a complex binding behavior. In salt-free aqueous suspension, the nucleic acid is able to bind to the magnetic nanoparticles but will be competed off by free PEI. In contrast, in salt-containing solution, the nucleic acid can be competed off the magnetic nanoparticles by free PEI, but the resulting nucleic acid–PEI nanoparticles can then undergo salt-induced colloid aggregation with the magnetic nanoparticles. At large excess of free PEI, the abundant species can be PEI–nucleic acid particles coexisting with magnetic nanoparticles not associated with the nucleic acid. Therefore, it is essential that for any combination of magnetic nanoparticles with nucleic acids or vectors, the binding behavior is determined. This can be carried out most accurately with radioactive-labeled vectors or vector components as we have described previously [2,16] (Figure 17.4B and C). In general, however, any commercially available transfection reagent can be transformed into a magnetic vector via salt-induced aggregation [16,76]. Apart from actually determining the association behaviors, also serial titrations of vector compositions can be carried out and the optimal vector composition can be determined in transfection experiments. If magnetic field application displays a strong enhancing effect on transfection efficiency, one can *bona fide* assume that the vector or the nucleic acid was indeed associated with magnetic particles. Magnetic vector compositions can be further refined by carrying out chemistry on any of the components pre- or post-assembly in order to attach effectors of nucleic acid delivery such as targeting moieties, endosomolytic components, or molecules for steric stabilization [77]. Although salt-induced colloid aggregation provides a simple and efficient binding method, it has to be considered, on the one hand, that very large aggregates could lead to embolism when injected into blood vessels. Appropriate aggregate sizes can be chosen by incubation times in salt-containing medium (Figure 17.4D). On the other hand, noncovalently associated magnetic vector preparations may dissociate in the blood stream due to opsonization or mediated by the extracellular matrix in target organs. Therefore, different ways of magnetic vector preparation can be advantageous for *in vivo* applications.

Another approach exploiting electrostatic interactions for vector assembly was chosen by Hirao et al. [5] who prepared magnetic nanoparticle-containing cationic liposomes, which can be associated with DNA. In a further physical strategy, Haim et al. [11] formed complexes between lentiviral vectors and negatively charged magnetite nanoparticles (coated with starch-phosphate) by colloidal clustering which was facilitated by divalent cations. Similarly, for virus concentration,

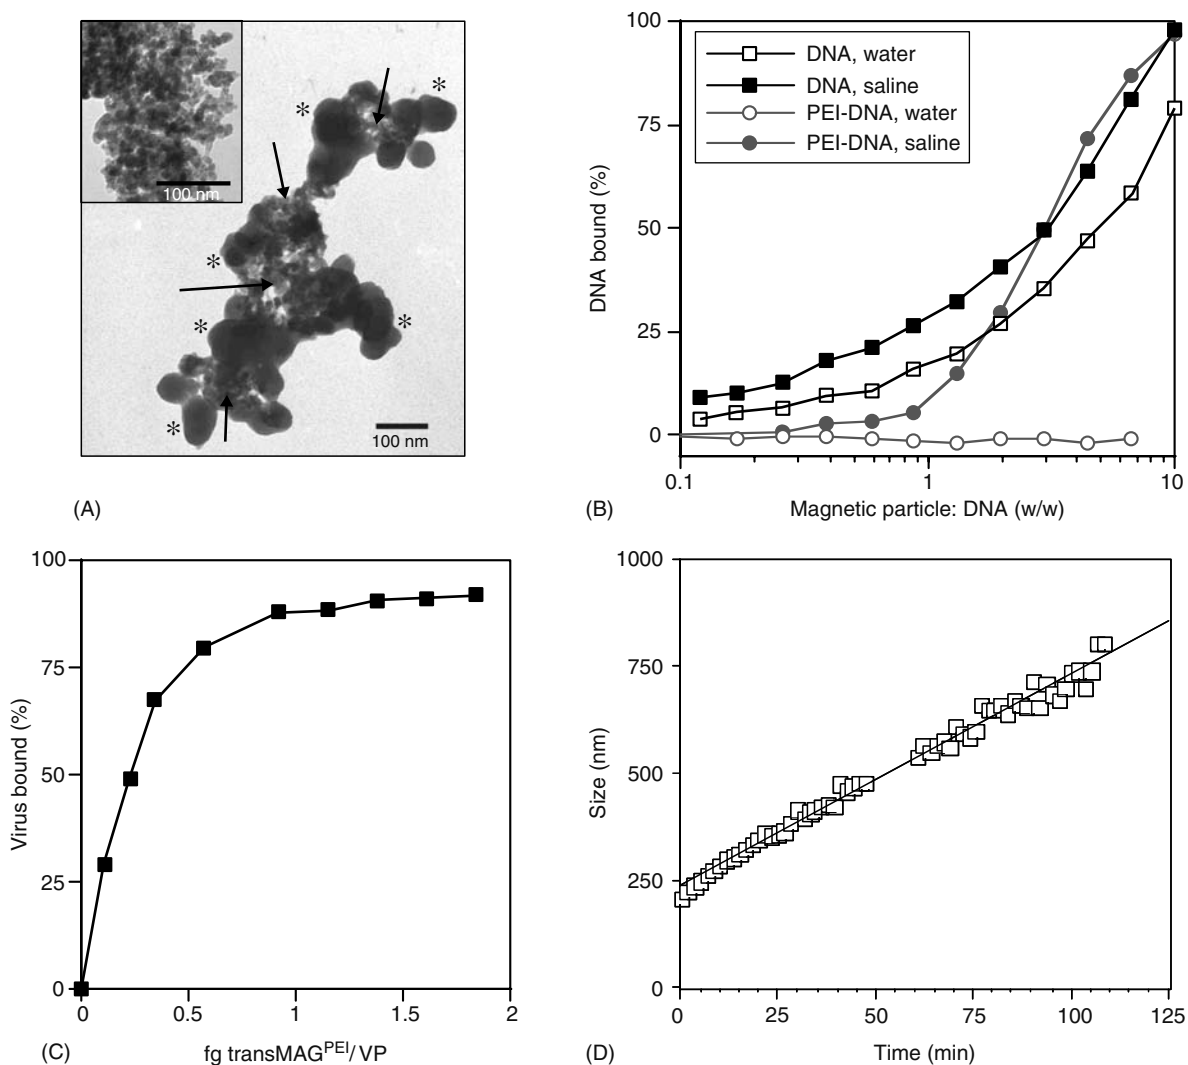

FIGURE 17.4 Binding of nucleic acid (vectors) to iron oxide (magnetite) nanoparticles coated with the polycation PEI. (A) Electron micrograph showing an extended associate of magnetic particles (arrows) and PEI-DNA vectors (asterisks) produced through salt-induced aggregation. For comparison, the inset shows only the iron oxide crystals. (From Plank, C., Anton, M., Rudolph, C., Rosenecker, J., and Krotz, F., *Expert Opin. Biol. Ther.*, 3, 745, 2003. With permission.) (B) Percentage of radio-labeled DNA bound to magnetic particles in dependence of the particle/DNA weight ratio. Only in salt-containing solution (150 mM NaCl) binding of positively charged PEI-DNA vectors is possible. This phenomenon is the result of salt-induced aggregation. (From Scherer, F., et al., *Gene Ther.*, 9, 102, 2002. With permission.) (C) Percentage of radio-labeled adenovirus bound through salt-induced aggregation to magnetic particles in dependence of the particle/virus ratio. (From Plank, C., Schillinger, U., Scherer, F., Bergemann, C., and Remy, J.S., *Biol. Chem.*, 384, 737, 2003. With permission.) (D) Time-dependent growth of salt-induced aggregates (measured by dynamic light scattering) resulting from magnetic particles plus PEI-DNA in 150 mM NaCl. The particles aggregate with approximately linear kinetics starting at 217 ± 2 nm and remaining in the submicrometer range within 2 h. (From Plank, C., Schillinger, U., Scherer, F., Bergemann, C., and Remy, J.S., *Biol. Chem.*, 384, 737, 2003.)

Iwata et al. bound sulfonated magnetic beads to porcine parvovirus and poliovirus via divalent cations like Zn^{2+} or Cu^{2+} [78].

Of course, not only physical binding can be exploited for nucleic acid or vector association with magnetic particles but also biological conjugation. Hughes et al. [1] used three different biological strategies to bind retroviral vectors to magnetic microparticles. They conjugated streptavidinylated magnetic

particles to (1) a biotinylated antibody directed against the retroviral vectors, (2) biotinylated lectin, which binds to retroviral vectors, and (3) biotinylated retroviruses. Chan et al. and Nesbeth et al. linked streptavidin magnetic microspheres to biotinylated nonviral producer cell proteins that were incorporated into lentiviral surfaces [10,79]. Further, Pandori et al. coupled biotinylated adenoviral vectors to streptavidin-coated magnetic microparticles [4]; Mah et al. used magnetic

avidin-microspheres to bind biotinylated heparan sulfate, which was reversibly bound to adeno-associated viruses [3]; and Raty et al. associated avidin-displaying baculoviruses to biotinylated magnetic particles [9].

An interesting chemical strategy for binding was used by Cao et al. [80]. They conjugated plasmid DNA to dextran iron oxide nanoparticles by an oxidation–reduction reaction [80].

One can assume that biotin–streptavidin bridges between vectors and magnetic particles will be more stable *in vivo* than noncovalent linkages. On the other hand, the noncovalent ways of association may facilitate intracellular processing due to the reversibility of the linkage. These questions require further experimentation. In summary, any of the described methods yielded very favorable results in magnetofection applications *in vitro*.

17.3.4 MAGNETS

To an average citizen and even to most scientists, if they are not physicists or electrical engineers, magnetic fields still have something mysterious. One cannot see these fields and usually one cannot feel them. Much remains to be elucidated on their impacts on cell physiology. But concerning their actions on magnetic nanoparticles, there is nothing mysterious at all. The magnetic force acting on magnetic nanoparticles is described by the following formula [81]:

$$F_m = (m \cdot \nabla)B = \frac{1}{2} \cdot \frac{\Delta\chi V}{\mu_0} \cdot \nabla B^2$$

where

- m is the magnetic moment of the particle
- B is the magnetic flux density
- $\Delta\chi$ is the magnetic susceptibility difference of between the magnetic particles and the surrounding medium
- V is the volume of the particles
- μ_0 is the permeability of vacuum
- ∇B is the magnetic field gradient

This means that the essential parameters for magnetic accumulation are the volume (and thus the third power of the radius) of the particle and the field gradient. The magnetic flux density (measured in tesla [T]) only has an influence below the limit of saturation magnetization of the particles, which is a material property (measured in $A \cdot m^2/kg$). Magnetic nanoparticles will move in a magnetic field only if it is not homogenous, if the particles experience a field gradient (measured in T/m). In other words, they will migrate toward the highest density of magnetic field lines. Further implications of this formula are discussed toward the end of the chapter. In magnetofection, the applied magnet has the task to move the magnetic particle–nucleic acid associates to the target site. This means in practice that target sites ought to be subject to a magnetic flux density, which is sufficient to cause saturation magnetization of the magnetic drug carrier and ought to be subject to the highest field gradient possible. This implies that for *in vivo* applications, magnets ought to be tailor-made according to the anatomy of the target site to optimize

magnetic retention. This is all the more important as magnetic flux density and field gradient rapidly decrease with the distance from the source of the magnetic field.

For magnetofection in cell culture, the requirements are not that challenging. As described above, the magnetic force acting on magnetic vectors is proportional to the size of the magnetic particle associated with the vector. Hughes et al. [1], for example, have used micrometer-sized magnetic particles in their work [1]. This is probably the reason why a thin magnetic sheeting (Bisiflex II) was sufficient to attract their vector (a retrovirus) to the target cells (though, during a 24-h incubation period). In most cases, however, rare earth permanent magnets are used (e.g., neodymium–iron–boron magnets), which produce magnetic flux densities of around 1 T at their surfaces. The field gradients they produce are dependent on the magnet geometry. We have, for example, developed a magnetic plate in the 96-well format where cylindrical shaped Nd–Fe–B magnets are inserted in an acrylic glass template in strictly alternating orientation (Figure 17.5A). These plates produce a magnetic flux density between 0.13 and 0.24 T and a magnetic field gradient between 67 and 123 T/m at a distance of ~2 mm from the individual magnets' surfaces. This would be the position where the cells are located when seeded in a 96-well plate and positioned on this magnetic plate. This magnetic induction leads to approximately 80% saturation of particles consisting of almost pure magnetite for which an induction of 0.5–0.6 T is necessary to achieve 100% saturation (Mykhaylyk O., unpublished data, 2005). Although induction and gradient decrease rapidly with increasing distance from the surface of the magnet, for magnetic sedimentation in cell culture this magnetic device is very efficient. In the meantime, such devices are commercially available (www.ozbiosciences.com, www.chemicell.com). Individual magnets can be bought from numerous companies, so anyone can build their own devices for magnetofection [12].

Nd–Fe–B magnets were also used successfully for some *in vivo* applications where the magnet could be applied directly onto the target tissue (e.g., onto the ear vein of pigs, the ear artery of rabbits, the surface of tumors or through surgery onto the ileum of rats, the stomach of mice, and the testicles of mice) [2,82,83]. The magnets used in these proof-of-principle experiments were not optimized in design and shape. Whether magnetic retention against the viscous drag force of the blood flow is feasible or not is dependent on many parameters. On the basis of the physical considerations, it is not possible, for example, to retain individual nonaggregated nanoparticles upon first pass with reasonable magnetic force at high blood flow rates, which are prevalent, for example, in the aorta (20 cm/s). On the other hand, magnetic retention is feasible even upon first pass at more moderate flow rates and is increased if a magnetic formulation passes the target site several times (this is the so-called avalanche effect). Particles that have been deposited upon first pass are a source of strong field gradients themselves in an external magnetic field and contribute to the retention of further particles at second and third pass, etc.

FIGURE 17.5 Magnets. (A) Example for an array of permanent Nd–Fe–B magnets on which a 96-well plate can be positioned. The cylindrical magnets are inserted in an acrylic glass template in strictly alternating polarization to permit a relatively homogenous sedimentation of magnetic particles on cells growing in the wells. (B) Electromagnet constructed for magnetic drug targeting by Siemens AG. The magnet is high scalable in field gradient. (From www.siemens.de/pof. With permission.)

As mentioned above, for *in vivo* applications, magnetic devices ought to be tailor-made in the optimal case. Recently, Siemens AG, Germany, has developed a prototype electromagnet for magnetic drug targeting (Figure 17.5B). This magnet produces a field gradient of more than 100 T/m at the pole tip and at a distance of 22 mm of 10 T/m [84]. The magnetic flux density is scalable and is sufficient to induce magnetic saturation of iron oxide nanoparticles in a target volume at some distance of the pole shoe, which would, for example, be suitable for magnetic drug targeting in superficial tumors. Also Gleich and colleagues have reported on the design of electromagnets for magnetic drug targeting [85] and have come up with similar designs as Siemens. Evaluation of these magnets for *in vivo* magnetic drug targeting and magnetofection is in process.

It has been mentioned in Section 17.1 that one of the earliest accounts of magnetofection-type methods can be found in the patent literature. In his patent issued in 1998, Chan describes the use of magnetic field pulses acting on oligonucleotides bound to magnetic nanoparticles (U.S. patent 5753477). The equipment he used produced extremely strong field pulses (micro- to millisecond pulses of 2–50 T). Chan describes that his method worked best if he first induced magnetization of the particles (and at the same time orientation along the field lines) with a permanent magnet and then applied the strong field pulses.

A novel technique using alternating magnetic fields in a magnetofection-type method has been described recently by Kamau and colleagues [56]. The magnetic device they use (the so-called dynamic marker) produces a relatively complex pulsating field with a sinus type wave perpendicular to the cell culture plate overlaid with a field modulation in the plane of the cell culture plate at low frequency. It is speculated that

such alternating fields may cause some oscillation of magnetic particles, which may facilitate cellular uptake when the particles are bound to cell surfaces. What really happens is not understood. In any case, using this technique, Kamau et al. achieved quite substantial improvements in the percentage of transfected cells in a variety of cell lines. Again, a combination of premagnetization with a permanent field followed by application of the dynamic field resulted in synergistic enhancements.

Highly surprising results have been reported by Cai and coworkers who report on a method they call nanotube spearing [57]. They prepared carbon nanotubes grown by plasma-enhanced chemical vapor deposition, which have ferromagnetic nickel in their tips. DNA was bound to such nanotubes. Gene delivery even to very difficult transfect cells such as primary B cells was highly successful when the cells were immobilized on grids or coverslips and were exposed to the carbon nanotube spears in a simple beaker, which was placed on a simple magnetic stirrer operated at 1200 rpm. Obviously, the weak rotating field of a laboratory magnetic stirrer is sufficient to induce rotation or oscillation in the magnetic nanotubes. Also, in this case, exposition to a permanent field combined with the application of the rotating field resulted in synergistic enhancements of gene delivery.

In summary, efficient magnetofection in cell culture can be achieved with very simple magnetic devices even with weak gradient fields and can reportedly be improved with still somewhat exotic nonstatic fields. For the latter, substantial research is required to understand their mechanisms of action. *In vivo* magnetofection can be mediated with simple permanent magnets; however, it is expected that magnetic drug targeting, in general, will greatly profit from tailor-made magnets.

17.4 USE OF MAGNETOFECTION

The previous chapters have given an overview on the historical development of magnetofection techniques and on the tools that are required to perform magnetofection. In this section, we discuss magnetofection techniques in cell culture and *in vivo* and highlight its fundamental features which in summary are the following:

1. Magnetofection appears to be applicable with any known nucleic acid vector and nucleic acid type.
2. Magnetofection can improve the dose-response profile of many vectors when compared with nucleic acid delivery with the same vector under conventional conditions. This improvement applies to the overall expression of a transfected/transduced gene or the overall downregulation of target gene expression (antisense, siRNA) as well as to the percentage of transfected/transduced cells. This improvement allows the user to save valuable vector material.
3. Magnetofection can greatly improve the transfection kinetics of many vector types.
4. Magnetofection can be used to localize nucleic acid delivery *in vitro* and *in vivo*.
5. The transfection/transduction mechanism with magnetofection does not appear to differ fundamentally from conventional transfection/transduction. The major impact of magnetic field influence in cell culture appears to be the rapid sedimentation of the full

applied vector dose on the target cells within a short period. In this manner, transfection/transduction likely proceeds in a more synchronized manner than in conventional transfection/transduction.

17.4.1 MAGNETOFECTION IN CELL CULTURE

17.4.1.1 Comparison to Standard Transfections/Transductions with Regard to the Nucleic Acid Transfer Efficiency

In our first published reports on magnetofection, we have compared reporter gene expression upon transfection/transduction with a variety of nonviral and viral vectors under conventional and magnetofection conditions [2,55]. For example, two different cell types (NIH 3T3 and CHO-K1) were incubated for 4h or only for 10min with four different standard vectors (PEI-DNA, PEI-DNA-inactivated adenovirus, GenePorter-DNA, and Lipofectamine-DNA) under conventional transfection conditions or under magnetofection conditions for 10 min (meaning the same vector associated with magnetic nanoparticles under the influence of a magnetic field) (Figure 17.6A). Depending on vector type and incubation time, the observed enhancements in luciferase reporter gene expression were quite substantial. In this example, magnetofection was always superior to conventional transfection when 10min incubation times were compared and was usually superior even when 10min magnetofection was compared with 4h conventional transfection. The enhancing effect was particularly strong with

FIGURE 17.6 (See color insert following blank page 206.) Enhancements achieved with nonviral magnetofection. (A) Comparison of magnetofections (with magnetic field 10 min incubation) with their corresponding standard transfections (4h incubation) in NIH 3T3 and CHO-K1 cells. In the table, enhancements of magnetofection over transfections without (w/o) magnet are specified. AVET, adenovirus enhanced transfection. (B) Comparison of Lipofectamine magnetofection and Lipofectamine standard transfection in CHO-K1 cells with regard to their DNA dose-response profile. (From Scherer, F., Anton, M., Schillinger, U., Henke, J., Bergemann, C., Krüger, A., Gänzbacher, B., and Plank, C., *Gene Ther.*, 9, 102, 2002. With permission.)

Lipofectamine but was less pronounced (10min magnetofection vs. 10min conventional) or absent (10min magnetofection vs. 4h conventional) with GenePorter. With Lipofectamine, the advantage in the dose–response profile was such pronounced that magnetofection with a low vector dose yielded higher reporter gene expression levels than an eightfold higher dose of the conventional vector (Figure 17.6B) [76]. At that time, we speculated that the observed enhancements were due to a higher number of vector–cell contacts within the incubation time mediated by magnetofection versus conventional transfection. Later, Gersting et al. verified this assumption when they examined adhesion patterns of fluorescently labeled gene transfer complexes on airway epithelial (16HBE) cells by fluorescence microscopy [86].

When establishing a novel method or research tool in life sciences, an important question is whether other researchers can reproduce the findings. Are the protocols that one has generated robust and comprehensible enough to be reproducible, was the interpretation of results unbiased enough? The question is also, whether a novel transfection method is only successful in a few cell types with selected vector types under very special conditions or whether there is universal applicability. We were lucky in that several research groups have reported about the success of magnetically guided nucleic acid delivery, which we called magnetofection, at the same time as we did. Confirmations of the utility of the method keep accumulating.

17.4.1.2 Enhancements in Transfection/Transduction

Gersting et al. found that in airway epithelial cells (16HBE cell line and primary cells) magnetofection was, with an incubation time of 15 min, more or at least equally efficient in gene transfer as standard PEI-polyfection with a 4h incubation time. Furthermore, the favorable dose–response relationship has been confirmed [86]. Morishita et al. showed that magnetic field–guided delivery significantly enhances transfections with HVJ-E vectors and that the required HVJ titers can be reduced [87]. In primary human umbilical vein endothelial cells (HUVECs), magnetofection with various cationic lipids and PEI strongly improved gene transfer (up to 360-fold) while cytotoxicity remained at acceptable levels [88]. Improved transfection efficiencies and DNA dose–response profiles through magnetofection were also observed with the lipofection reagent Metafectene in NIH 3T3 cells [16] and with the lipofection reagent DMRIE in CT26 cells [76]. In the latter experiment, it was demonstrated that not only the overall transgene expression but also the percentage of transfected cells can be enhanced by magnetofection. In a further publication of Krötz et al., it was shown that magnetofection with various lipid vectors and PEI does improve the transfection efficiencies and dose–response relationships not only with plasmid DNA but also with antisense oligodeoxynucleotides (ODNs) in HUVEC cells. It turned out that ODN-magnetofection with its shorter incubation time is significantly less toxic than the corresponding standard transfection [82]. But it has to be mentioned that in contrast to magnetofection with FUGENE

plus plasmid DNA [88], magnetofection with FUGENE plus antisense-ODNs was less efficient than the standard FUGENE transfection. Among the many comparisons, this is one of the few cases where magnetofection led to a decrease in transfection efficiency. In 293T cells, novel DNA fragments (PCR products of amplified EGFP gene) for transfections were tested by Kamau et al. and they found that with these molecules magnetofection leads to strong enhancements [56]. Earlier work from Isalan and coworkers had already demonstrated the utility of arrays of magnetic beads coated with PCR products [12]. Magnetofection also increased the efficiency of transfections of siRNA. We demonstrated that efficient knock down of stable eGFP expression in HT1080 cells with linear PEI and synthetic siRNA was only achieved through magnetofection [16] and not with linear PEI-siRNA alone. This result also indicates the potential of magnetofection for nucleic acid transfer into cells which are difficult to transfect with standard methods.

17.4.1.3 Applicability of Magnetofection with Different Nucleic Acid Types

Among the examined nucleic acid molecules are the DNA plasmids (Figure 17.6) [2,88,89], antisense ODN (Figure 17.7A) [82,90], PCR products [12,56], siRNAs (Figure 17.7B) [16, 90–92], mRNAs, dsRNAs, and shRNAs (www.ozbiosciences.com). Magnetofection is suitable to achieve not only overexpression of a transfected/transduce gene but also silencing of gene expression.

17.4.1.4 Applicability with Different Vector Types or Transfection Reagents

Experiments showed that magnetofection is useful for both nonviral and viral vectors. Tested nonviral vectors are polyplexes with branched (Figure 17.6A) and linear PEI [16], polylysine (pL), and dendrimer (Superfect from Qiagen, unpublished data). Additionally, endosomolytic agents like a synthetic influenza virus peptide [93] or a chemically inactivated adenovirus [2] could be successfully integrated into polyplex-based magnetic DNA complexes. Examples for lipoplex-based vectors used are Lipofectamine and GenePorter (Figure 17.6A), DOTAP, DMRIE-C, Effectene [76], Metafectene [16], Fugene [88], and the lipopolyamine DreamFect (www.ozbiosciences.com). As mentioned, magnetofection can be combined with the HVJ-E vector (hemagglutinating virus of Japan-envelope) [87]. Viral vectors tested in combination with magnetic particles are adenoviruses [2,4,94], retroviruses (Figure 17.7C) [1,2,10,11,95], measles viruses [13], adeno-associated viruses [3], herpes viruses (HSV-1), alpha viruses (Sindbis virus), polyomaviruses (SV40) [6], baculoviruses [9], rhabdoviruses (VSV) (www.ozbiosciences.com), porcine parvoviruses (PPV), polyoviruses, and monkey cytomegaloviruses [78]. An essential finding with viral vectors is that magnetofection, due to its favorable dose–response relationship can compensate for low viral titers.

Particularly interesting results have been obtained with adenoviruses. These vectors rank among the most efficient

FIGURE 17.7 (See color insert following blank page 206.) Some examples for the applicability of magnetofection. (A) Magnetofection of primary HUVEC-C cells with fluorescence-labeled phosphorothioate oligonucleotides (ODN). Right panel: In the presence of a magnetic field, up to 90% of the cells had oligonucleotide bound or internalized within 15 min of incubation with complexes of ODN with magnetic nanoparticles. Left panel: In the absence of a magnet, only very little binding/uptake was observed within this short period. (From Krotz, F., Wit, C., Sohn, H.Y., Zahler, S., Gloe, T., Pohl, U., and Plank, C., *Mol. Ther.*, 7, 700, 2003. With permission.) (B) Magnetofection of HeLa cells stably expressing GFP with siRNA to knock down GFP expression. From left to right: untreated cells (control), 1 nM siRNA directed against GFP, 4 nM siRNA, 10 nM siRNA, respectively, associated with magnetic nanoparticles and incubated on the cells in the presence of a magnetic field. This experiment was carried out in a 96-well plate. During transfection, the cell culture plate was positioned on a magnetic plate, which is shown in Figure 17.5A. The magnetic nanoparticles used here are a commercially available magnetofection reagents. (From the homepage of Oz Biosciences (www.ozbiosciences.com).) (C) Magnetofection of HeLa (left panel) and A549 (human non-small cell lung carcinoma) (right panel) cells with a pseudo-type HI virus carrying a GFP reporter gene. (From the homepage of OZ Biosciences (www.ozbiosciences.com).

vehicles for nucleic acid delivery. They can infect a broad range of host cell types, dividing and nondividing cells, and have a large capacity to package foreign gene inserts. However, these vectors are inefficient in transducing cells that do not express the coxsackie and adenovirus receptor (CAR) or are even incapable of doing so. Among such cells are the important targets of gene therapy such as various tumor cell types. Therefore, it was particularly encouraging that magnetofection

can mediate adenoviral transduction of cells like NIH 3T3 that express little or no CAR (Figure 17.8) [2]. In our work, this effect has been achieved with PEI-coated magnetic nanoparticles that might mediate cell binding via their positive charge. But Pandori and coworkers [4] got similar results with biotinylated adenovirus bound to streptavidin beads. This would suggest that electrostatic interaction with the plasma membrane is not the driving force of adenoviral magnetofection in cells

FIGURE 17.8 Infection of NIH 3T3 cells with adenoviruses (Adv) containing the LacZ gene. As NIH 3T3 cells express only little or no CAR, no transduction can be detected at a multiplicity of infection (MOI) of 200 with the virus alone. With magnetic particles (3 μg/six-well) and magnet (magnetofection) even at lower MOIs gene transfer is obtained. (From Scherer, F., Anton, M., Schillinger, U., Henke, J., Bergemann, C., Krüger, A., Gänsbacher, B., and Plank, C., *Gene Ther.*, 9, 102, 2002. With permission.)

that are nonpermissive to adenoviral infection. In analogy to what has been found with adenoviruses, Kadota and coworkers reported that measles viruses associated with magnetic nanoparticles were to transduce cells lacking the SLAM-receptor under magnetofection conditions [13]. Thus, in summary, magnetofection is a particularly interesting tool in viral transduction as it allows working with low viral titers (and thus saves time and money), allows localizing viral delivery (see further below), and is able to expand the host range of some viruses to otherwise nonpermissive cells.

17.4.1.5 Applicability of Magnetofection in Different Cell Types

There are many examples of successfully magnetofected cell lines described in publications (Table 17.1). Researchers use magnetofection primarily as a tool in basic research rather than continuing establishing or refining the method itself. An updated list of references where magnetofection has been used successfully can be found at the Web page of OZ Biosciences (Marseille, France; www.ozbiosciences.com). The cell types that have been magnetofected include cell lines

and primary cells many of which are considered difficult to transfect/transduce. From these references, it can be concluded that magnetofection is an efficient transfection/transduction method for a large number of different cells and has become a valuable tool in the life sciences. Figure 17.7 shows results we have obtained in HeLa cells and HUVECs.

In summary, usually magnetofection is significantly more efficient than the corresponding standard transfection or transduction, but there are cases in which magnetofection is only equally or even less efficient. The high efficiency at tolerable toxicity makes magnetofection a useful tool for examinations in hard-to-transfect/transduce and sensitive primary cells. Owing to the often improved nucleic acid dose–response profiles and the reduced incubation times, magnetofection may be particularly useful for high throughput applications.

17.4.1.6 Critical Parameters in Magnetofection

As the magnetofection appears to involve similar mechanisms as conventional transfection/transduction (see below), it is dependent on the potency of the parent vector composition associated with magnetic nanoparticles. For example, components such as endosomolytic substances, which improve nonviral gene delivery, also improve nonviral magnetofection.

As the association of nucleic acids/vectors is a prerequisite for magnetofection to work, the ratio of magnetic particles to nucleic acids/vectors is an essential parameter [13,76]. In nonviral magnetofections, usually a magnetic particle/DNA ratios between 0.5 and 6 (w/w) yield optimum efficiencies (Figure 17.9A). Using an insufficient amount of magnetic nanoparticles may lead to insuffi-

cient vector binding and insufficient magnetic sedimentation. An excessive amount of magnetic nanoparticles may lead to toxicity [87]. Similarly, the overall vector dose is an important parameter and needs to be optimized. The optimal dose is usually lower in magnetofection than in standard transfections [88].

Another important parameter is the incubation time of cells with vectors and the exposure time to a magnetic field. Magnetofection experiments with lipoplexes revealed that only a few minutes of magnetic field influence can be sufficient to yield optimum gene transfer efficiency [16,76]. This turned out to be an advantage when the cells to be transfected were sensitive to longer incubation times as was the case with HUVECs in transfections with antisense oligonucleotides [82], (Figure 17.9B). To achieve efficient ODN uptake with conventional means, long incubation times were required that were toxic to the cells. Magnetofection conditions required only a few minutes of incubation, which was far less toxic to the cells. Also with lentiviral vectors it has been demonstrated that very short incubation times (1 min) are sufficient to achieve optimal transduction with magnetofection procedures [11].

Finally, as mentioned before, further improvements in magnetofection can be achieved with alternating fields [56] (Figure 17.9C), a topic that certainly requires further examination.

17.4.1.7 Mechanism of Magnetofection in Cell Culture

Already our initial experiments had indicated that the uptake mechanism of magnetic complexes, at least with nonviral vectors, is probably the same as for their nonmagnetic counterparts.

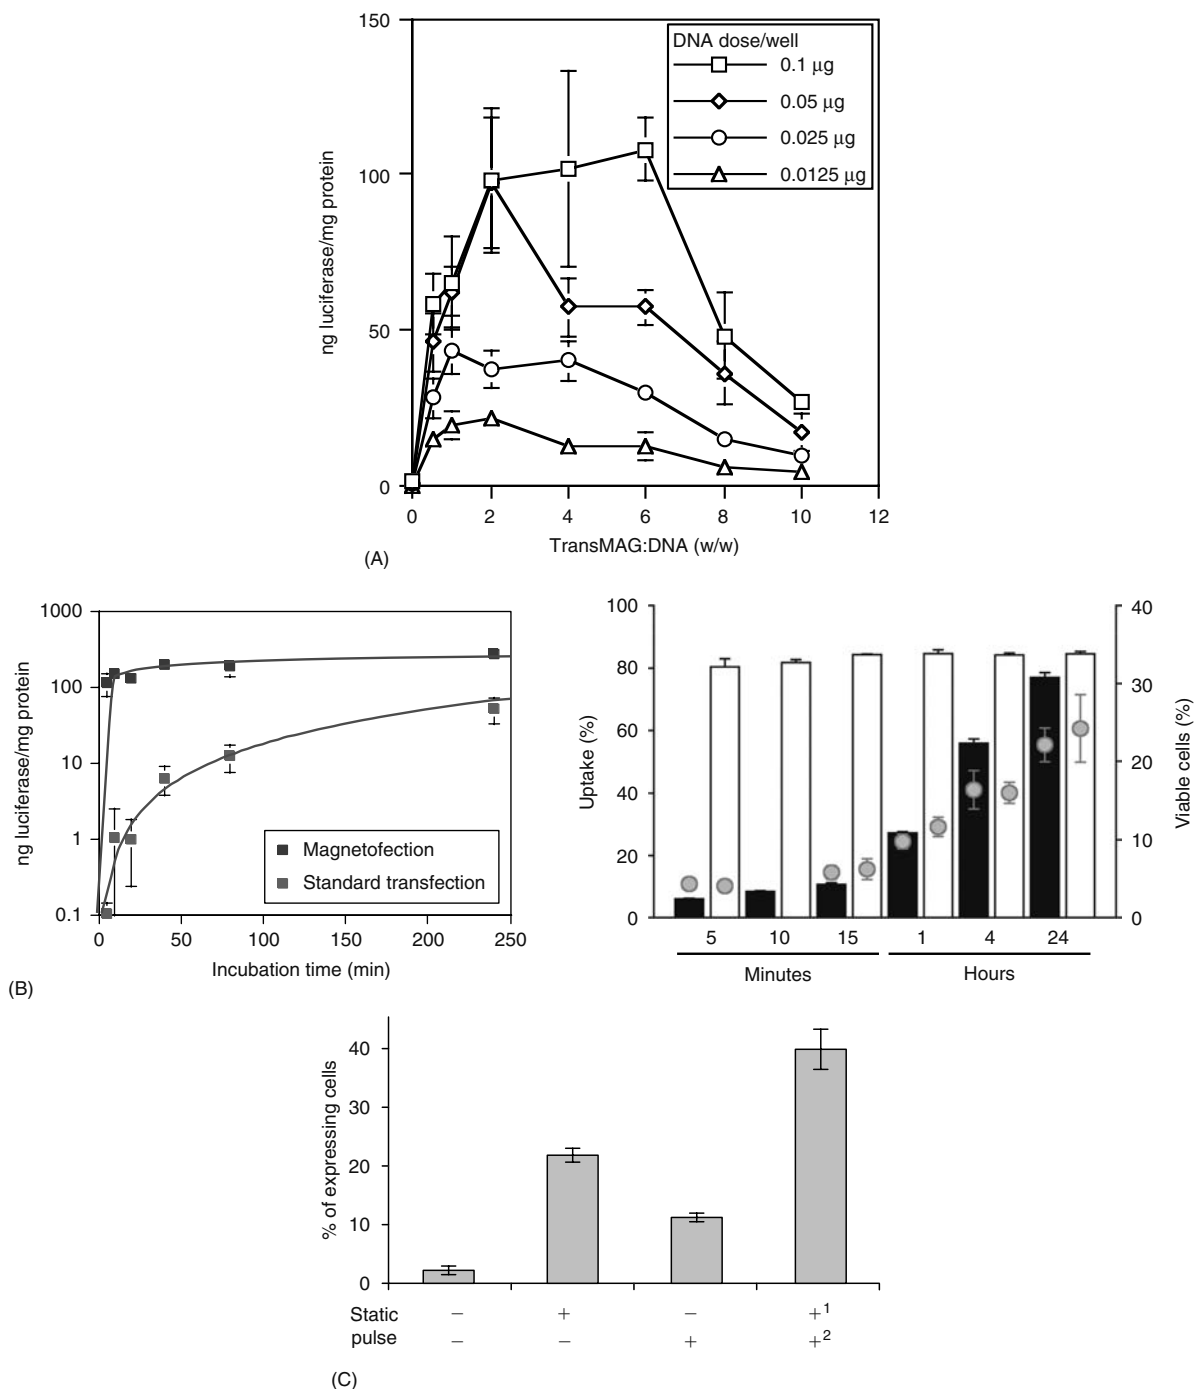

FIGURE 17.9 Optimizing magnetofection parameters. (A) Magnetofection of CHO-K1 cells with GenePorter liposomes at different magnetic particle/DNA ratios and DNA doses. (From Plank, C., Schillinger, U., Scherer, F., Bergemann, C., and Remy, J.S., *Biol. Chem.*, 384, 737, 2003. With permission.) (B) Lipofections with different incubation times for cells with vectors. Left panel: In contrast to the standard GenePorter transfection (grey), in GenePorter magnetofection (black) already 5 min incubation are sufficient to obtain a gene transfer efficiency close to the optimum. (Modified from Plank, C., Anton, M., Rudolph, C., Rosenecker, J., and Krotz, F., *Expert Opin. Biol. Ther.*, 3, 745, 2003.) Right panel: In magnetofection (white bars) with Effectene an incubation time of 5 min leads to nearly maximum ODN uptake while in the corresponding standard transfection (black bars) 24 h are necessary. Additionally, 5 min are significantly less toxic to cells (see circles) than longer incubation times. (From Krotz, F., Wit, C., Sohn, H.Y., Zahler, S., Gloe, T., Pohl, U., and Plank, C., *Mol. Ther.*, 7, 700, 2003. With permission.) (C) 293T cells were transfected with magnetic particle/DNA complexes and placed either on a static magnetic plate for 5 min, or a pulsating magnetic field was applied for 5 min, or the pulsating field was applied after the static field. The combination of premagnetization with a static field followed by the application of a pulsating field yielded significant enhancements in the percentage of transfected cells. (From Kamau, S.W., Hassa, P.O., Steitz, B., Petri-Fink, A., Hofmann, H., Hofmann-Antenbrink, M., von Rechenberg, B., and Hottiger, M.O. *Nucl. Acid Res.*, 34, e40, 2006. With permission.)

Magnetofection with a binary complex consisting only of naked DNA and PEI-coated magnetic nanoparticles worked far less efficiently than magnetofection with ternary complexes comprising also endosomolytic agents such as the influenza peptide INF7, free PEI, or chemically inactivated adenovirus. This strongly indicated that the uptake mechanism involved endocytosis. This was confirmed by Huth and coworkers [22] who have performed a detailed examination on the uptake mechanism of PEI-DNA complexes in comparison to the same vector associated with magnetic nanoparticles. They carried out transfections in the presence and in the absence of magnetic field influence and various inhibitors of cellular uptake mechanisms. The results clearly showed that the uptake mechanism for this vector type, no matter whether under magnetofection or conventional conditions, is mainly endocytosis (Figure 17.10) including clathrin-dependent pathways as well

as caveolae-mediated endocytic uptake. Whether this similarity of uptake mechanisms applies also to lipoplexes and viral vectors has not been examined so far.

An important question was whether the magnetic field would have any further impact on transfection (as measured by reporter gene expression) beyond the rapid sedimentation of the vector on the target cells. It is well documented that low frequency electromagnetic fields (EMFs) and static magnetic fields can have biological effects on cells and tissues. It is assumed that their primary site of action is the plasma membrane [141,142] and that for example phagocytosis [143] or cellular metabolic activity [144] can be reduced by magnetic fields. Further, it is known that EMFs activate genes under the control of EMF-sensitive promoters [145], that static electromagnets can induce the expression of oncogenes in tumor cell lines [146,147] and that a permanent magnetic field (300mT)

FIGURE 17.10 Electron microscopy of HeLa cells magnetofected with PEI-containing magnetofectins. If not otherwise stated the scale bars indicate 5 μm . The insets show a higher magnification of the labeled area. (A) Cells were exposed to magnetic DNA complexes and a magnetic field for 15 min. Arrows indicate the electron-dense iron oxide particles. The DNA is not electron dense and is not visible in this micrograph. The magnetic particles are concentrated around the cell and their uptake already starts. (B) Cells were exposed to magnetic DNA complexes and a magnetic field for 15 min and subsequently they were incubated for 24 h without magnet in fresh medium. In this micrograph, magnetic particles are found within the cell and the accumulation in endosomal structures suggests endocytosis as uptake mechanism. (C) The only difference to (B) is that the DNA is gold-labeled to make it electron dense. Thus, not only the magnetic particles but also the DNA is visible. This micrograph, especially the inset, reveals that magnetic particles and gold-labeled DNA are cointernalized into the cell. For better recognition, both components and their complexation are illustrated in (D). (D) Electron microscopic presentation of the components of magnetic particle/gold-labeled DNA complexes. In the left panel, gold-labeled DNA (scale bar: 100 nm), in the middle panel iron oxide particles (scale bar 100 nm), and in the right panel complexes (scale bar: 200 nm) are shown. Arrows indicate gold-labeled DNA. (From Huth, S., Lausier, J., Gersting, S.W., Rudolph, C., Plank, C., Welsch, U., and Rosenecker, J., *J. Gene. Med.*, 6, 923, 2004. With permission.)

changes the expression of some genes in *Escherichia coli* [148]. We examined whether the exposition of cells to Nd-Fe-B permanent magnets during conventional transfection (i.e., without magnetic particles) has an impact on reporter gene expression and found no such difference [93]. Huth et al. sedimented PEI-DNA complexes and the same vector associated with magnetic nanoparticles on the target cells by centrifugation and only subsequently applied a magnetic field [22]. There was no enhancement in reporter gene expression upon exposition to the magnetic field even with cells that received magnetic nanoparticle-associated vectors. Thus, it can be concluded that the enhancing effect of a magnetic field is mainly the result of accelerated vector sedimentation and not of changes in cell physiology, enhancement of cellular uptake, or activation of reporter gene expression.

In summary, the following mechanism is proposed for magnetofections. The magnetic nucleic acid vectors are concentrated efficiently by magnetic force on the cell surface within minutes and their uptake starts immediately. The uptake of magnetofectins follows a similar mechanism as the corresponding standard vectors but it occurs earlier and is more synchronized. The high efficiency in nucleic acid transfer with magnetofection is probably mainly a result of efficient sedimentation and, therefore, high availability of nucleic acid vectors at the cell surface for uptake.

17.4.1.8 Targeting (Localization) of Nucleic Acid Delivery with Magnetofection

The major motivation of magnetic drug targeting comes, of course, from *in vivo* applications. Concerning magnetic targetability, experiments in cell culture have served as models. Permanent magnets of different shape were positioned underneath the culture dishes in which magnetofection experiments were carried out. It turned out that gene delivery becomes confined to an area which is determined by the shape of the magnet in use. This was demonstrated with nonviral vectors and adenoviruses (Figure 17.11) [82,2]. Further, e.g., Hughes et al. [1], Pandori et al. [4], Mah et al. [3], and Raty et al. [9] showed magnetic field-guided targeting with retroviruses, adenoviruses, adeno-associated viruses, and baculoviruses. This confinement is the result of the physics of interaction of magnetic nanoparticles with magnetic fields that have already been discussed. The particles are attracted toward the highest density of magnetic field lines, which is always found at edges and tips of magnets. Therefore, by choosing the shape of a permanent magnet, nucleic acid delivery can be targeted (localized) to a subpopulation of cells within a culture dish. In this way, magnetic field-guided nucleic acid vector delivery could offer, e.g., the possibility to evaluate cells transfected with different nucleic acids compared to the untransfected control cells within the same well or it could enable the examination of the influence of secreted transgene-encoded factors on neighboring untransfected cells. A step in this direction has been Isalan's work who used magnetic field-guided delivery of PCR products for multiple, parallel cell transfections on microscope cover-slip arrays [12].

FIGURE 17.11 Targeting (localization) of gene delivery with adenoviral magnetofection. Adenoviral vectors carrying the lacZ gene were associated with magnetic particles and incubated on NIH 3T3 cells in the absence (left), or in the presence (right) of a magnetic field. A rectangular permanent magnet was placed to the underside of the right well during incubation. Efficient gene transfer and reporter gene expression (indicated through the blue X-gal stain) is confined to the area where the magnet had been positioned. Similar experiments are shown in Refs. [16,55]. (From the homepage of OZ Biosciences (www.ozbiosciences.com))

Thus, as already mentioned, in combination with the shorter incubation times (reduced from hours to minutes) and the improved nucleic acid dose-response relationships, magnetofection may even be a method of choice for automated high throughput screening of genes and of therapeutically useful sequences.

17.4.2 MAGNETOFECTION *IN VIVO*

Although there is plenty of evidence for the utility of magnetofection in cell culture (see Table 17.1), the reports on magnetofection *in vivo* are far less abundant (Table 17.2). We have provided proof-of-principle that magnetic guidance of transfection in blood vessels upon intravascular administration is feasible. PEI-containing magnetic DNA complexes were injected into ear veins of pigs or ear arteries of rabbits and a permanent magnet was placed above the blood vessel downstream of the injection site [16,2]. Reporter gene expression was detected at the injection sites and at the position of the magnet. Upon intra-arterial administration, expression was also found downstream of the magnet position, possibly due to passive retention of the DNA complexes in the capillary beds of the rabbit ear vasculature. Except for the injection sites, no expression was found in the contralateral ear veins or arteries. These findings suggest that magnetofection upon intravascular administration may have potential if the vascular endothelium is the target tissue and if a suitable magnet can be positioned in direct vicinity of the target site. Appropriate medical indications may include the localized delivery of angiogenic growth factor genes in the case of ischemic diseases, or, on the other hand, the delivery of anti-angiogenic factor genes to the tumor vasculature for tumor therapy, just to name two examples.

Krötz et al. [82] have reported that at least in a particular mouse model, magnetic targeting of nucleic acids also works if the magnetically targeted site is not in direct vicinity of the

injection site. They injected magnetofectins containing fluorescence-labeled antisense ODNs into the femoral arteries of mice, and during injection a permanent magnet was applied to one testicle, which was exposed by surgery. Confocal fluorescence microscopy revealed that specific uptake of ODNs was only observed in cremaster muscle blood vessels of testicles, which were exposed to a magnetic field (Figure 17.12C) and not on the contralateral site in the same animal.

Whether magnetofection upon intravascular administration has any therapeutic potential has still not been demonstrated. In the case of nonviral compositions associated with magnetic nanoparticles via noncovalent interactions, similar limitations apply upon intravascular administration as applicable to nonviral vectors in general. These include strong interactions with blood components, vector inactivation, dissociation of the composition, or rapid removal by the reticulo-endothelial system. Further, current limitations of the method with respect to intravascular administrations are discussed further below.

However, magnetofection also has potential in orthotopic administrations. In a rat model, we administered nonviral magnetic vectors into the ileum lumen after laparotomy in the presence of a magnetic field (Figure 17.12B). Reporter gene expression was found specifically where the permanent magnet had been positioned [2]. A similar result was found when magnetic particle–adenovirus associates were applied into the stomachs (which were exposed after laparotomy) of mice while a magnet was positioned outside the stomach wall [2]. In summary, the results of these experiments revealed that reporter gene transfer was strongly enhanced in the area under influence of a magnetic field whereas without application of a magnet (controls), either no or much poorer transfection/transduction was achieved. Interestingly, effective localized

reporter gene delivery was obtained even in the gut and in the stomach where harsh conditions (degradative enzymes and low pH) prevail.

Unfortunately, not in all applications a magnetic field enhanced the nucleic acid transfer efficiency. For example, Xenariou et al. examined nonviral gene transfer to the murine nasal epithelium and application of a magnetic field did not improve the transfection efficiency [136]. Analogously, in the experiments of Morishita et al. who directly injected maghemite nanoparticles associated with HVJ-E vectors into the liver of mice, a magnet placed onto the liver resulted in no significant local enhancement [87]. Nevertheless, in both studies very valuable results were obtained because both Xenariou et al. and Morishita et al. already observed that magnetic nanoparticles alone can lead to enhanced gene transfer. Concerning the design of magnetic nanoparticles, Morishita and colleagues found out that in contrast to *in vitro* experiments *in vivo*, a coating of magnetic particles with heparin, but not with protamine sulfate, works enhancing. This finding indicates that a magnetic particle-coating that is efficient in cell culture is not necessarily successful *in vivo* and vice versa. However, as already mentioned, up-to-date magnetic field–guided nucleic acid delivery does not work in all animal models and one possible explanation is that for some applications, magnetic fields are not strong enough. Therefore, improvements in magnetic field technology and eventually also in magnetic vector design are desirable. Some ideas are presented in Section 17.5.2.

Important insights about the tolerability of magnetic field–guided gene delivery *in vivo* were gained in a preliminary study in sheep by Galuppo et al. [138]. Intra-articular injection of PEI-coated iron oxide nanoparticles linked to plasmids and application of a static and a pulsating magnetic field resulted in mild-to-moderate inflammatory responses in the majority of synovial membrane samples whereas larger particles (200–250 nm) tended to be associated with more inflammation than smaller ones (50 nm). Nevertheless, intra-articular application of all magnetic nanoparticles was well tolerated. With regard to the tolerability of iron oxide, Weissleder et al. found in earlier studies that iron oxide particles used as contrast agents in MRI are fully biocompatible [67]. After intravenous application in rats, the particles were cleared by macrophages in liver and spleen, the iron oxides were degraded in lysosomes via hydrolytic enzymes, and the resulting elementary iron was integrated into the natural iron metabolism (e.g., incorporation into hemoglobin). Additionally, Weissleder and coworkers showed that in rats and beagle dogs, a relatively high dose of 167 mg iron/kg body mass still had no toxic effects on the liver or other organs and they mentioned that for clinical MRI a dose of approximately 1 mg iron/kg is proposed. Therefore, e.g., the 76.9 µg iron oxide particles/kg applied intravenously in pigs for magnetic nucleic acid targeting (Figure 17.12A) [2] can be assumed to be safe. A further interesting finding about iron oxide nanoparticles was obtained by Xiang et al. who showed that intravenously delivered polylysine-coated iron oxide nanoparticles can even transfer DNA across the blood–brain barrier to glial cells and

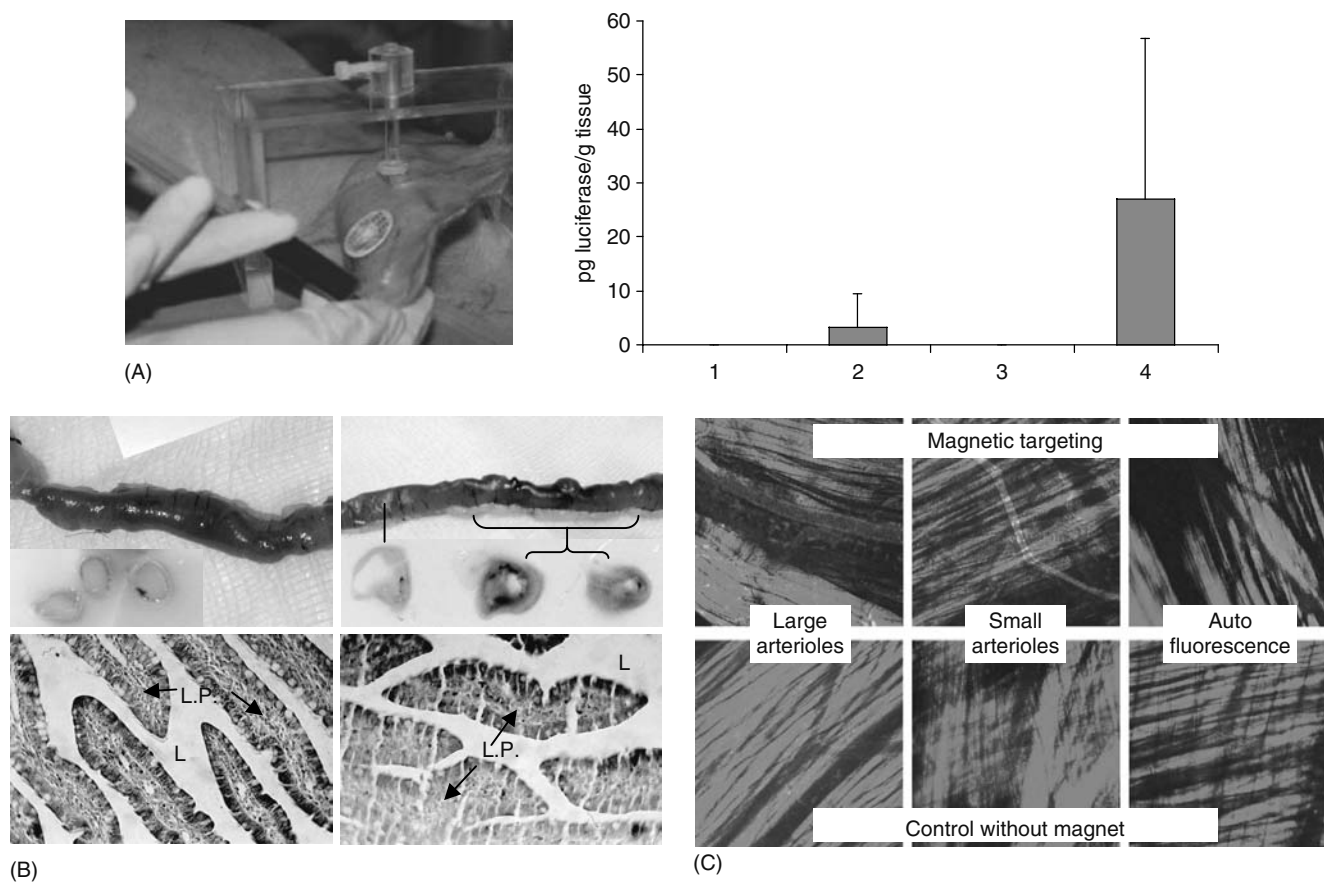

FIGURE 17.12 (See B and C in color insert following blank page 206.) (A) Left panel: Experimental setup: A permanent magnet, attached to a plunger adjustable for height, was placed above the ear vein of a pig without causing any pressure on the blood vessel. Subsequently, magnetic gene vectors (brown suspension in the syringe) were injected via a cannula into the ear vein upstream of the magnet. Right panel: Luciferase gene expression in the ear veins after injection with or without a magnet placed downstream. The graph shows that on the average without magnet (1 and 3) no significant gene transfer was monitored whereas with magnet, maximum values were obtained underneath the magnetic field. (B) X-gal staining performed 48 h after magnetic particle/DNA complexes were applied to the ilea of rats in the absence (left panels) and under the influence of a magnetic field for 20 min (right panels). Blue staining reveals efficient gene delivery only in the presence of magnet (right panels). Upper panels: intestinal tubes after X-gal stain. Insets: cross-sections of tubes. Lower panels: Paraffin sections counterstained with eosin, 400 \times magnification. X-gal staining is found in the lamina propria. L, lumen; LP, lamina propria. (From Scherer, F., Anton, M., Schillinger, U., Henke, J., Bergemann, C., Krüger, A., Gänsbacher, B., and Plank, C., *Gene Ther.*, 9, 102, 2002. With permission.) (C) Injection of fluorescence-labeled ODN/magnetic particle associates into the femoral artery caused site-specific accumulation in the vessels of the ipsilateral mouse cremaster at which a magnet was placed (upper panel, left: large arterioles, middle: small arterioles, right: autofluorescence before injection of magnetic complexes) but not into the contralateral cremaster, which was not in contact with a magnetic field (lower panel). (From Krotz, F., Wit, C., Sohn, H.Y., Zahler, S., Gloe, T., Pohl, U., and Plank, C., *Mol. Ther.*, 7, 700, 2003. With permission.)

neurons of the brain. Thus iron oxide nanoparticles (eventually in combination with a magnetic field) may have potential for gene therapy of CNS diseases [7] if such findings can be reproduced by other researchers.

Speculating about the future, magnetofection may become a useful *in vivo* research tool for the local examination of gene function similar to as it is now used in cell culture. Of course, we and others also envisage therapeutic applications. A first step toward tumor therapy was undertaken in a veterinary clinical study using immuno gene therapy for feline fibrosarcoma [83]. This is one of the most frequent tumors in cats and has an extremely high recurrence rate upon standard therapy, which is surgical excision. The gene coding for human GM-CSF (granulocyte macrophage colony stimulating factor) in a

nonviral magnetic formulation was administered twice in a 1 week interval before surgery into the biologically active margins of the fibrosarcoma, and a permanent magnet was fixed on the tumor adjacent to the injection site during 1 h after vector injection. The immunohistochemistry showed that the GM-CSF gene was expressed in the tumor and some tissue penetration by the vector could be observed. The preliminary clinical outcome after a phase II study with more than 20 patients is a significant increase in tumor-free survival of the cats from only 23% at the 1 year time point in the case of standard therapy (surgery only) to 52% with presurgical magnetofection of the human GM-CSF gene. The long-term follow up will be very interesting as it will reveal the true benefits of this treatment.

17.5 PLACE OF MAGNETOFECTION IN THE FIELD OF NUCLEIC ACID DELIVERY, LIMITATIONS, REQUIRED IMPROVEMENTS, AND POTENTIAL ADVANCES

Now that the benefits and potentials of magnetofection have been highlighted comprehensively, it is time to acknowledge that the method is not a solution for any limitation in nucleic acid delivery. After many years of research, conventional forms of delivery have been advanced successfully to clinical trials. Other forms of targeting and other physical methods of delivery are highly promising. Up to date, side by side comparisons or combinations, for example, with electroporation, sonoporation, hydroporation, aerosolization, ballistic methods, occlusion of the blood outflow from the target organ, or biological targeting are still missing. In the absence of further evidence, any of the named methods needs to be considered as promising as magnetofection is. Electroporation is probably the most advanced method and the efficiency of this method *in vitro* and *in vivo*, particularly with nondividing cells, still needs to be achieved with magnetofection. When compared to all the other physical methods, the major advantage of magnetofection is that it is able to combine simplicity, nonexpensiveness, localization of delivery, enhanced efficiency, and reduction of incubation time and of vector doses.

17.5.1 LIMITATIONS AND REQUIRED IMPROVEMENTS

As has been described above, there are strong indications that the mechanism of magnetofection involves natural uptake mechanisms into cells that are also prevalent for conventional methods. This also means that limitations apply. Once a natural uptake mechanism is saturated, no further improvements can be expected from an increased vector dose at the plasma membrane, which at least *in vitro* can easily be achieved by magnetofection. This explains why, although in principle any vector can be used in magnetofection, not necessarily any vector can be improved by doing so. In certain cases, the association with magnetic particles may even turn out inhibitory.

Similar considerations apply *in vivo*. So far, no magnetic vector formulation has been described that overcomes the limitations of opsonization, vector inactivation, and dissociation that also apply for conventional vectors. The same efforts of vector shielding and providing them with biological targeting functionality dedicated to conventional vector development need to be dedicated to magnetic vector formulation. Only with long-circulating magnetic vectors it can be expected that substantial magnetic vector accumulation at a target site will be feasible, particularly if the target site is not in direct vicinity of the administration site. In addition, substantial physical limitations apply to magnetofection *in vivo*, in particular upon administration into the blood circulation. First of all, not any target structure is accessible to the source of a magnetic field of high enough flux density and field gradient. It has been described above that these quantities decline rapidly with increasing distance from the source of the field. Field gradients

so far cannot be produced arbitrarily in space. Hence, as of yet magnetic drug targeting is limited mostly to superficial target structures. Other essential parameters are the hydrodynamic forces prevalent *in vivo*. Magnetic force needs at least to compensate for blood flow rates in the target structure. In cases where the endothelium does not represent the actual target tissue, extravasation is also required. And although extravasation from the blood circulation by a yet unknown mechanism has been observed in magnetic drug targeting [83,28], this alone will not warrant uptake into target cells. Tissue penetration and uptake into target cells also remain among the major limitations where magnetic vectors are administered directly into a target tissue.

Thus, given all the potential advantages and benefits of magnetic drug targeting and magnetofection that have been discussed here, it becomes clear that major advances are required before the method can be considered superior to any other way of nucleic acid delivery *in vivo*.

17.5.2 POTENTIAL ADVANCES

With the above considerations and from what has been described earlier in this chapter, it becomes clear that potential advances need to come from two sides: improved magnetic formulations and the side of physical forces that are applied. The objective is optimizing retention, tissue penetration, and cellular uptake.

It can be expected that progress will come from a combination of physical targeting with biological targeting. Vector shielding ought to bring about sufficient stability *in vivo* and providing magnetic vectors with targeting ligands may improve target cell specificity and cellular uptake once the vector has been magnetically accumulated in the target tissue.

Advances that can be contributed by tailor-made magnetic field generating devices have already been discussed. The major goal is maximizing magnetic field gradients at target sites. In this respect, an interesting suggestion has been made by Babincova and Babinec [149]. They placed a ferromagnetic wire alongside a tube, which served as a model blood vessel and positioned the whole setup in a strong homogenous magnetic field. Because of its ferromagnetic properties, the wire induces strong local field gradients in the exogenous homogenous field. This effect can be used advantageously to trap magnetic particles against hydrodynamic force. Therefore, Babincova and Babinec suggest that the strong homogenous magnetic fields of MRI equipment may be exploited for magnetic retention, which then could be several magnitudes more efficient than with permanent magnets. The procedure would, however, require a minimal invasive implantation of ferromagnetic material at the target site.

As has been described before, the magnetic force acting on magnetic nanoparticles [81] is

$$F_m = (m \cdot \nabla) B = \frac{1}{2} \cdot \frac{\Delta \chi V}{\mu_0} \cdot \nabla B^2$$

where

m is the magnetic moment of the particle

B is the magnetic flux density

$\Delta\chi$ is the magnetic susceptibility difference of between the magnetic particles and the surrounding medium

μ_0 is the permeability of vacuum

∇B is the magnetic field gradient

V is the volume of the particles

The latter is proportional to the third power of the particle radius. Upon intravascular administration, the magnetic force needs to counterbalance the viscous drag force caused by the blood flow, which, as a first approximation, is described by Stoke's law

$$F_D = 6\pi R\eta\Delta v$$

and which is dependent on the first power of the particle radius. This means, based on a very simplified consideration, one can predict that increasing the particle size will over-proportionally be in favor of the magnetic force. On the other hand, constraints on a suitable particle size for *in vivo* applications are given by the diameter of blood capillaries (around 5 μm). For most envisaged applications, embolisms need to be avoided.

Therefore, magnetic formulations are required that appear to be large diameter magnetic particles to the magnetic field, which, however, have inherent flexibility to travel through the blood capillaries like blood cells do. Liposomes containing an optimized amount of magnetic nanoparticles in their aqueous lumen appear to be suitable for this purpose [150,151]. Our own current approach is to combine sonoporation and magnetofection. Microbubbles are gas bubbles usually of a few micrometers in diameter surrounded by a shell, which can consist of proteins, polymers, lipids, or combinations thereof. Because of their gas content, they are excellent reflectors of ultrasound. Consequently, they are used as contrast agents in medical ultrasound imaging. Both low molecular weight drugs and nucleic acids can be associated with microbubbles in various ways. In addition, microbubbles can be targeted exploiting receptor–ligand type interactions (including antigen–antibody interactions) [152,153]. Drug-loaded microbubbles hold potential as “magic bullet” agents to deliver drugs to precise locations in the body, these precise locations are determined by where the ultrasound energy is focused [153,154]. The interaction of microbubbles and ultrasound in the low MHz range leads to cavitation, microstreaming, and, eventually to, bubble burst and consequent drug release [155]. In addition, cavitation can lead to microvessel rupture leading to increased permeability of the endothelial barrier [156,157]. This effect has been used to deliver nanoparticles and even red blood cells to the interstitium of rat skeletal muscle [158]. Cavitation nuclei formed by microbubbles have also been used to permeabilize the blood–brain barrier [159]. Essential for a combination with magnetofection is that microbubbles have been used very successfully in nucleic acid delivery in a variety of tissues [3,152,153,160–170].

On the basis of this state of the art, we reasoned that microbubbles may be ideal carriers to incorporate a high quantity of magnetic nanoparticles as well as active agents such as drugs or nucleic acids. This idea had already been published in 2000 by Soetanto and coworkers [171]. We postulate that the flexibility of this carrier should be sufficient to “squeeze” through blood capillaries and that magnetic accumulation of the carrier against hydrodynamic forces ought to be facilitated compared with “free,” physically uncoupled magnetic nanoparticles. This is because in magnetic microbubbles, one carrier object would comprise a plurality of magnetic particles that would be immobilized in the bubble shell in close vicinity and thus Brownian relaxation would be greatly reduced. Active agents, once magnetically accumulated at a target site would be released locally by the application of ultrasound, which might also improve tissue penetration by the active agent. Last but not least, magnetic microbubbles might be highly useful contrast agents both for ultrasound and MRI.

In the meantime, we have succeeded in manufacturing magnetic microbubbles and we have confirmed that indeed the magnetic accumulation of magnetic nanoparticles against hydrodynamic forces is greatly superior in microbubble formulation than in the form of free magnetic nanoparticles. This ongoing work is still unpublished. Promising preliminary results have been presented at scientific conferences [172–174]. Currently, we are examining magnetically targeted and ultrasound-triggered delivery of nucleic acids *in vivo*. In one study, magnetic microbubbles are injected into the circulation and magnetic accumulation and ultrasound-triggered deposition of nucleic acids is observed by intravital microscopy in a mouse dorsal skin chamber model. The other model, exemplary for topical administration, is a ventral skin flap model. Magnetic microbubbles carrying the gene of an angiogenic factor are injected subcutaneously. Later on, a skin flap is excised and repositioned. The encouraging result is that only the combination of magnetic field and ultrasound yields a local deposition of nucleic acids in the circulation model or an improved skin-flap survival in the orthotopic model. One of our goals is to target endothelial cells in the vasculature of tumors with the help of magnetic microbubbles and in this manner deposit anticancer agents there, be it classical pharmaceuticals or nucleic acids.

Through combined efforts in magnetic field physics, in magnetic particle physics and chemistry, in pharmaceutical formulations, and in medical application, we envisage that magnetofection some time may become a therapeutic option for many diseases. The coming years will show whether the existing technical hurdles will be overcome.

17.6 SUMMARY

Magnetofection is a recently developed method that applies magnetic particles in combination with magnetic force to enhance and to target nucleic acid delivery *in vitro* and *in vivo*. It is universally applicable to different types of nucleic acid molecules (e.g., plasmid DNA, oligodesoxynucleotides, PCR products, siRNA, mRNA), vectors (nonviral and viral), and cells (including primary and others that are hard to

transfect/transduce). In cell culture, magnetofection improves conventional (standard) nucleic acid transfer methods like polyfection, lipofection, or viral transduction with regard to efficiency, nucleic acid dose–response profile, and reduced incubation time in many cases. In animal experiments, it is demonstrated that magnetofection can also enable targeted (localized) and efficient transfection/transduction *in vivo*. But it also has to be mentioned that for a broader *in vivo* applicability and especially for the development of clinical applications many significant improvements are necessary.

ACKNOWLEDGMENT

This work has been supported by grants from the German government and the European union. Financial support of the German Excellence initiative via the “Nanosystems Initiative Munich (NIM)” is gratefully acknowledged.

18.1 INTRODUCTION

Immunotherapeutics (e.g., vaccines, allergens) are most commonly administered using a needle and syringe, a method first invented in 1853. The needle and syringe is effective, but unpopular, and creates a risk of iatrogenic disease from needle-stick injury or needle reuse as a consequence of the billions of administrations each year. Further, the needle and syringe does not deliver the vaccine ingredients optimally to the antigen-presenting cells (APCs), which alone can respond to the combination of antigen and adjuvant (innate immune stimulus) that makes a successful vaccine.

The provision of safe and efficient routes of delivery of immunotherapeutics to the immunologically sensitive dendritic cells in the skin (and mucosa) has the potential to

enhance strategies in the treatment of major disease. Examples of these include DNA vaccines and the immunotherapy of allergies. The application of physical methods to achieving this goal presents unique engineering challenges in the physical transport of immunotherapeutic biomolecules (e.g., polynucleotides) to these cells.

In this chapter, the physiology, immunology, and material properties of the skin are examined in the context of the physical cell-targeting requirements of the viable epidermis. Selected cell-targeting technologies engineered to meet these needs are briefly presented. The operating principles of these approaches are described, together with a discussion of their effectiveness for the noninvasive targeting of viable epidermis cells and the DNA vaccination against major diseases.

The focus then moves to one of these methods, called biolistics, that ballistically delivers millions of microparticles coated with biomolecules to outer skin layers. The engineering of these devices is presented, beginning with earlier prototypes before examining a more advanced system configured for clinical use. Then, follows a theoretical and experimental analysis of the ballistic microparticle impact process, including the examination of induced cell death. Finally, the results of applying this technology to key human clinical trials are presented.

18.2 IMPORTANCE OF TARGETING SKIN AND MUCOSAL CELLS

Why are outer skin cells important targets in the treatment of disease? The answer is found from a consideration of skin structure, shown schematically in Figures 18.1 and 18.3. Human skin can be subdivided into a number of layers: the outer stratum corneum (SC, 10–20 μm in depth), the viable epidermis (50–100 μm), and the dermis (1–2 mm) [1,2]. The SC is the effective physical barrier of dead cells in a “bricks

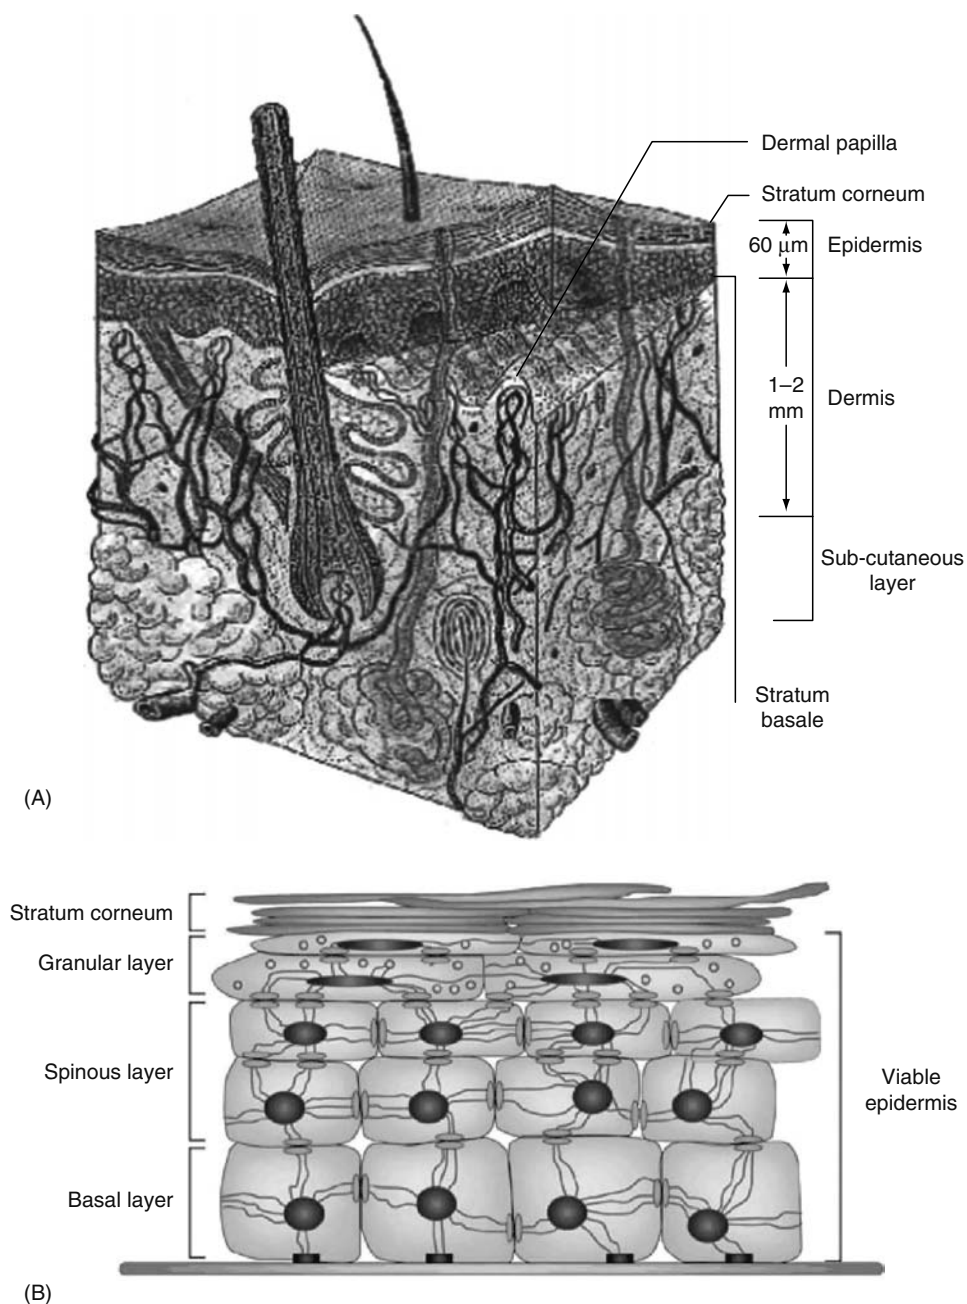

FIGURE 18.1 (A) Structure of mammalian skin and (B) the epidermis of mammalian skin

(C)

FIGURE 18.1 (continued) (C) the corresponding bilayer approximation of the epidermis used for the theoretical penetration model. Penetration case A denotes particle delivery into the SC (d_{sc}), whereas, in case B, the SC is fully breached (t_{sc}), and the final particle location is within the viable epidermis (d_{ve}). The impact velocity is v_i , while the input velocity for the viable epidermis is $v_{i,ve}$. (Adapted from Kendall, M.A.F., Rishworth, S., Carter, F.V., and Mitchell, T.J., *J. Invest. Dermatol.*, 122, 739, 2004. With permission.)

and mortar” structure [3,4]. The underlying viable epidermis is composed of cells, such as immunologically sensitive Langerhans cells, keratinocytes, stem cells, and melanocytes [2]. Unlike the dermis below, the viable epidermis lacks blood vessels and sensory nerve endings—important characteristics of a site for pain-free delivery with minimal damage.

In the viable epidermis, the skin has evolved a highly competent immunological function, with an abundance of Langerhans cells ($500\text{--}1000\text{ cells mm}^{-2}$) [5–7], often serving as the first line of defense against many pathogens [8]. In particular, Langerhans cells (illustrated in Figure 18.3) are extremely effective APCs, responsible for the uptake and processing of foreign materials in order to generate an effective immune response. Such cells are reported to be up to 1000-fold more effective than keratinocytes, fibroblasts, and myoblasts at eliciting a variety of immune responses [9–12]. Effective *in situ* (*in vivo*) targeting of Langerhans cells and other epidermal cells with polynucleotides or antigens will open up novel applications in disease control [9], including vaccination against major viruses/diseases, such as human immunodeficiency virus (HIV) and cancer.

18.3 ENGINEERING OF PHYSICAL APPROACHES FOR THE TARGETING OF SKIN AND MUCOSAL CELLS

Within the viable epidermis, the location of Langerhans cells—as a delivery target for immunotherapeutics—is tightly defined by:

- Vertical position at a consistent suprabasal location [13]
- Spatial distribution in the horizontal plane evenly distributed throughout the skin [14]
- Constitution of 2% of the total epidermal cell population [15] (in human skin)

How can these and other epidermal skin cells be targeted? Despite its recognized potential, the viable epidermis has only recently been viewed as a feasible cellular targeting site with the emergence of new biological and physical technologies. The challenge is the effective penetration of the SC and precise targeting of the cells of interest.

18.3.1 MECHANICAL PROPERTIES OF THE SC BARRIER

The SC is a semipermeable barrier that—owing to its variable mechanical properties—is challenging to breach, in a minimally invasive manner, to target the viable epidermal cells below. Mechanically, the SC is classified as a bio-viscoelastic solid and shows highly variable properties. Obvious differences include the huge variation in thickness and composition with the skin site and the age of an individual [16]. However, there are more subtle and equally important variations in SC properties to consider when configuring targeting methods.

As one example, the SC mechanical breaking stress is strongly influenced by the ambient humidity/moisture content [17–21]—the relative humidity range from 0% to 100% results in a decrease in excised human SC breaking stress from 22.5 to 3.2 MPa [22]. Similarly, an increase in ambient temperature also results in an SC breaking stress decrease by an order of magnitude [23].

More recently, with indentation studies using small probes (diameters of 2 and 5 μm) fitted to a NANO indenter [24], we have found even more complexity and variation in key SC—and underlying viable epidermis—mechanical properties. Specifically:

- Storage modulus and mechanical breaking stress both dramatically decrease through the SC (Figure 18.2A and B).

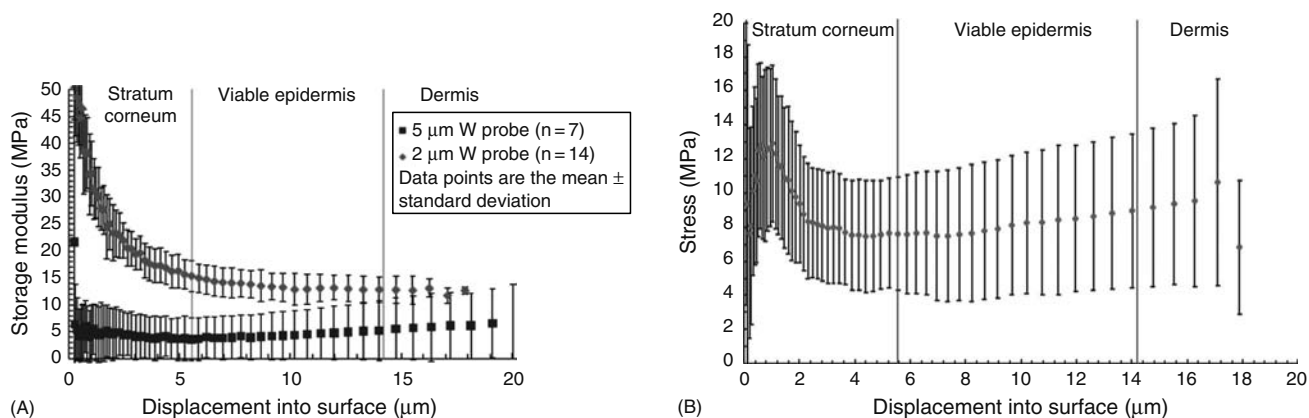

FIGURE 18.2 (See A in color insert following blank page 206.) Mechanical properties (mean \pm standard deviation) as a function of displacement obtained with microprobes indented into murine ears. (A) Storage modulus with 5 and 2 μm microprobes. (B) Stress with a 2 μm microprobe. (Adapted from Kendall, M.A.F., Chong, Y., and Cock, A., *Biomaterials*, 28, 4968, 2007. With permission.)

- At a given depth within the SC and VE, decreasing the probe size significantly increases the storage modulus (Figure 18.2A).

These and other sources of variability in the SC mechanical properties present challenges in configuring approaches to breach, in a minimally invasive manner, the SC and effectively deliver biomolecules (e.g., polynucleotides, antigens or allergens) to the underlying cells.

18.3.2 BIOLOGICAL APPROACHES

Although the focus of this chapter is on physical approaches to target epidermal cells, it is also important to highlight biological approaches. A powerful biological approach to the transport

of biomolecules to epidermal (and other) cells, *in vivo*, exploits the evolved function of viruses in the transport to cells. In gene delivery, researchers have made use of genetically engineered viruses in the DNA vaccination and gene therapy of major diseases with encouraging results. However, viral gene delivery is hindered by safety concerns, a limited DNA-carrying capacity, production and packaging problems, and a high cost [25,26].

18.3.3 PHYSICAL CELL-TARGETING APPROACHES

Alternatively, many physical technologies are being developed. Potentially, they can overcome some limitations of biological approaches using needle-free mechanisms to breach the SC barrier to facilitate drug and vaccine administration directly to epidermal cells. Figure 18.3 illustrates schematically

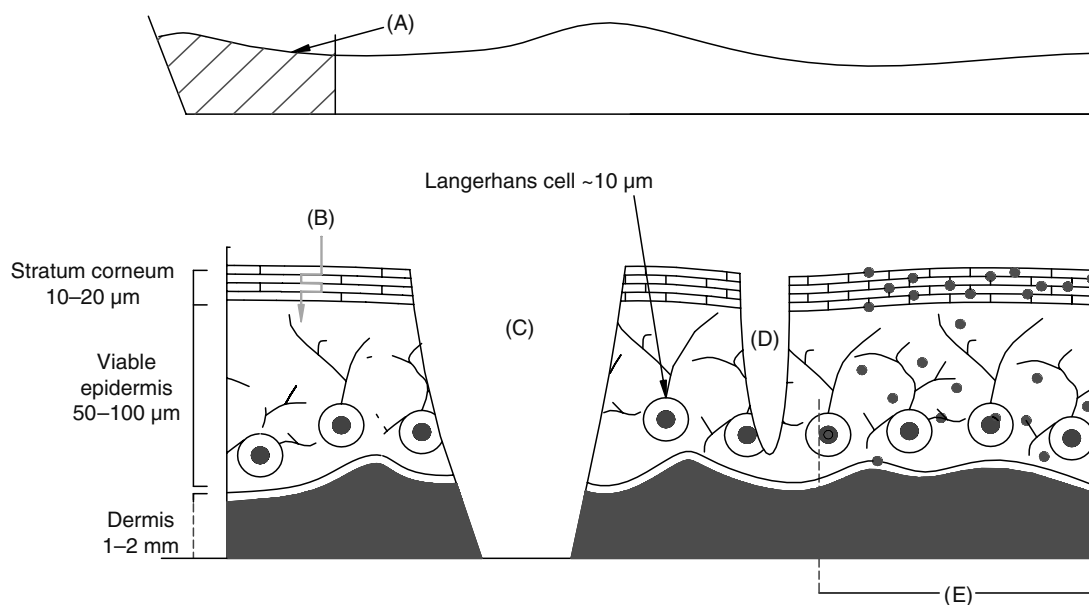

FIGURE 18.3 Cross-section of the skin showing Langerhans cells. Five physical cell-targeting approaches are also shown. (A) A half-section of a small gauge needle and syringe; (B) route of diffusion from patches; (C) penetration from a liquid jet injector; (D) a hole from a microinjector; and (E) distribution of microparticles following biolistic injection. (From Kendall, M.A.F., *Vaccine*, 24, 4651, 2006. With permission.)

key physical targeting approaches relative to the scale of typical skin and the Langerhans cell layer of interest.

18.3.3.1 Needle and Syringe

For the illustration of the most common physical delivery method, a small gauge needle and syringe is shown in half-section in Figure 18.3A. Although this approach easily breaches the SC, precise targeting of the Langerhans cell-rich viable epidermis cannot be practically achieved. Hence, the needle and syringe is used for intradermal or intramuscular injection. This inefficient, indirect targeting of dendritic cells with DNA has resulted in modest immune responses [27]. Other disadvantages of the needle and syringe include risks due to needle-stick injuries [28] and needle phobia [1].

18.3.3.2 Diffusion/Permeation Delivery

Perhaps the least invasive method of breaching the SC is by permeation through it, driven by diffusion from patches applied to the skin (Figure 18.3B) [29]. However, currently, the general view is that this mode of delivery is best suited to smaller biomolecules (<500 Da [29])—considerably smaller than oligonucleotides and antigens. This view is being challenged, with a recent study showing that very large recombinant antigens of ~1 MDa can be delivered to elicit systemic responses by diffusion from patches [30]. The transport of larger biomolecules through the SC can be further enhanced by simple approaches, including tape stripping with an adhesive tape, brushing with sandpaper [31,32], or the application of depilatory agents [26,33,34]. Amongst the more advanced technologies are electroporation [35,36], ablation by laser or heat, radiofrequency high-voltage currents [37], iontophoresis [38–40], sonophoresis, and microporation [8]. Many of these approaches remain untested for complex entities such as vaccines and immunotherapies. Permeation through the SC can also be enhanced by the coating of plasmid DNA on nanoparticles (~100 nm) for DNA vaccination [41].

18.3.3.3 Liquid Jet Injectors

Interest in using high-speed liquid jet injectors arose in the mid-twentieth century because of its needle-free approach [42]. This technique has seen a recent resurgence, with liquid delivered around the Langerhans cells in gene transfer and DNA vaccination experiments [42], and the delivery of drugs [43]. As shown in Figure 18.3C, current liquid jet injectors typically disrupt the skin in the epidermal and dermal layer. To target exclusively the viable epidermal cells, such as Langerhans cells, the challenge of more controlled delivery needs to be addressed. With the dermal disruption induced by administration, liquid jet injectors are also reported to cause pain to patients.

18.3.3.4 Microneedle Arrays/Patches

Researchers have overcome some of the disadvantages described by fabricating arrays of micrometre-scale projections to breach the SC and to deliver naked DNA to several cells in live animals [44]. Similar microprojection devices are

used to increase the permeability of drugs [45] and “conventional” protein antigen vaccines [45,46]. Figure 18.3D shows that, unlike current liquid jet injectors, these microneedles can accurately target the viable epidermis. Furthermore, they are as simple to use as patches, while overcoming the SC diffusion barrier to many molecules. Moreover, compared with both the needle and syringe and liquid jet injectors, these microneedle methods are pain-free because of epidermal targeting. By drawing upon a range of manufacturing techniques, McAllister et al. [46] have shown that these microneedle arrays can be made from a range of materials, including silicon, metal, and biodegradable polymers. This advantage makes microneedle patches a promising practical and cost-effective method of delivering oligonucleotides to epidermal cells for DNA vaccination [47].

18.3.4 BIOLISTICS MICROPARTICLE DELIVERY

Currently, the most established physical method of DNA vaccination is biolytic microparticle delivery, otherwise known as gene guns (Figure 18.3E). Biolytic delivery is the focus of the remainder of this chapter.

18.4 BIOLISTICS MICROPARTICLE DELIVERY

18.4.1 BIOLISTICS OPERATING PRINCIPLE

In this needle-free technique, pharmaceutical or immunomodulatory agents, formulated as particles, are accelerated in a supersonic gas jet to sufficient momentum to penetrate the skin (or mucosal) layer and to achieve a pharmacological effect.

Sanford and Klein [48] pioneered this innovation with systems designed to deliver DNA coated metal particles (of diameter of the order of 1 μm) into plant cells for genetic modification, using pistons accelerated along the barrels of adapted guns. The concept was extended to the treatment of humans with particles accelerated by entrainment in a supersonic gas flow [49]. Prototype devices embodying this concept have been shown to be effective, painless, and applicable to pharmaceutical therapies ranging from protein delivery [50] to conventional vaccines [51] and DNA vaccines [9,52,53].

Different embodiments of the concept (e.g., in Figures 18.4 and 18.6) all have a similar procedure of operation. Consider the prototype shown schematically in Figure 18.4A as one example.

Prior to operation, the gas canister is filled with helium or nitrogen to 2–6 MPa and the vaccine cassette, comprising two 20 μm diaphragms, is loaded with a powdered pharmaceutical payload of 0.5–2 mg. The pharmaceutical material is placed on the lower diaphragm surface. Operation commences when the valve in the gas canister is opened to release gas into the rupture chamber, where the pressure builds up until the two diaphragms retaining the vaccine particles sequentially burst. The rupture of the downstream diaphragm initiates a shock which propagates down the converging–diverging nozzle. The ensuing expansion of stored gas results in a short-duration flow in which the drug particles are entrained and accelerated

FIGURE 18.4 (A) Simplified prototype vaccine device instrumented for Pitot and static pressure measurements. The static pressure transducers are labeled P_1 – P_{10} . (B) Experimental and ideal axial Mach number within the conical nozzle of investigation. The profiles are provided after the starting process. (C) Sample Schlieren image within the nozzle. through the device. After leaving the device, particles impact on the skin and penetrate to the epidermis to deliver a pharmacological effect.

18.4.2 ENGINEERING OF HAND-HELD BIOLISTIC DEVICES FOR CLINICAL USE

Biolistic delivery of immunotherapeutics is an application of transonic flow technology that is otherwise applied to

aerospace applications. In this section we introduce prototype devices and discuss the key engineering challenges in applying this aerospace technology to clinical biomedical applications. Key parameters used to guide the engineering of biolistic devices are

1. Nominally uniform, controlled, and quantified microparticle velocity and spatial distribution impacting the tissue target. Further, the impact momentum

is to be within the range needed for delivery to particular locations (e.g., the Langerhans cells for DNA vaccines).

2. Sufficient “footprint” on the tissue to deliver sufficient payload and target the appropriate number of cells.
3. Noise levels within the user guidelines, for both the operator and patient.
4. Device is to be hand-held.
5. For long-term stability, the pharmaceutical is to be stored within a sealed environment.
6. Device is to be produced from biocompatible materials.
7. Devices, manufactured in large numbers, are to be cost competitive with other relevant technologies.

18.4.2.1 Earlier Generation Systems

Early attempts to address these parameters were with a prototype device family generated from empirical studies. A schematic of one of these devices, using a convergent–divergent nozzle design, is shown in Figure 18.4A [54]. Working with these devices, the challenge was to establish the gas-particle dynamics behavior of the systems. A significant research programme was directed at this goal.

A suite of methods were used to characterize the gas and particle dynamics of these systems. Quinlan et al. [55] performed static pressure measurements to interrogate the gas flow, together with time-integrated Doppler global velocimetry (DGV) measurements of drug particle velocity. These measurements were very useful, but gave an incomplete description of the predominantly unsteady flow in the device.

In subsequent, broader studies, the transient gas and particle flow within the device were interrogated with Pitot–static pressure measurement (as instrumented in Figure 18.4A), together with Schlieren imaging, and time resolved DGV [55] and computational fluid dynamics (CFD) modeling [56]. The findings of this study are summarized with measured axial Mach number profiles through the nozzle (Figure 18.4B) and a single Schlieren image (Figure 18.4C).

The axial profiles of Mach number at various times after termination of the starting process (based on total-static and Pitot–static pressure measurements) are compared with the theoretical Mach number profile for steady isentropic quasi-one-dimensional supersonic flow (with the assumption of a choked throat) in Figure 18.4B. Pitot and static pressure measurements (P_2 and P_3 , respectively, in Figure 18.4A) suggest that 500 μ s after diaphragm rupture, the flow 38.5 mm upstream of the nozzle exit is supersonic and close to the isentropic ideal. Further downstream, however, the overexpanded nozzle flow is processed through an oblique shock system which induces flow separation. Consequently, the experimentally determined Mach number (determined from Pitot and static pressure) gradually falls from between 2 and 2.5 (23.5 mm upstream of the exit plane) to 1.5 at the exit plane. The Mach number in the downstream region of the nozzle decays with time as the shock system moves upstream.

Sequences of Schlieren images such as the sample shown in Figure 18.4C ($t = 132 \mu$ s) reveal the structure of the evolving flowfield with greater detail and clarity [54].

The oblique shocks visible have evolved to form at least three oblique shock cells that have interacted with the boundary layer and separated the nozzle flow.

DGV images show particles were entrained in the nozzle starting process and the separated nozzle flow—regimes with large variations in gas density and velocity—giving rise to large variations in particle velocity (200–800 ms^{-1}) and spatial distributions [54]. Clearly, parameter (1) from above is not satisfied with this geometry.

Furthermore, the gas flow throughout much of the nozzle (Figure 18.4C) is highly sensitive to variations in the nozzle boundary condition imposed by inserting a tissue target and a silencer—because the boundary condition information can be communicated upstream. This means that this silenced device applied to the tissue target would have considerably lower and more variable impact velocities. In some cases, it is questionable whether these subsonic nozzle flow silenced devices would deliver particles with a sufficient momentum to reach the target tissue layer.

18.4.2.2 Improved Devices for Clinical Use

To overcome the large variations in particle impact conditions in earlier described devices—and meet the other important criteria of a practical clinical system (outlined above)—a next generation biolytic device, called the contoured shock tube (CST), was conceived and developed [57–62]. The devices operate with the principle of delivering a payload of microparticles to the skin with a narrow range of velocities, by entraining the drug payload in a quasi-one-dimensional, steady supersonic flowfield.

In experiments with simple prototype CST devices, it was shown that the desired gas flow was achieved repeatedly [57]. Importantly, further work with particle payloads measured a variation in free-jet particle velocity of $\pm 4\%$ [57]. In this research, measurements were made with particle image velocimetry (PIV). A sample PIV result is shown in Figure 18.5. Similar PIV images at a range of times after diaphragm rupture were processed to extract the mean centerline axial particle velocity profiles. Importantly, these PIV measurements show particle payloads do achieve near uniform exit-plane velocities at the device exit over the time interval studied. This CST device prototype was a benchtop prototype, not addressing the key criteria for a practical, hand-held clinical immunotherapeutic system.

An embodiment of the CST configured to meet these clinical needs is shown in Figure 18.6, with the key components labeled. The device was fabricated from biocompatible materials and the device wall thickness was kept relatively constant to meet autoclave sterilization requirements.

To reduce the overall system length, the bottle reservoir (which operates by an actuation pin) is located within the driver annulus. A challenge of this coaxial arrangement was to maintain integrity of transonic gas flow within the driver

FIGURE 18.5 (See color insert following blank page 206.) (A) Raw image and (B) derived PIV velocity map of the instantaneous particle flowfield of a CST prototype, taken 225 μ s after diaphragm rupture. The payload was 2.2 mg of 39 μ m diameter polystyrene spheres. (Adapted from Kendall, M.A.F., *Shock Waves J.*, 12, 22, 2002. With permission.)

initiated after diaphragm rupture. This challenge was met by carefully contouring the driver and obstacle of the mounting arrangement [60]. Possible fragments from opening of the aluminium gas bottle are contained by a sealed filter at the bottle head.

The powdered pharmaceutical is enclosed and sealed by a cassette created by the inclusion of additional diaphragms upstream of the particle payload. In this case, the cassette houses two jets designed to mix the particles into a cloud, hence reducing the dependence on the initial particle location [57,59]. Therefore, a nominally uniform spatial distribution of particles is released within the quasi-steady flow through the shock tube and nozzle. Repeated *in vitro* and *in vivo* experiments show that polycarbonate diaphragm fragments do not damage the target.

Elements of the silencing system are also shown in Figure 18.6. The primary shock initiated by diaphragm rupture, reflected from the target, is identified as the main source of sound to be attenuated. This shock is collapsed into compression waves by a series of compressions–expansions induced by an array of orifices and saw-tooth baffles, resulting in appropriate sound levels for the operator and patient.

The device lift-off force is also to be well within user constraints. A peak lift-off force of 13 N is achieved by the careful selection of endbell contact diameter, silencer volume, flow-rates through the reservoir, and silencer geometry. This peak was for only a very short time within a gas flow lasting only $\sim 200 \mu$ s (with a helium driver gas). The point of contact between the device and skin target was selected to maintain a target seal and to minimize the lift-off force, while not adversely

FIGURE 18.6 CST prototype configured for clinical biolistic delivery. (Adapted from Kendall, M.A.F., *Shock Waves J.*, 12, 22, 2002. With permission.)

affecting the impact velocities of the particles. The effect of silencing was also minimized by maintaining a supersonic gas flow transporting particles through the nozzle—so changes in the nozzle boundary condition were not fed upstream.

The range of impact conditions for the CST platform was achieved by the selection of appropriate helium/nitrogen mixtures within the gas bottle driver/driven area ratios.

18.4.3 BALLISTICS MICROPARTICLE DELIVERY TO SKIN

We now examine delivery of microparticles from these quantified and highly controlled biolistics devices, impacting the skin. Shown in Figure 18.1, this skin is a highly variable, bio-viscoelastic material.

The described biolistic devices have been applied to a range of tissue targets for immunotherapeutic applications, including the skin of rodents [65], pigs [67], dogs [68], and humans [66]. Typically, two classes of particles are delivered to the tissue. In the powder delivery of conventional vaccines and allergens for allergy immunotherapy, particles of 10–20 μm in radius are delivered to the epidermis of the skin to achieve a therapeutic effect [65]. DNA vaccination, however, is an application in which smaller (radius 0.5–2 μm) gold particles coated with a DNA construct are targeted at the nuclei of key immunologically sensitive cells within the epidermis [53].

18.4.3.1 Theoretical Model for Ballistic Impact into Skin

In these particle impact studies, the mechanisms of particle impact were explored with a theoretical model based on a representation first proposed by Dehn [63]. The model attributes the particle resistive force (D) to plastic deformation and target inertia

$$D = \frac{1}{2} \rho_t A v^2 + 3A \sigma_y \quad (18.1)$$

where

- ρ_t and σ_y are the density and yield stress of the target
- A is the particle cross-sectional area
- v is the particle velocity

The yield stress (sometimes known as the breaking stress) is the stress at which the tissue begins to exhibit plastic behavior. Equation 18.1 may be integrated to obtain the penetration depth as a function of particle impact and target parameters. The key parameters of the skin used in the model are summarized in Table 18.1. Note that these parameters have all been obtained at low, quasi-static strain-rates, and not the high ballistic strain-rates.

The theoretical model of particle penetration into the epidermis using Equation 18.1 in a two layer model is shown in Figure 18.1C. Equation 18.1 shows that the yield stress and density of the SC and viable epidermis are important in the ballistic delivery of particles to the epidermis.

In the case of particle delivery only to the SC (labeled “A” in Figure 18.1C), the particle depth into the SC (d_{sc}) is obtained by the integration of Equation 18.1.

$$d_{sc} = \frac{4\rho_p r_p}{3\rho_{sc}} \left\{ \ln \left(\frac{1}{2} \rho_{sc} v_i^2 + 3\sigma_{sc} \right) - \ln(3\sigma_{sc}) \right\} \quad (18.2)$$

where the subscripts sc and p denote the SC and particle properties, respectively. Also, v_i and σ_{sc} , respectively, are the particle impact velocity and SC yield stress.

If the particle impact momentum is sufficient to breach the SC (labeled “B” in Figure 18.1C), Equation 18.2 is rearranged to obtain the velocity of the particle at the SC–viable epidermis boundary ($v_{i,ve}$), i.e.,

$$v_{i,ve} = \left\{ \left(v_i^2 + \frac{6\sigma_{sc}}{\rho_{sc}} \right) e^{\frac{-3\rho_{sc} t_{sc}}{4\rho_p r_p}} - \frac{6\sigma_{sc}}{\rho_{sc}} \right\}^{\frac{1}{2}} \quad (18.3)$$

where t_{sc} is the thickness of the SC.

TABLE 18.1
Parameters and Assigned Values Used in the Theoretical Calculations of the Particle Penetration Depth as a Function of the Relative Humidity

Skin Region	Parameter	Value	Source
SC	σ_{sc} (MPa)	22.5–3.2 (0%–100% RH)	Wildnauer et al. (1971)
	ρ_{sc} (kg m ⁻³)	1500	Duck (1990)
	t_{sc} (μm)	10–15.6 (0%–93% RH)	Blank et al. (1984) (measurement)
Viable epidermis	σ_{ve} (MPa)	2.2	Kishino and Yanagida (1988) (actin tensile)
		10	Mitchell et al. (2003) (epithelium)
	ρ_{ve} (kg m ⁻³)	1150	Duck (1990)

Source: From Kendall, M.A.F., Rishworth, S., Carter, F.V., and Mitchell, T.J., *J. Invest. Dermatol.*, 122, 739, 2004.

The subsequent particle penetration in the viable epidermis (d_{ve}) is then calculated using Equation 18.2, using instead the material properties of the viable epidermis and $v_{i,ve}$. The total particle penetration depth (d_t) is thus

$$d_t = t_{sc} + d_{ve} \quad (18.4)$$

An alternative fully numerical discrete element model approach has also been applied [64], but will not be discussed here.

18.4.3.2 Locations of Microparticles into Skin

As one example, particle delivery to excised human skin is shown for both classes of particles (Figure 18.7) [66]. In Figure 18.7A, a glass particle of 20 μm radius delivered to the skin at a nominal entry velocity of 260 m/s is shown. Note the variation in both the SC and epidermal thicknesses. Histological sampling of the three skin sites from the backs of cadavers. Measured SC and epidermal thickness compared very well with previous reports from the literature. Over 1800 readings of the deepest particle edge and size of the particles were made on similar histological sections with polystyrene, stainless steel, and glass particles, selected for different density and size ranges.

In Figure 18.7B, a histological section is shown after the impact of gold particles with a measured mean radius of $1 \pm 0.2 \mu\text{m}$ on the skin with a mean calculated impact velocity of $580 \pm 50 \text{ m/s}$. A sample particle depth measurement is labeled as d_i . Over 1200 readings of the deepest edge and size of the gold particles were made on similar histological sections. All the raw data collected from the histology sections (such as in

Figure 18.7) are plotted as a function of the particle impact parameter, ρvr where ρ is the density, v is the velocity, and r is the radius, in Figure 18.8. The variability of penetration as shown in Figure 18.8 is typical of results obtained with other tissues.

Some insights into the sources of scatter in the penetration data of Figure 18.8 can be gained when the data are grouped and processed. Consider, for instance, the gold particles shown in Figure 18.7 grouped by particle radius as shown in Figure 18.9. The error bars correspond to one standard deviation in collapsed particle penetration depth and ρvr . Note the trend indicating that for a given value of ρvr , an increase in radius (and hence a decrease in impact velocity) corresponds to a decrease in penetration depth. These data, together with other (unpublished) work, show the different particle sizes and the cell matrix results in different penetration depths. For instance, the gold particles are smaller than the average cell size, and, during deceleration through the skin tissue, are more likely to penetrate through individual cell membranes. For the larger particles, however, the tissue would primarily fail between the cell boundaries. Indeed, these ballistic penetration data are qualitatively consistent with findings from microprobe indentation studies [24], albeit at considerably higher strain rates.

Corresponding calculated penetration profiles using the theoretical model are also shown in Figure 18.8, and illustrate a similar trend with good agreement. Importantly, in this case the yield stress was held constant at 40 MPa, to achieve the closest fit with the data. This is considerably higher than the quasi-static yield stresses reported in the literature (summarized in Table 18.1 and Figure 18.2). This discrepancy is

FIGURE 18.7 Photomicrographs of particles delivered to human skin. (A) A 20 μm radius glass sphere delivered at 260 m/s and (B) gold particles ($1.0 \pm 0.2 \mu\text{m}$ radius) delivered at $580 \pm 50 \text{ m/s}$ are shown. (Adapted from Kendall, M.A.F., Mitchell, T.J., and Wrighton-Smith, P., *J. Biomech.*, 37, 1733, 2004. With permission.)

FIGURE 18.8 (See color insert following blank page 206.) Raw gold and larger particle penetration into excised human skin as a function of the particle radius, density, and impact velocity. FIGURE 18.9 Impact parameters and penetration depth of gold particles within excised human skin. (Adapted from Kendall, M.A.F., Mitchell, T.J., and Wrighton-Smith, P., *J. Biomech.*, 37, 1733, 2004. With permission.)

attributed to a huge strain-rate effect: the ballistic impact of the microparticle has a peak strain-rate of $\sim 10^6 \text{ s}^{-1}$. In a subsequent, more refined study [22], these strain-rate effects are further elucidated.

In addition to the described scale and strain-rate effects, another source of variability stems from the high sensitivity in SC mechanical properties to hydration and temperature, deriving from variation in ambient conditions (detailed in [22]). Increasing the RH from 15% to 95% (temperature at 25°C) led to a particle penetration increase by a factor of 1.8. Temperature increases from 20°C to 40°C (RH at 15%) enhanced particle penetration twofold. In both cases, these increases were sufficient to move the target layer from the SC to the viable epidermis. In immunotherapeutic applications, this is the difference between the ineffectual delivery of particles to the SC and the targeted delivery of specific cells in the viable epidermis.

These collective data show the momentum range obtained from the described biolistic devices primarily translate into delivery within targeted viable epidermis and SC. With the precise delivery conditions achieved from these devices, we have obtained new insights into the important biological variability in microparticle impact. This variability, together with more obvious differences in tissue thicknesses (with the tissue site of target, age, and gender), must be considered when

selecting device conditions for clinical biolistic immunotherapeutic delivery.

18.4.3.3 Skin Cell Death from Ballistic Impact

Of great importance in biolistics applications is the biological responses induced by biolistic impact. When delivered to the tissue surface, the microparticles undergo a tremendous deceleration—peaking at $\sim 10^{10} \text{ g}$ —and coming to rest within $\sim 100\text{--}200 \text{ ns}$. Such deceleration induces shock and stress waves within the tissue, and it is important to determine under which conditions skin cells are killed. This was investigated in mice, where following the delivery of gold microparticles, the cell death was assayed with mixtures of ethidium bromide and acridine orange and images noninvasively with multiphoton microscopy (MPM) [69]. The data are summarized in Figures 18.10 and 18.11. It was found that each direct impact of a gold microparticle resulted in cell death. Further, even in cases where microparticles passed within $\sim 10 \mu\text{m}$ of the cell surface—but not touching the cell—cell death resulted. A sufficiently high number density in the tissue can result in complete cell death within the viable epidermis. Clearly, this is important when considering the biological responses induced by microparticle impact.

FIGURE 18.10 Viability of epidermal cells targeted by biolistic microparticle delivery. Data for this plot were generated by first enumerating the number of perforations per $1000 \mu\text{m}^2$ in the SC caused by microparticle penetration (Figure 18.11 slide A). The perforations were equated to microparticles. Second, percent cell death was calculated in the viable epidermis below the SC using the acridine orange/ethidium bromide assay for discriminating live and dead cells (see Figure 18.11 slide B–D). (From Raju, P.A., Truong, N.K., and Kendall, M.A.F., *Vaccine*, 24, 4644, 2006. With permission.)

FIGURE 18.11 (See color insert following blank page 206.) Murine tissue stained for live–dead cell discrimination with a cocktail of acridine orange/ethidium bromide and imaged with near-infrared two-photon excitation. Cells emitting red fluorescence are dead whereas cells emitting green fluorescence are alive. In slide A, the dark spots are perforations in the SC caused by microparticle bombardment. Slide B is the corresponding viable epidermis 11.3 μm below the SC. Slides A and B represent an image set of “high particle density” shown in Figure 18.10. Slide C is the viable epidermis of the control (9.7 μm below the SC) where particle delivery to the tissue was not made. Slide D is representative of the viable epidermis of tissue with intermediate particle densities (10.5 μm below the SC). Images were collected with LaserSharp software (Carl Zeiss, Hertfordshire, U.K.). (From Raju, P.A., Truong, N.K., and Kendall, M.A.F., *Vaccine*, 24, 4644, 2006. With permission.)

18.4.4 CLINICAL RESULTS AND COMMERCIAL APPLICATION

18.4.4.1 Commercial Application

Biolytics is a platform technology for delivering a broad range of drugs and immunotherapeutics. Currently, the technology is progressing commercially in two streams:

- Delivery of lidocaine local anesthetic to the skin (the larger class of particles shown in Figure 18.8), approved by the FDA for market application (Zingo, Anesiva)
- Delivery of DNA vaccines on gold-microparticles (PowderMed, Pfizer), undergoing phase III clinical trials

18.4.4.2 Clinical Results

Although strong results are achieved in other immunotherapeutics such as allergy immunotherapy of the animal model [65] and lidocaine for anesthesia, the key clinical progress with DNA vaccines is discussed in this section.

The DNA plasmid that forms the active component DNA vaccines is precipitated onto microscopic gold particles

(typically 2 μg DNA on 1 mg gold). Microscopic elemental gold particles (mean particle diameter $\sim 2 \mu\text{m}$) are used as the plasmid DNA carrier, because it is inert and has the appropriate density needed to deliver the vaccine directly into the target epidermal immunologically sensitive cells, including Langerhans cells.

Following delivery into the APC, the DNA elutes off the gold particle and is transcribed into RNA. The RNA in turn is translated into the relevant antigen, which is then processed and presented on the cell surface as if it were an intracellular viral protein. An efficient cellular and humoral immune response is thus induced.

A series of clinical trials have been conducted to assess the immunogenicity and safety of a prophylactic hepatitis B virus DNA vaccine [52,70,71]. These studies have demonstrated that biolytic DNA vaccination can elicit antigen-specific humoral and T-cell responses. In the study by [52], DNA vaccination with 1–4 μg of hepatitis B surface antigen elicited measurable cytotoxic T-cell responses and Th cell responses in all 12 healthy adults who had not previously been immunized with a hepatitis B vaccine [52]. Furthermore, all 12 previously nonvaccinated subjects also seroconverted with levels of hepatitis B-specific antibody ranging from 10 to over

TABLE 18.2
Serum Antibody Responses, Seroconversion, and Seroprotection Rate

Group	Day	GMT (Range)	Seroconversion ^a (%)	Seroprotection ^b (%)	Mean GMT Increase (Fold)
1	0	16 (15–40)	—	17 (2/12)	—
	14	23 (5–160)	8 (1/12)	42 (5/12)	1.4
	21	28 (10–240)	17 (2/12)	33 (4/12)	1.7
	56	44 (10–320)	33 (4/12)	58 (7/12)	2.8
2	0	17 (5–40)	—	33 (4/12)	—
	14	29 (10–60)	17 (2/12)	50 (6/12)	1.7
	21	36 (20–80)	8 (1/12)	58 (7/12)	2.1
	56	65 (20–320)	67 (8/12)	92 (11/12)	3.9
3	0	12 (5–40)	—	8 (1/12)	—
	14	21 (5–80)	17 (2/12)	25 (3/12)	1.8
	21	40 (10–160)	33 (4/12)	67 (8/12)	3.4
	56	97 (40–640)	64 (7/11)	100 (11/11)	8.1

Source: From Drape, R.J., Macklin, M.D., Barr, L.J., Jones, S., Haynes, J.R., and Dean, H.J., *Vaccine*, 24, 4475, 2006. With permission.

Note: Values meeting CPMP criteria are bold.

^a Seroconversion is defined as either a negative pre-vaccination titer (≤ 10) to a post-vaccination titer ≥ 40 , or a significant increase in antibody titer, i.e., at least a fourfold increase between pre- and post-vaccination titers where the pre-vaccination titer is ≥ 10 .

^b Seroprotection rate is defined as the proportion of subjects achieving a titer ≥ 40 .

5000 mIU/mL. This is of particular significance as intramuscular delivery of DNA—using the needle and syringe—with up to 1000-fold more DNA has generated only low or no antibody responses [72,73]. The same biolistic hepatitis B DNA vaccine was also shown to increase serum antibody titers in 7 of 11 subjects who had previously failed to seroconvert after three or more doses of conventional vaccination with licensed recombinant protein vaccine [70]. Finally this plasmid DNA construct has been used to successfully bridge between the earlier bulky experimental device and the simple, hand held disposable device that will be used for product commercialization [71].

A phase I study [74] has been carried out to investigate the safety and immunogenicity of biolistic administration of an influenza prophylactic plasmid, which encodes a single HA antigen of influenza A/Panama/2007/99 (H3N2). A total of 36 healthy subjects with low preexisting serological responses to this strain received a vaccination of either 1, 2, or 4 μg of DNA at a single administration session. The antibody response was then assessed according to the CHMP criteria for the approval of annual flu vaccines in the European Union. Table 18.2 summarizes these humoral responses, determined as a hemagglutination inhibition titre elicited on days 0 (pre-dose), 14, 21, and 56. Time points, where responses met the levels required by the CHMP guidelines for licensing of annual influenza vaccine, are shown in bold.

The 4 μg dose group met the CHMP criteria at day 21, demonstrating the ability of biolistic DNA vaccination to stimulate serological responses equivalent to those seen in

protein based approaches. Furthermore, the responses in all groups continued to increase up to day 56 (the last day monitored) indicating that responses to biolistic vaccination may show a more sustained increase than is typically seen with protein vaccines. By day 56 100% of those subjects vaccinated with the 4 μg dose were seroprotected.

Overall vaccination was well tolerated and local reactogenicity results were typical of those seen in other biolistics studies.

18.5 CONCLUSION

Many immunotherapeutics (e.g., vaccines) can be radically improved by targeted delivery to particular immunologically sensitive cells within the outer skin layers. The push is on to develop a range of technologies to meet this need, either using physical or biological targeting approaches. One of these methods, called biolistics, ballistically delivers biomolecule-coated gold microparticles to the outer layers of the skin. The method of particle acceleration relies heavily on approaches usually applied to the aerospace industry. Consequently, many unique challenges had to be overcome in engineering biolistic devices for clinical use. Research with the resultant devices has yielded unique insights into the skin at microscale dynamic loading—both from mechanical and biological perspectives. Important progress is also being made in clinical trials using biolistic devices to deliver DNA vaccines in the following fields: hepatitis B, influenza, genital herpes, human papilloma virus, HIV/AIDS, Hantaan virus, melanoma, and a variety of other cancers.

19.1 INTRODUCTION

Many investigators are focused on the production of effective nonviral gene therapeutics and on creating improved delivery systems that mix viral and nonviral vectors. Use of improved liposome formulations for delivery *in vivo* is valuable for gene therapy and would avoid several problems associated with viral delivery. Delivery of nucleic acids using liposomes is promising as a safe and nonimmunogenic approach to gene therapy. Furthermore, gene therapeutics composed of artificial reagents can be standardized and regulated as drugs rather than as biologics. Cationic lipids have been used for efficient delivery of nucleic acids to cells in tissue culture for several years [1,2]. Much effort has also been directed toward developing cationic liposomes for efficient delivery of nucleic acids in animals and in humans [3–12]. Most frequently, the formulations that are best to use for transfection of a broad range of cell types in culture are not optimal for achieving efficacy in small and large animal disease models.

Much effort has been devoted to the development of nonviral delivery vehicles due to the numerous disadvantages of viral vectors that have been used for gene therapy. Following viral delivery, *in vivo* immune responses are generated to express viral proteins that subsequently kill the target cells

required to produce the therapeutic gene product; an innate humoral immune response can be produced to certain viral vectors due to previous exposure to the naturally occurring virus; random integration of some viral vectors into the host chromosome could occur and cause activation of proto-oncogenes resulting in tumor formation; clearance of viral vectors delivered systemically by complement activation can occur, viral vectors can be inactivated upon re-administration by the humoral immune response, and potential for recombination of the viral vector with DNA sequences in the host chromosome that generates a replication-competent infectious virus also exists. Specific delivery of viral vectors to target cells can be difficult because two distinct steps in engineering viral envelopes or capsids must be achieved. First, the virus envelope or capsid must be changed to inactivate the natural tropism of the virus to enter specific cell types. Then sequences must be introduced that allow the new viral vector to bind and internalize through a different cell surface receptor. Other disadvantages of viral vectors include the inability to administer certain viral vectors more than once, the high costs for producing large amounts of high-titer viral stocks for use in the clinic, and the limited size of the nucleic acid that can be packaged and used for viral gene therapy. Attempts are

being made to overcome the immune responses produced by viral vectors after administration in immune competent animals and in humans, such as the use of gutted adenoviral vectors or encapsulation of viral vectors in liposomes [13]. However, complete elimination of all immune responses to viral vectors may be impossible.

Use of liposomes for gene therapy provides several advantages. A major advantage is the lack of immunogenicity after *in vivo* administration including systemic injections. Therefore, the nucleic acid–liposome complexes can be re-administered without harm to the patient and without compromising the efficacy of the nonviral gene therapeutic. Improved formulations of nucleic acid–liposome complexes can also evade complement inactivation after *in vivo* administration. Nucleic acids of unlimited size can be delivered ranging from single nucleotides to large mammalian artificial chromosomes. Furthermore, different types of nucleic acids can be delivered including plasmid DNA, RNA, oligonucleotides, DNA–RNA chimeras, synthetic ribozymes, antisense molecules, RNAi, viral nucleic acids, and others. Certain cationic formulations can also encapsulate and deliver viruses [13], proteins or partial proteins with a low isoelectric point (pI), and mixtures of nucleic acids and proteins of any pI. Creation of nonviral vectors for targeted delivery to specific cell types, organs, or tissues is relatively simple. Targeted delivery involves elimination of nonspecific charge interactions with nontarget cells and addition of ligands for binding and internalization through target cell surface receptors. Other advantages of nonviral vectors include the low cost and relative ease in producing nucleic acid–liposome complexes in large scale for use in the clinic. In addition, greater safety for patients is provided using nonviral delivery vehicles due to few or no viral sequences present in the nucleic acids used for delivery thereby precluding generation of an infectious virus. The disadvantage of nonviral delivery systems had been the low levels of delivery and gene expression produced by first-generation complexes. However, recent advances have dramatically improved transfection efficiencies and efficacy of liposomal vectors [14–18]. Reviews of other *in vivo* delivery systems and improvements using cationic liposomes have been published recently [19,20].

Cationic liposome–nucleic acid complexes can be administered via numerous delivery routes *in vivo*. Routes of delivery include direct injection (e.g., intratumoral), intravenous, intraperitoneal, intra-arterial, intrasplenic, mucosal (nasal, vaginal, rectal), intramuscular, subcutaneous, transdermal, intradermal, subretinal, intratracheal, intracranial, and others. Much interest has focused on noninvasive intravenous administration because many investigators believe that this route of delivery is the “holy grail” for the treatment or cure of cancer, cardiovascular, and other inherited or acquired diseases. Particularly for the treatment of metastatic cancer, therapeutics must reach not only the primary tumor but also the distant metastases.

Optimization of cationic liposomal complexes for *in vivo* applications and therapeutics is complex, involving many distinct components. These components include nucleic acid

purification, plasmid design, formulation of the delivery vehicle, administration route and schedule, dosing, detection of gene expression, and others. Often I make the analogy of liposome optimization to a functional car. Of course the engine of the car, analogous to the liposome delivery vehicle, is extremely important. However, if the car does not have wheels, adequate tires, etc., the motorist will not be able to drive the vehicle to its destination. This chapter focuses on optimization of these distinct components for use in a variety of *in vivo* applications. Optimizing all components of the delivery system will allow broad use of liposomal complexes to treat or cure human diseases or disorders.

19.2 OPTIMIZATION OF CATIONIC LIPOSOME FORMULATIONS FOR USE *IN VIVO*

Much research has been directed toward the synthesis of new cationic lipids. Some new formulations led to the discovery of more efficient transfection agents for cells in culture. However, their efficiency measured *in vitro* did not correlate with their ability to deliver DNA after administration in animals. Functional properties defined *in vitro* do not assess the stability of the complexes in plasma or their pharmacokinetics and biodistribution, all of which are essential for optimal activity *in vivo*. Colloidal properties of the complexes in addition to the physicochemical properties of their component lipids also determine these parameters. In particular, in addition to efficient transfection of target cells, nucleic acid–liposome complexes must be able to traverse tight barriers *in vivo* and penetrate throughout the target tissue to produce efficacy for the treatment of disease. These are not issues for achieving efficient transfection of cells in culture with the exception of polarized tissue culture cells. Therefore, we are not surprised that optimized liposomal delivery vehicles for use *in vivo* may be different than those used for efficient delivery to cells in culture.

In summary, *in vivo* nucleic acid–liposome complexes that produce efficacy in animal models of disease have extended half-life in the circulation, are stable in serum, have broad biodistribution, efficiently encapsulate various sizes of nucleic acids, are targetable to specific organs and cell types, penetrate across tight barriers in several organs, penetrate evenly throughout the target tissue, are optimized for nucleic acid/lipid ratio and colloidal suspension *in vivo*, can be size fractionated to produce a totally homogenous population of complexes prior to injection, and can be repeatedly administered. Recently, we demonstrated efficacy of a robust liposomal delivery system in small and large animal models for lung [15], breast [17], head and neck, and pancreatic cancers [16], and for hepatitis B and C. On the basis of efficacy in these animal studies, this liposomal delivery system has been used successfully in a phase I clinical trial to treat end-stage nonsmall cell lung carcinoma patients who have failed to respond to chemotherapy (Lu et al., *AACR Meeting*, Los Angeles 2007). These patients have prolonged life spans and have demonstrated objective responses including tumor regression. This liposomal delivery system will also be used

in upcoming clinical trials to treat other types of cancer including pancreatic, breast, and head and neck cancers. Our studies have demonstrated broad efficacy in the use of liposomes to treat disease and have dispelled several myths that exist concerning the use of liposomal systems.

19.3 LIPOSOME MORPHOLOGY AND EFFECTS ON GENE DELIVERY AND EXPRESSION

Efficient *in vivo* nucleic acid–liposome complexes have unique features including their morphology, mechanisms for crossing the cell membrane and entry into the nucleus, ability to be targeted for delivery to specific cell surface receptors, and ability to penetrate across tight barriers and throughout target tissues. Liposomes have different morphologies based upon their composition and the formulation method. Furthermore, the morphology of complexes can contribute to their ability to deliver nucleic acids *in vivo*. Formulations frequently used for the delivery of nucleic acids are lamellar structures which include small unilamellar vesicles (SUVs), multilamellar vesicles (MLVs), or bilamellar invaginated vesicles (BIVs) recently developed in our laboratory (Figure 19.1). Several investigators have developed liposomal delivery systems using hexagonal structures, however, they have demonstrated efficiency primarily for the transfection of some cell types in culture and not for *in vivo* delivery. SUVs condense nucleic acids on the surface and form “spaghetti and meatballs” structures [21]. DNA–liposome complexes made using SUVs produce little or no gene expression upon systemic delivery although these complexes transfect numerous cell types efficiently *in vitro* [1,2]. Furthermore, SUV liposome–DNA complexes cannot be targeted efficiently. SUV liposome–DNA complexes also have a short half-life within the circulation, generally about 5–10 min. Polyethylene glycol (PEG) has been added to liposome formulations to extend their half-life [22–24], however, PEGylation created other problems that have not been resolved. PEG seems to hinder delivery of cationic liposomes into cells due to its sterically hindering ionic interactions, and it interferes with optimal condensation of nucleic acids onto the cationic delivery vehicle. Furthermore, extremely long half-life in the circulation, e.g., several days, has caused problems for patients because the bulk of the PEGylated liposomal formulation doxil that encapsulates the cytotoxic agent, doxorubicin, accumulates in the skin, hands, and feet. For example, patients contract mucositis and hand and foot syndrome [25,26] that cause extreme discomfort to the patient. Attempts to add ligands to doxil for delivery to specific cell surface receptors have not resulted in much cell-specific delivery, and the majority of the injected targeted formulation still accumulates in the skin, hands, and feet. Addition of PEG into formulations developed in our laboratory also caused steric hindrance in the bilamellar invaginated structures that did not encapsulate DNA efficiently, and gene expression was substantially diminished.

Some investigators have loaded nucleic acids within SUVs using a variety of methods; however, the bulk of the DNA does not load or stay within the liposomes. Furthermore, most

FIGURE 19.1 Diagrams drawn from cryo-electron micrographs of cross-sections through vitrified films of various types of liposomes and DNA–liposome complexes. SUVs are small unilamellar vesicles that condense nucleic acids on the surface and produce spaghetti and meatballs structures. MLVs are multilamellar vesicles that appear as Swiss Rolls after mixing with DNA. BIVs are bilamellar invaginated vesicles produced using a formulation developed in our laboratory. Nucleic acids are efficiently encapsulated between two bilamellar invaginated structures (BIVs). (From Templeton, N.S. et al., *Nat. Biotechnol.*, 15, 647, 1997.)

of the processes used for loading nucleic acids within liposomes are extremely time consuming and not cost effective. Therefore, SUVs are not the ideal liposomes for creating nonviral vehicles for targeted delivery.

Complexes made using MLVs appear as “Swiss rolls” when viewing cross-sections by cryo-electron microscopy [27]. These complexes can become too large for systemic administration or deliver nucleic acids inefficiently into cells due to inability to “unravel” at the cell surface. Addition of ligands onto MLV liposome–DNA complexes further aggravates these problems. Therefore, MLVs are not useful for the development of targeted delivery of nucleic acids.

Using a formulation developed in our laboratory, nucleic acids are efficiently encapsulated between two BIVs [14]. We created these unique structures using 1,2-bis(oleoyloxy)-3-(trimethylamino)propane (DOTAP) and cholesterol (Chol) and a novel formulation procedure. This procedure is different because it includes a brief, low frequency

FIGURE 19.2 Proposed model showing cross-sections of extruded DOTAP:Chol:liposomes (BIVs) interacting with nucleic acids. Nucleic acids adsorb onto a BIV via electrostatic interactions. Attraction of a second BIV to this complex results in further charge neutralization. Expanding electrostatic interactions with nucleic acids cause inversion of the larger BIV and total encapsulation of the nucleic acids. Inversion can occur in these liposomes because of their excess surface area, which allows them to accommodate the stress created by the nucleic acid–lipid interactions. Nucleic acid binding reduces the surface area of the outer leaflet of the bilayer and induces the negative curvature due to lipid ordering and reduction of charge repulsion between cationic lipid headgroups. Condensation of the internalized nucleic acid–lipid sandwich expands the space between the bilayers and may induce membrane fusion to generate the apparently closed structures. The enlarged area shows the arrangement of nucleic acids condensed between two 4 nm bilayers of extruded DOTAP:Chol.

sonication followed by manual extrusion through filters of decreasing pore size. The 0.1 and 0.2 μm filters used are made of aluminum oxide and not polycarbonate that is typically used by other protocols. Aluminum oxide membranes contain more pores per surface area, evenly spaced and sized pores, and pores with straight channels. During the manual extrusion process the liposomes are passed through each of four different sized filters only once. This process produces 88% invaginated liposomes. Use of high frequency sonication or mechanical extrusion produces only SUVs.

The BIVs produced condense unusually large amounts of nucleic acids of any size (Figure 19.2) or viruses (Figure 19.3). Furthermore, addition of other DNA condensing agents including polymers is not necessary. For example, condensation of plasmid DNA onto polymers first before encapsulation in the BIVs did not increase condensation or subsequent gene expression after transfection *in vitro* or *in vivo*. Encapsulation of nucleic acids by these BIVs alone is spontaneous and immediate, and therefore, cost effective requiring only one step of simple mixing. The extruded DOTAP:Chol–nucleic acid complexes are also large enough so that they are not cleared rapidly by Kupffer cells in the liver and yet extravasate across tight barriers, including the endothelial cell barrier of the lungs in a normal mouse, and diffuse through target organs efficiently [15]. Our recent work demonstrating efficacy for

treatment of nonsmall cell lung cancer [15] showed that only BIV DOTAP:Chol–p53–DNA:liposome complexes produced efficacy, and SUV DOTAP:Chol–p53–DNA:liposome complexes produced no efficacy. Therefore, the choice of lipids

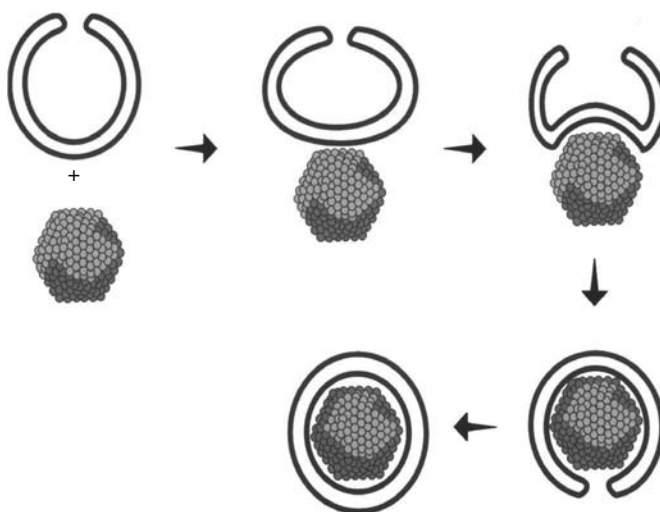

FIGURE 19.3 Proposed model showing cross-sections of an extruded DOTAP:Chol:liposome (BIV) interacting with adenovirus. Adenovirus interacts with a BIV causing negative curvature and wrapping around the virus particle.

alone is not sufficient for optimal DNA delivery, and the morphology of the complexes is essential.

19.4 OPTIMAL LIPIDS AND LIPOSOME MORPHOLOGY: EFFECTS ON GENE DELIVERY AND EXPRESSION

Choosing the best cationic lipids and neutral lipids are also essential for producing the optimal *in vivo* formulation. For example, using our novel manual extrusion procedure does not produce BIVs using the cationic lipid dimethyldioctadecyl ammonium bromide (DDAB). Furthermore, DOTAP is biodegradable, whereas DDAB is not biodegradable. Use of biodegradable lipids is preferred for use in humans. Furthermore, only DOTAP and not DDAB containing liposomes produced highly efficient gene expression *in vivo* [14]. DDAB did not produce BIVs and was unable to encapsulate nucleic acids. Apparently, DDAB and DOTAP containing SUVs produce similar efficiency of gene delivery *in vivo*; however, these SUVs are not as efficient as BIV DOTAP:Chol [14]. In addition, use of L- α dioleoyl phosphatidylethanolamine (DOPE) as a neutral lipid creates liposomes that cannot wrap or encapsulate nucleic acids. Several investigators have reported efficient transfection of cells in culture using DOPE in liposomal formulations. However, our data showed that formulations consisting of DOPE were not efficient for producing gene expression *in vivo* [14].

Investigators must also consider the source and lot of certain lipids purchased from companies. For example, different lots of cholesterol from the same vendor can vary dramatically and will affect the formulation of liposomes. Recently, we are using synthetic cholesterol (Sigma, St. Louis, MO). Synthetic cholesterol instead of natural cholesterol that is purified from the wool of sheep is preferred by the Food and Drug Administration for use in producing therapeutics for injection into humans.

Our BIV formulations are also stable for a few years as liquid suspensions. Freeze-dried formulations can also be made that are stable indefinitely even at room temperature. Stability of liposomes and liposomal complexes is also essential particularly for the commercial development of human therapeutics.

19.5 LIPOSOME ENCAPSULATION, FLEXIBILITY, AND OPTIMAL COLLOIDAL SUSPENSIONS

A common belief is that artificial vehicles must be 100nm or smaller to be effective for systemic delivery. However, this belief is most likely true only for large, inflexible delivery vehicles. Blood cells are several microns (up to 7000nm) in size, and yet have no difficulty circulating in the blood including through the smallest capillaries. However, sickle cell blood cells, that are rigid, do have problems in the circulation. Therefore, we believe that flexibility is a more important issue than small size. In fact, BIV DNA-liposome complexes in the size range of 200–450nm produced the highest levels of gene expression in all tissues after intravenous injection [14]. Delivery vehicles, including nonviral vectors and viruses, that are

FIGURE 19.4 Cryo-electron micrograph of BIV DOTAP:Chol-DNA:liposome complexes. The plasmid DNA is encapsulated between two BIVs.

not PEGylated and are smaller than 200nm are cleared quickly by the Kupffer cells in the liver. Therefore, increased size of liposomal complexes could extend their circulation time particularly when combined with injection of high colloidal suspensions. BIVs are able to encapsulate nucleic acids and viruses apparently due to the presence of cholesterol in the bilayer (Figure 19.4). Whereas, formulations including DOPE instead of cholesterol could not assemble nucleic acids by a “wrapping type” of mechanism (Figure 19.5) and produced little gene

FIGURE 19.5 Cryo-electron micrograph of extruded DOTAP:DOPE liposomes complexed to plasmid DNA. Although these liposomes were prepared by the same protocol that produces BIV DOTAP:Chol, these vesicles cannot wrap and encapsulate nucleic acids. The DNA condenses on the surfaces of the liposomes shown.

expression in the lungs and no expression in other tissues after intravenous injections. Because the extruded DOTAP:Chol BIV complexes are flexible and not rigid, are stable in high concentrations of serum, and have extended half-life, they do not have difficulty circulating efficiently in the bloodstream.

We believe that colloidal properties of nucleic acid–liposome complexes also determine the levels of gene expression produced after *in vivo* delivery [14,28]. These properties include the DNA/lipid ratio that determines the overall charge density of the complexes and the colloidal suspension that is monitored by its turbidity. Complex size and shape, lipid composition and formulation, and encapsulation efficiency of nucleic acids by the liposomes also contribute to the colloidal properties of the complexes. The colloidal properties affect serum stability, protection from nuclease degradation, blood circulation time, and biodistribution of the complexes.

Our *in vivo* transfection data showed that an adequate amount of colloids in suspension was required to produce efficient gene expression in all tissues examined [14]. The colloidal suspension is assessed by measurement of adsorbance at 400 nm using a spectrophotometer optimized to measure turbidity. Our data showed that transfection efficiency in all tissues corresponded to OD400 of the complexes measured prior to intravenous injection.

19.6 OVERALL CHARGE OF COMPLEXES AND ENTRY INTO THE CELL

In addition, our delivery system is efficient because the complexes deliver DNA into cells by fusion with the cell membrane and avoid the endocytic pathway (Figure 19.6). Cells are negatively charged on the surface, and specific cell types vary in their density of negative charge. These differences in charge density can influence the ability of cells to be transfected. Cationic complexes have nonspecific ionic charge interactions with cell surfaces. Efficient transfection of cells by cationic complexes is, in part, contributed by adequate charge interactions. In addition, recent publications report

that certain viruses have a partial positive charge around key subunits of viral proteins on the virus surface responsible for binding to and internalization through target cell surface receptors. Therefore, this partial positive charge is required for virus entry into the cell. Thus, maintenance of adequate positive charge on the surface of targeted liposome complexes is essential for optimal delivery into the cell. Different formulations of liposomes interact with cell surfaces via a variety of mechanisms. Two major pathways for interaction are by endocytosis or by direct fusion with the cell membrane [27,29–34]. Preliminary data suggest that nucleic acids delivered *in vitro* and *in vivo* using complexes developed in our laboratory enter the cell by direct fusion (Figure 19.6). Apparently, the bulk of the nucleic acids do not enter endosomes, and therefore, far more nucleic acid enters the nucleus. Cell transfection by direct fusion produced increased levels of gene expression, and numbers of cells transfected versus cells transfected through the endocytic pathway by several orders of magnitude.

We believe that maintenance of adequate positive charge on the surface of complexes is essential to drive cell entry by direct fusion. Therefore, we create targeted delivery of our complexes *in vivo* without the use of PEG. These ligand-coated complexes also reexpose the overall positive charge of the complexes as they approach the target cells. Through ionic interactions or covalent attachments, we have added monoclonal antibodies, Fab fragments, proteins, partial proteins, peptides, peptide mimetics, small molecules, and drugs to the surface of our complexes after mixing. These ligands efficiently bind to the target cell surface receptor, and maintain entry into the cell by direct fusion. Using novel methods for addition of ligands to the complexes for targeted delivery results in further increased gene expression in the target cells after transfection. Therefore, we design targeted liposomal delivery systems that retain predominant entry into cells by direct fusion versus the endocytic pathway. Figure 19.7 shows our optimized strategy to achieve targeted delivery, deshielding, fusion with the cell membrane, entry of nucleic acids into

FIGURE 19.6 Mechanisms for cell entry of nucleic acid–liposome complexes. Two major pathways for interaction are by endocytosis or by direct fusion with the cell membrane. Complexes that enter the cell by direct fusion allow delivery of more nucleic acids to the nucleus because the bulk of the nucleic acids do not enter endosomes.

FIGURE 19.7 (See color insert following blank page 206.) Optimized strategy for delivery and gene expression in the target cell. Optimization of many steps is required to achieve targeted delivery, shielding from nonspecific uptake in nontarget organs and tissues, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

19.7 SERUM STABILITY OF OPTIMIZED NUCLEIC ACID-LIPOSOME COMPLEXES FOR USE *IN VIVO*

Serum stability of cationic complexes is complicated and cannot be assessed by simply performing studies at a random concentration of serum. Figure 19.8 shows results from serum stability studies of DNA-liposome complexes that have been optimized in our laboratory for systemic delivery. Serum stability of these complexes was studied at 37°C out to 24h at concentrations of serum ranging from 0% to 100%. Two different serum stability assays were performed. The first assay measured the OD400 of BIV DOTAP:Chol-DNA:liposome complexes added into tubes containing a different concentration of serum in each tube, ranging from 0% to 100%. The tubes were incubated at 37°C and small aliquots from each tube were removed at various time points out to 24h. The OD400 of each aliquot was measured on a spectrophotometer calibrated to accurately measure turbidity. Previous work in our laboratory demonstrated that the OD400 predicted both the stability of the complexes and the transfection efficiency results obtained for multiple organs after intravenous injections [14,28]. Percent stability for this assay is defined as the transfection efficiency that is obtained at a particular OD400 of the

complexes used for intravenous injections. Therefore, this assay is rigorous because slight declines in OD400 of these complexes result in obtaining no transfection *in vivo*. Declines in the OD400 also measure precipitation of the complexes.

A second assay was performed to support the results obtained from the OD400 measurements described above.

FIGURE 19.8 Serum stability profile for DNA-liposome complexes optimized for systemic delivery. Serum stability of these complexes was studied at 37°C out to 24h at concentrations of serum ranging from 0% to 100%. Serum stability at the highest concentrations of serum, about 70%–100%, that are physiological concentrations of serum found in the bloodstream is required.

A different concentration of serum, ranging from 0% to 100%, was placed into each well of a 96-well microtiter dish. BIV DOTAP:Chol–DNA:liposome complexes were added to the serum in the wells, and the plate was incubated at 37°C. The plate was removed at various time points out to 24 h and complexes in the wells were observed under the microscope. Precipitation of complexes in the wells was assessed. 100% stability was set at no precipitation observed. Results from this assay were compared to those obtained in the first assay. 100% stability of complexes was set at no decline of OD400 in assay #1 and no observed precipitation in assay #2 at each percent serum concentration, and the results were plotted (Figure 19.8).

The results showed serum stability at the highest concentrations of serum, about 70%–100%, that are physiological concentrations of serum found in the bloodstream. In addition, these complexes were also stable in no or low concentrations of serum, whereas, the complexes were unstable at 10%–50% serum, perhaps due to salt bridging. Therefore, *in vitro* optimization of serum stability for formulations of cationic complexes must be performed over a broad range of serum concentration to be useful for applications *in vivo*.

19.8 OPTIMIZED HALF-LIFE IN THE CIRCULATION

As stated above, the extruded BIV DOTAP:Chol–nucleic acid complexes are large enough so that they are not cleared rapidly by Kupffer cells in the liver and yet extravasate across tight barriers and diffuse through the target organ efficiently. Further addition of ligands to the surface of extruded BIV DOTAP:Chol–nucleic acid complexes does not significantly increase the mean particle size. Extravasation and penetration through the target organ and gene expression produced after transfection are not diminished. These modified formulations are positively charged and deliver nucleic acids efficiently into cells *in vitro* and *in vivo*. Because extruded BIV DOTAP:Chol–nucleic acid complexes with or without ligands have a 5 h half-life in the circulation, these complexes do not accumulate in the skin, hands, or feet. Extended half-life in the circulation is provided primarily by the formulation, preparation method, injection of optimal colloidal suspensions, and optimal nucleic acid/lipid ratio used for mixing complexes, serum stability, and size (200 to 450 nm). Therefore, these BIVs are ideal for use in the development of effective, targeted nonviral delivery systems that clearly require encapsulation of nucleic acids.

19.9 BROAD BIODISTRIBUTION OF OPTIMIZED LIPOSOME FORMULATIONS

Our “generic” BIV nucleic acid–liposome formulation transfects many organs and tissues efficiently after intravenous injection [14] and has demonstrated efficacy in animal models for lung cancer [15], pancreatic cancer [17], breast cancer [16],

hepatitis B and C, and cardiovascular diseases [35]. Therefore, optimization of the morphology of the complexes, the lipids used, flexibility of the liposomes and complexes, colloidal suspension, overall charge, serum stability, and half-life in circulation allows for efficient delivery and gene expression in many organs and tissues other than the lung. Apparently, these extruded DOTAP:Chol BIV–nucleic acid:liposome complexes can overcome the tendency to be adsorbed only by the endothelial cells lining the circulation surrounding the lungs described by other investigators [36]. However, as discussed above and below, we can further direct delivery to specific target tissues or cells by our targeted delivery strategies in combination with reversible masking used to bypass nonspecific transfection.

19.10 OPTIMIZATION OF TARGETED DELIVERY

Much effort has been made to specifically deliver nucleic acid–liposome complexes to target organs, tissues, or cells. Ligands that bind to cell surface receptors are usually attached to PEG and then attached to the cationic or anionic delivery vehicle. Due to shielding the positive charge of cationic complexes by PEG, delivery to the specific cell surface receptor can be accomplished by only a small fraction of complexes injected systemically. Furthermore, delivery of PEGylated complexes into the cell occurs predominantly through the endocytic pathway, and subsequent degradation of the bulk of the nucleic acid occurs in the lysosomes. Thus, gene expression is generally lower in the target cell than using the nonspecific delivery of highly efficient cationic complexes.

As discussed above, the vast majority of the injected PEGylated complexes bypasses the target cell. Apparently, the PEGylated complexes cannot utilize critical charge interactions for optimal transfection into cells by direct fusion. Inability to expose positive charge on the surface of optimized complexes results in the transfection of fewer cells. PEGylation was first used to increase the half-life of complexes in the circulation and to avoid uptake in the lung. However, this technology also destroys the ability to efficiently transfect cells. We were able to increase the half-life in circulation of BIVs to 5 h without the use of PEG. Because the extended half-life of BIVs is not too long, this delivery system does not result in the accumulation of complexes in nontarget tissues that circulate for 1–3 days. Some investigators have now reported targeted delivery that produces increased gene expression in the target cell over their nontargeted complexes. However, these nontargeted and targeted delivery systems are inefficient [37] compared to efficient delivery systems such as the BIVs.

In using the extruded BIV DOTAP:Chol–nucleic acid:liposome complexes, we produced an optimal half-life in the circulation without the use of PEG [14]. Extended half-life was produced primarily by the formulation, preparation method, injection of optimal colloidal suspensions, serum stability, and optimal nucleic acid/lipid ratio used for mixing complexes, and size (200 to 450 nm). Furthermore, we avoid

uptake in the lungs using the negative charge of the ligands and shielding/deshielding compounds that can be added to the complexes used for targeting just prior to injection or administration *in vivo*. Our strategy to bypass nonspecific transfection is called reversible masking (U.S. Patent No. 7,037,520 B2). By addition of ligands using the novel approaches that we developed, adequate overall positive charge on the surface of complexes is preserved. In summary, we achieve optimal circulation time of the complexes, reach and deliver to the target organ, avoid uptake in nontarget tissues, and efficiently interact with the cell surface to produce optimal transfection.

19.11 EFFICIENT DISSEMINATION THROUGHOUT TARGET TISSUES AND MIGRATION ACROSS TIGHT BARRIERS

A primary goal for efficient *in vivo* delivery is to achieve extravasation into and penetration throughout the target organ/tissue ideally by noninvasive systemic administration. Without these events therapeutic efficacy is highly compromised for any treatment including gene and drug therapies. Achieving this goal is difficult due to the many tight barriers that exist in animals and people. Furthermore, many of these barriers become tighter in the transition from neonates to becoming adults. Penetration throughout an entire tumor is further hindered due to the increased interstitial pressure within most tumors [38–40]. We believe that nonviral systems can play a pivotal role in achieving target organ extravasation and penetration needed to treat or cure certain diseases. Our preliminary studies have shown that extruded BIV DOTAP:Chol–nucleic acid:liposome complexes can extravasate across tight barriers and penetrate evenly throughout entire target organs, and viral vectors cannot cross identical barriers. These barriers include the endothelial cell barrier in a normal mouse, the posterior blood retinal barrier in adult mouse eyes, complete and even diffusion throughout large tumors [15], and penetration through several tight layers of smooth muscle cells in the arteries of pigs [35]. Diffusion throughout large tumors was measured by expression of β -galactosidase or the pro-apoptotic gene p53 in about half of the p53-null tumor cells after a single injection of BIV DOTAP:Chol–DNA:liposome complexes into the center of a tumor. Transfected cells were evenly spread throughout the tumors. Tumors injected with complexes encapsulating plasmid DNA encoding p53 showed apoptosis in almost all of the tumor cells by TUNEL staining. Tumor cells expressing p53 mediate a bystander effect on neighboring cells perhaps due to upregulation by Fas ligand that causes non-transfected tumor cells to undergo apoptosis. Currently, we are investigating the mechanisms used by extruded DOTAP:Chol–nucleic acid:liposome complexes to cross barriers and penetrate throughout target organs. By knowing more about these mechanisms, we hope to develop more robust nonviral gene therapeutics.

19.12 OPTIMIZATION OF PLASMIDS FOR *IN VIVO* GENE EXPRESSION

Delivery of DNA and subsequent gene expression may be poorly correlated [18,41]. Investigators may focus solely on the delivery formulation as the source of poor gene expression. In many cases, however, the delivery of DNA into the nucleus of a particular cell type may be efficient, although little or no gene expression is achieved. The causes of poor gene expression can be numerous. The following issues should be considered independent of the delivery formulation including suboptimal promoter–enhancers in the plasmid, poor preparation of plasmid DNA, and insensitive detection of gene expression.

Plasmid expression cassettes typically have not been optimized for animal studies. For example, many plasmids lack a full-length CMV promoter–enhancer. Over 100 variations of the CMV promoter–enhancer exist, and some variations produce greatly reduced or no gene expression in certain cell types [18]. Even commercially available plasmids contain suboptimal CMV promoters–enhancers, although these plasmids are advertised for use in animals. Furthermore, upon checking the company data for these plasmids, one would discover that these plasmids have never been tested in animals and have been tested in only one or two cultured cell lines. Conversely, plasmids that have been optimized for overall efficiency in animals may not be best for transfection of certain cell types *in vitro* or *in vivo*. For example, many investigators have shown that optimal CMV promoters–enhancers produce gene expression at levels several orders of magnitude less in certain cell types. In addition, one cannot assume that a CMV promoter that expresses well within the context of a viral vector, such as adenovirus, will function as well in a plasmid-based transfection system for the same cell context. Virus proteins produced by the viral vector are required for producing high levels of mRNA by the CMV promoter in specific cell nuclei.

Ideally, investigators design custom promoter–enhancer chimeras that produce the highest levels of gene expression in their target cells of interest. Recently, we designed a systematic approach for customizing plasmids used for breast cancer gene therapy using expression profiling [18]. Gene therapy clinical trials for cancer frequently produce inconsistent results. We believe that some of this variability could result from differences in transcriptional regulation that limit expression of therapeutic genes in specific cancers. Our systemic liposomal delivery of a nonviral plasmid DNA showed efficacy in animal models for several cancers. However, we observed large differences in the levels of gene expression from a CMV promoter–enhancer between lung and breast cancers. To optimize gene expression in breast cancer cells *in vitro* and *in vivo*, we created a new promoter–enhancer chimera to regulate gene expression. Serial analyses of gene expression (SAGE) data from a panel of breast carcinomas and normal breast cells predicted promoters that are highly active in breast cancers, for example the glyceraldehyde 3-phosphate dehydrogenase (GAPDH) promoter. Furthermore, GAPDH is upregulated

by hypoxia which is common in tumors. We added the GAPDH promoter, including the hypoxia enhancer sequences, to our *in vivo* gene expression plasmid. The novel CMV-GAPDH promote–enhancer showed up to 70-fold increased gene expression in breast tumors compared to the optimized CMV promoter–enhancer alone. No significant increase in gene expression was observed in other tissues. These data demonstrate tissue-specific effects on gene expression after nonviral delivery and suggest that gene delivery systems may require plasmid modifications for the treatment of different tumor types. Furthermore, expression profiling can facilitate the design of optimal expression plasmids for use in specific cancers.

Several reviews have stated that nonviral systems are intrinsically inefficient compared to viral systems. However, as discussed above, one must separate issues of the delivery vehicle versus the plasmid that is delivered. Case in point, we have shown that our extruded liposomes optimized for systemic delivery could out-compete delivery using a lentivirus. For example, we have compared SIVmac239, a highly noninfectious virus, with nonviral delivery of SIVmac239 DNA complexed to BIVs in adult rhesus macaques after injection into the saphenous vein of the leg. Our data showed that the monkeys injected with SIV DNA encapsulated in DOTAP:Chol BIVs were infected 4 days postinjection, and high levels of infection were produced in these monkeys at 14 days postinjection. Furthermore, higher levels of SIV RNA in the blood were produced using our BIV liposomes for delivery versus using the SIV virus. CD4 counts were measured before and after injections. CD4 levels dropped in all monkeys to the lowest levels ever detected in the macaques in any experiment by 28 days postinjection, the first time point at which these counts were measured postinjection. All monkeys had clinical SIV infections and lost significant weight by day 28. These results were surprising because SIVmac239 is not highly infectious, and monkeys become sick with SIV infection only after several months or years postinjection with SIVmac239 virus. Therefore, we were able to induce SIV infection faster using our nonviral delivery of SIV plasmid DNA. In this case, we delivered a replication competent plasmid so that gene expression increased over time post-transfection. Our delivery system was highly efficient and exceeded that of the lentivirus. The critical feature in this nonviral experiment was the plasmid DNA that was delivered.

Plasmids can be engineered to provide for specific or long-term gene expression, replication, or integration. Persistence elements, such as the inverted terminal repeats from adenovirus or adeno-associated virus, have been added to plasmids to prolong gene expression *in vitro* and *in vivo*. Apparently, these elements bind to the nuclear matrix thereby retaining the plasmid in cell nuclei. For regulated gene expression, many different inducible promoters are used that promote expression only in the presence of a positive regulator or in the absence of a negative regulator. Tissue specific promoters have been used for the production of gene expression exclusively in the target cells. As discussed in the previous

paragraph, replication competent plasmids or plasmids containing sequences for autonomous replication can be included that provide prolonged gene expression. Other plasmid-based strategies produce site-specific integration or homologous recombination within the host cell genome (Reviewed in Ref. [42]). Integration of a cDNA into a specific “silent site” in the genome could provide long-term gene expression without disruption of normal cellular functions. Homologous recombination could correct genetic mutations upon integration of wild-type sequences that replace mutations in the genome. Plasmids that contain fewer bacterial sequences and that produce high yield upon growth in *Escherichia coli* are also desirable.

19.13 OPTIMIZATION OF PLASMID DNA PREPARATIONS

The transfection quality of plasmid DNA is dependent on the preparation protocol and training of the person preparing the DNA. For example, we performed a blinded study asking three people to make DNA preparations of the same plasmid from the same box of a Qiagen Endo-Free plasmid preparation kit. One person then mixed all of the DNA–liposome complexes on the same morning using a single vial of liposomes. One person performed all tail vein injections, harvesting of tissues, preparation of extracts from tissues, and reporter gene assays on the tissue extracts. *In vivo* gene expression differed 30-fold among these three plasmid DNA preparations.

One source for this variability is that optimized methods to detect and remove contaminants from plasmid DNA preparations have not been available. We have identified large amounts of contaminants that exist in laboratory and clinical grade preparations of plasmid DNA. These contaminants co-purify with DNA by anion exchange chromatography and by cesium chloride density gradient centrifugation. Endotoxin removal does not remove these contaminants. HPLC cannot detect these contaminants. Therefore, we developed three proprietary methods for the detection of these contaminants in plasmid DNA preparations. We can now make clinical grade (GMP) DNA that does not contain these contaminants. To provide the greatest efficacy and levels of safety, these contaminants must be assessed and removed from plasmid DNA preparations. These contaminants belong to a class of molecules known to inhibit both DNA and RNA polymerase activities. Therefore, gene expression post-transfection can be increased by orders of magnitude if these contaminants are removed from DNA preparations. The presence of these contaminants in DNA also precludes high dose delivery of DNA–liposome complexes intravenously. Our group and other investigators have shown that intravenous injections of high doses of improved liposomes alone cause no adverse effects in small and large animals.

Some investigators have removed the majority of CpG sequences from their plasmids and report reduced toxicity after intravenous injections of cationic liposomes complexed to these plasmids [43]. However, only low doses containing

up to 16.5 μg of DNA per injection into each mouse were shown to reduce toxicity. To achieve efficacy for cancer metastases, particularly in mice bearing aggressive tumors, most investigators are interested in injecting higher doses in the range of 50–150 μg of DNA per mouse. Therefore, removal of CpG sequences from plasmid based gene therapy vectors will not be useful for these applications because no difference in toxicity was shown after intravenous injections of these higher doses of plasmids, with or without reduced CpG sequences, complexed to liposomes [43]. Therefore, we believe that removal of the other contaminants in current DNA preparations, discussed above, is the major block to the safe intravenous injection of high doses of DNA–liposome complexes.

19.14 DETECTION OF GENE EXPRESSION

Thought should also be given to choosing the most sensitive detection method for every application of nonviral delivery rather than using the method that seems most simple. For example, detection of β -galactosidase expression is far more sensitive than that for the green fluorescent protein (GFP). Specifically, 500 molecules of β -galactosidase (β -gal) per cell are required for detection using X-gal staining. Whereas, about one million molecules of GFP per cell are required for direct detection. Furthermore, detection of GFP may be impossible if the fluorescence background of the target cell or tissue is too high. Detection of chloramphenicol acetyltransferase (CAT) is extremely sensitive with little or no background detected in untransfected cells. Often, assays for CAT expression can provide more useful information than using β -gal or GFP as reporter genes.

Few molecules of luciferase in a cell can be detected by luminescence assays of cell or tissue extracts post-transfection. The sensitivity of these assays is highly dependent on the type of instrument used to measure luminescence. However, luciferase results may not predict the therapeutic potential of a nonviral delivery system. For example, if several hundred or thousand molecules per cell of a therapeutic gene are required to produce efficacy for a certain disease, then production of only few molecules will not be adequate. If only few molecules of luciferase are produced in the target cell using a specific nonviral delivery system, then the investigator may be misled in using this system for therapeutic applications.

Furthermore, noninvasive detection of luciferase expression *in vivo* is not as sensitive as luminescence assays of cell or tissue extracts post-transfection. Recently, some colleagues of mine tried cooled charge coupled device (CCD) camera imaging on live mice after intravenous injection of other cationic liposomes complexed to plasmid DNA encoding luciferase, and they were not able to detect any transfection. However, these liposomal delivery systems had been used to detect luciferase by luminescence assays of organ extracts. My colleagues detected luciferase expression by CCD imaging after intravenous injections of BIV DOTAP:Chol–luciferase DNA:liposome complexes [44]. Because the luciferase protein is short-lived, maximal expression was detected at 5 h post-transfection. Whereas, detection of HSV-TK gene expression

using microPET imaging in the same mice was highest at 24 h posttransfection. In contrast to luciferase, the CAT protein accumulates over time, and therefore, the investigator is not restricted to a narrow time frame for assaying gene expression. Furthermore, detection of CAT seems to be more sensitive than CCD imaging of luciferase following intravenous injections of DNA–liposome complexes. However, the animals must be sacrificed in order to perform CAT assays on tissue or organ extracts. In summary, further work is still needed to develop *in vivo* detection systems that have high sensitivity and low background.

19.15 OPTIMIZATION OF DOSE AND FREQUENCY OF ADMINISTRATION

To establish the maximal efficacy for the treatment of certain diseases or for the creation of robust vaccines, injections, or administrations of the nonviral gene therapeutic, etc., via different routes may be required. For particular treatments, one should not assume that one delivery route is superior to others without performing the appropriate animal experiments. In addition, people with the appropriate expertise should perform the injections and administrations. In our experience, only a minority of people who claim expertise in performing tail vein injections can actually perform optimal injections.

The optimal dose should be determined for each therapeutic gene or other nucleic acid that is administered. The investigator should not assume that the highest tolerable dose is optimal for producing maximal efficacy. The optimal administration schedule should also be determined for each therapeutic gene or other nucleic acid. To progress faster, some investigators have simply used the same administration schedule that they used for chemotherapeutics. The investigator should perform *in vivo* experiments to determine when gene expression or efficacy drops significantly. Most likely, re-administration of the nonviral gene therapeutic is not necessary until this drop occurs. Loss of the therapeutic gene product will vary with the half-life of the protein produced. Therefore, if a therapeutic protein has a longer half-life, then the gene therapy could be administered less frequently.

19.16 SUMMARY

Overcoming some hurdles remain in the broad application of nonviral delivery, however, we are confident that we will successfully accomplish the remaining challenges soon. Furthermore, we predict that eventually the majority of gene therapies will utilize artificial reagents that can be standardized and regulated as drugs rather than biologics. We will continue to incorporate the molecular mechanisms of viral delivery that produce efficient delivery to cells into artificial systems. Therefore, the artificial systems, including liposomal delivery vehicles, will be further engineered to mimic the most beneficial parts of the viral delivery systems while circumventing their limitations. We will also maintain the numerous benefits of the liposomal delivery systems discussed in this chapter.

20.1 INTRODUCTION

Photochemical internalization (PCI) is a technology that enables light-directed delivery of a variety of therapeutic molecules into the cell cytosol. The technique can be used *in vitro* and *in vivo* for site-specific delivery of proteins, DNA carried by nonviral and viral vectors, peptide nucleic acids (PNA), and small interfering RNA (siRNA). PCI is based on light activation of amphiphilic photosensitizers that localize in the membranes of the endocytic vesicles. When photosensitizer-containing cells or tissues are exposed to light at wavelengths absorbed by the photosensitizers, photochemical reactions are induced that rupture the membranes of the endocytic vesicles. Hence, the constituents of these vesicles (e.g., drugs or nucleic acids) can be released into the cytosol where they may act on their target or further translocate to the nucleus. As the effect of the photochemical treatment is dependent on light exposure, the enhancement of drug- or gene delivery is achieved only at illuminated regions. This chapter presents the background of PCI and its role for obtaining efficient delivery of nucleic acids.

20.2 PRINCIPLES OF PHOTOCHEMICAL INTERNALIZATION

The PCI technology derives from the field of photodynamic therapy (PDT). In PDT, the phototoxic effects induced by a photosensitizer, light, and oxygen are used therapeutically [1]. It is a minimally invasive treatment with great potential in malignant disease and premalignant conditions. PDT involves the application of a photosensitizer in combination with the targeted delivery of light, at a wavelength specific for the activation of the photosensitizer. Usually, wavelengths in the 600–800 nm range are used for optimal therapeutic effects. Upon light-dependent activation, the photosensitizers undergo photophysical reactions that lead to generation of reactive oxygen species (ROS) under aerobic conditions, most predominantly $^1\text{O}_2$. In PDT, the photochemical generation of ROS results in apoptosis or necrosis, harnessed therapeutically for the purpose of eliminating malignant tissue. However, as $^1\text{O}_2$ has a short lifetime ($<0.04\ \mu\text{s}$) and a short range of action (10–20 nm) in cells [2], only structures very close to the photosensitizer will be affected after light exposure. The

FIGURE 20.1 PCI-mediated delivery of nucleic acids. The nucleic acids are endocytosed and localize in endocytic vesicles. If not translocated, the nucleic acids are degraded inside the endocytic vesicles. The PCI treatment (i.e., light exposure of photosensitizer-treated cells) permeabilizes the endocytic membranes, leading to the release of the nucleic acids into the cytosol.

affected structures depend thus on the localization of the photosensitizer in the cell. PCI is based on the observation that light exposure of cells preloaded with amphiphilic photosensitizers that localize to the membranes of the endocytic vesicles leads to permeabilization of the vesicles [3]. Hence, the PCI treatment can induce a release of endocytosed compounds into the cell cytosol (Figure 20.1). This finding is of great importance because the translocation of genes from the endocytic vesicles into the cytosol is an important step and a possible barrier in the gene delivery process. Since the first publication in 1999, PCI has been shown to significantly enhance the delivery of a variety of macromolecules to cells and tissues.

To date, aluminium phthalocyanine with two sulfonate groups on adjacent phenyl rings (AlPcS_{2a}) and meso-tetraphenylporphine with two sulfonate groups on adjacent

phenyl rings (TPPS_{2a}) are the most efficient photosensitizers for enhancing gene delivery (4; Figure 20.2). Photosensitizers that localize to other cellular structures than the endocytic vesicles are not efficient for inducing the PCI effect [4–6]. The light source used to induce the photochemical reactions may be any source emitting light of wavelengths absorbed by the photosensitizer. Typically, a red light source (peak wavelength at 670 nm) is used for the excitation of AlPcS_{2a} and a blue light source (peak wavelength at 420 nm) for TPPS_{2a}.

20.2.1 PHOTOCHEMICAL INTERNALIZATION METHOD

The PCI procedure must be performed in subdued light to avoid unwanted uncontrollable activation of the photosensitizer and to protect the cells from undesirable photochemical damage. As an example, in *in vitro* assays, the cells are first incubated with cell culture medium containing the photosensitizer (either AlPcS_{2a} or TPPS_{2a}) for 18 h at 37°C in a CO₂ incubator. Then, the cells are washed three times in photosensitizer-free medium, and chased for 4 h at 37°C prior to exposure to red or blue light at light doses inducing around 50%–70% cell survival. The DNA, PNA, or siRNA is added at different time points prior to light exposure, so that they localize in the endocytic vesicles at the time of light exposure (see Figure 20.3 for suggested time intervals).

An alternative PCI technique for obtaining increased transfection is to expose photosensitizer-treated cells to light before the gene vector is added [7]. The mechanism behind this technique is not fully clarified. However, it has been proposed that fusion events between the photochemically disrupted endocytic vesicles and intact vesicles containing the vector may lead to cytosolic release of the vector and increased transfection levels [7]. Illumination before gene delivery may be advantageous in some clinical situations. For example, if PCI is employed as an adjuvant treatment of residual disease after surgical removal of tumors, it would be an advantage to be able to apply both the light treatment and the therapeutic molecule at the end of surgical procedures and immediately following each other.

For *in vivo* treatment procedures, AlPcS_{2a} is the preferred photosensitizer due to its higher extinction coefficient compared

FIGURE 20.2 The photosensitizers AlPcS_{2a} (A) and TPPS_{2a} (B).

FIGURE 20.3 Experimental scheme for PCI treatment *in vitro*. The cells are incubated with the photosensitizer (PS) for 18 h. Then, the cells are washed and incubated in photosensitizer-free medium for 4 h prior to light exposure to disrupt the membranes of the endocytic vesicles. To perform PCI of siRNA or PNA, the cells can be incubated with the siRNA or PNA molecules at the same time as the photosensitizer and for a total of 18 h. Alternatively, siRNA or PNA can be added to the cells 4 h prior to light exposure. To perform PCI of DNA polyplexes, the DNA polyplexes are added to the cells 4 h prior to light exposure. Finally, for PCI of adenovirus and adeno-associated virus, the cells are chased for 3 h in photosensitizer-free medium prior to the adding of the virus to the cells.

to TPPS_{2a} in the wavelength region where light penetration through tissue is high (above 600 nm). In order to perform PCI treatment on mouse xenograft models, the photosensitizer AlPcS_{2a} is first injected intraperitoneally, intravenously, or intratumorally at 10 mg/kg [8,9]. Following the injection of the photosensitizer, the animals must be kept in the dark for at least 4 days in order to avoid undesirable photochemical damage to tissues [9]. Forty-eight hours after the injection of the photosensitizer, an intratumoral injection of the gene vector is performed under subdued light. After 6 h, the animals are covered in aluminium foil except above the tumor area, and the tumors are exposed to red light, typically from a diode laser. The photochemical doses must be optimized for the laser and the tumor model. Typically, light doses around 20–40 J/cm² are delivered to tumors around 100 mm³ from a light source with an irradiance of less than 150 mW/cm².

20.3 EFFECTS OF PCI ON THE DELIVERY OF GENES AND OLIGONUCLEOTIDES *IN VITRO*

20.3.1 PCI WITH NONVIRAL GENE VECTORS

The physicochemical properties of plasmid DNA impede cell membrane translocation. Therefore, a variety of nonviral delivery systems have been proposed. Nonviral-based carriers, like cationic lipoplexes and polyplexes, are usually taken up by cells through charge-based binding and endocytosis. Once inside the endosomes, these complexes need to efficiently escape into the cytosol prior to acidification, in order to avoid lysosomal degradation of the DNA. Some vector materials are known to be able to destabilize the endosomal membrane, by acting as a proton sponge or a fusogen (e.g., polyethylenimine

[PEI], lipids) [10]. Nevertheless, the effect of PCI on gene delivery has been demonstrated both for gene vectors with low efficiency for endosomal release, such as polylysine (PLL), and for gene vectors able to induce endosomal release on their own, such as cationic lipids and PEI [4,11].

The first documentation of the PCI effect was obtained using a plasmid carrying the enhanced green fluorescent protein (EGFP) gene and complexed with PLL [5]. Further, it has been shown that the PCI-induced enhancement of transgene expression depends on the photochemical dose and the cell line, indicating the possible involvement of cellular processes or pathways that depending on the cell type might be differently affected by the photochemical treatment [12]. Moreover, the effect of PCI on transfection of DNA/cationic lipid complexes was more variable than found for PLL, and it was highly dependent on the composition of the lipid vector [11,13]. PCI also improved the efficiency of various PEI-based vectors, although PEI is one of the most potent nonviral vectors known [14,15]. However, the relative effect of PCI was most pronounced at doses of DNA/PEI that were suboptimal on their own. For example, PCI efficiently enhanced transfection of DNA/PEI polyplexes at N/P ratios ≤ 6 . PEI displays only moderate endosomolytic activity in such formulations [16]. This is probably because the concentration of PEI inside the endocytic vesicles is too low to perform its endosomolytic function at these ratios, and therefore, the transfection may be enhanced by PCI. For *in vivo* gene therapy approaches, the observation that PCI is particularly suited to enhance gene delivery when the amount of PEI is low might be important. Due to the *in vivo* extracellular barriers, the amount of vector reaching the target cells will often be very low and probably often considerably below the threshold where PEI is able to induce efficient endosomal escape.

20.3.2 PCI WITH VIRAL GENE VECTORS

In a variety of cancer cell lines, the transgene expression from several adenovirus vectors was substantially increased in PCI-treated cells compared to photochemically untreated cells. The photochemical effect on transduction was most pronounced at lower virus doses, where in some cases the same transduction efficiency could be achieved with a 20 times lower virus dose than with conventional infection. Moreover, the photochemical effect was dependent on the photochemical dose delivered to the cells and on the cell line tested [17].

Adenoviral transduction is believed to be an efficient process [18,19]. Nevertheless, the photochemical enhancement of transduction was not due to a change in the uptake mechanism of the adenoviral particles into the cells, as the viral infection occurred through clathrin-dependent, receptor-mediated endocytosis in both photochemically treated and untreated cells [20]. Results using real-time polymerase chain reaction (PCR) and fluorescence in situ hybridization (FISH) showed that the level of viral DNA in the nucleus of photochemically treated samples was increased compared to photochemically untreated samples. In addition, real-time PCR was also applied to measure the photochemically induced increase in the level of transgene mRNA. The increase in transgene mRNA level after photochemical treatment was higher than the fold increase observed at both the DNA and the protein level. This was not due to the CMV promoter, as adenovirus carrying the SV40-promoter instead of the CMV promoter responded in a similar manner to PCI. Finally, the cellular localization of the viral particles at the time of illumination was important to achieve increased transgene expression [6].

Cells lacking expression of the coxsackie- and adenovirus receptor (CAR) are resistant to adenoviral infection. However, as the adenovirus particles are negatively charged, they can be coated with positively charged polymers (e.g., polylysine) to transduce CAR-negative cells. Transduction is thus enhanced due to improved binding to the negatively charged cell surfaces. Photochemical treatment of cells infected with adenovirus/polylysine complexes enabled up to 38-fold increase in the percentage of β -galactosidase positive cells compared to photochemically untreated cells infected with uncomplexed virus [21].

The effect of PCI on transduction with adeno-associated virus (AAV) has been evaluated and compared to that of adenovirus or plasmid/polylysine complexes in two glioblastoma cell lines, U-87Mg and GaMg [22]. PCI had a similar effect on transfection with plasmid/polylysine complexes in these cell lines. Therefore, it was of interest to use these cell lines to compare the effect of PCI on transduction with different viral vectors. Adenoviral vectors have often been preferred for cancer gene therapy. However, recent studies have pointed out that AAV vectors seem highly suitable for gene delivery to malignant tumors [23,24]. PCI increased the transgene expression from AAV in GaMg, but not in U-87Mg cells. The lack of effect in U-87Mg was independent of viral dose, photochemical dose, and treatment sequence (e.g., photochemical treatment prior to or after infection). In contrast, PCI enhanced

transgene expression from a recombinant adenovirus vector in both cell lines, although the effect was more pronounced in U-87Mg than in GaMg. These results support findings from others, describing that different steps of intracellular trafficking may be limiting for AAV-based vectors depending on the cell line tested [25–27]. Of note, the PCI effect of AAV5 was the highest in the cell line that demonstrated the lowest efficiency of AAV5 transduction without PCI, perhaps due to a less efficient AAV5 escape from endosomes in the GaMg cell line compared to the U-87Mg cell line. However, further studies are needed to identify different barriers in intracellular trafficking between cell lines and viral vectors.

20.3.3 DOUBLE TARGETING

PCI can be combined with biologically targeted gene vectors in order to obtain both specific binding of the gene vector to target cells and light-enhanced release from the endocytic vesicles. Such dual targeting may reduce the risk of side effects due to inadvertent expression of transgenes in nontarget cells. PCI has been combined with several epidermal growth factor receptor (EGFR)-targeted compounds, such as DNA polyplexes [15], adenovirus [28], and the protein toxin saporin [29]. EGFR is a frequently used target due to its overexpression in many human tumors, and antibodies towards EGFR and Her2/neu are approved for clinical use.

The magnitude of enhancement of transgene expression due to photochemical treatment depended on the formulation of the targeted compound, the cell line, and the photochemical dose. In a study by Kloeckner and colleagues, nonviral DNA polyplexes containing polyethylenimine (PEI) conjugated with the EGF protein as a cell-binding ligand for EGFR-mediated endocytosis and polyethylene glycol (PEG) for masking the polyplex surface charge were used in combination with PCI treatment [15]. PCI of such targeted PEG-PEI/DNA polyplexes enabled high and EGFR-specific gene transfer activity in cells. In another study by Bonsted and colleagues, the importance of PEG in such targeted complexes was confirmed [28]. Recombinant adenoviral particles were coated with pDMAEMA-based polymers coupled with ligands towards EGFR. An additional incorporation of polyethylene glycol (PEG)-conjugated pDMAEMA into the viral complexes provided charge shielding of the viral complexes and increased the specificity of EGFR-mediated transduction. Furthermore, transgene expression was efficiently enhanced by photochemical treatment of cells infected with the PEGylated and EGFR-targeted complexes [28]. These findings have implications for the possible use of PCI of targeted Ad *in vivo*, as conjugation of PEG to viral vectors extends the circulation time and reduces the toxicity and immunogenicity of the vectors.

A double targeting effect may also be obtained by the use of promoters that are activated by the photochemical treatment, such as heat-shock proteins (HSPs). Consequently, it has been investigated whether PCI also could activate HSPp, a promoter from the HSP family gene, and thereby stimulate transcription of a HSPp-controlled gene, the HSP70. It was

shown that the photochemical treatment could enhance expression of cellular HSP70, which correlated with a photochemically enhanced expression (approximately twofold, at PCI-optimal doses) of the HSPp-controlled gene integrated in the genome. Furthermore, PCI also enhanced expression of the HSPp-controlled episomal transgene delivered as a plasmid. However, in plasmid-based transfection, the PCI-mediated enhancement with HSPp did not exceed the enhancement achieved with the constitutively active CMV promoter [30].

20.3.4 PCI OF THERAPEUTIC GENES

PCI has been evaluated for the delivery of therapeutic genes to cells. Plasmids carrying genes encoding p53 or HSV-tk (herpes simplex virus thymidine kinase) and adenovirus carrying a gene encoding TRAIL (tumor necrosis factor related apoptosis inducing ligand) have been used for this approach [14,31,32]. Enhanced transgene expression and biological activity of all three transgenes was demonstrated after photochemical treatment of cells. Thus, genes delivered by PCI are not only expressed, but are also able to perform a therapeutic function resulting in therapeutic effects in photochemically treated cells.

20.3.5 PCI OF OLIGONUCLEOTIDES

PNAs are oligonucleotide mimics that can specifically hybridize to DNA or mRNA, thus inhibiting the transcription and translation of their complementary target sequence. As PNAs are taken up into cells by endocytosis and tend to accumulate in endosomes, PCI is a candidate for enhancing their delivery into the cytosol. Folini and colleagues were the first to demonstrate a PCI-induced release of PNA into the cytoplasm of cells [33]. In their approach, they used naked PNA targeting the catalytic component of human telomerase reverse transcriptase (hTERT-PNA). After photochemical treatment, cells treated with the hTERT-PNA showed a marked inhibition of telomerase activity and a reduced cell survival, which was not observed after treatment with hTERT-PNA alone. Moreover, in a direct comparison, the PCI technology proved to be more efficient to internalize the hTERT-PNA than an alternative strategy based on the HIV-Tat internalization protein. In another study, Shiraishi and Nielsen showed that PCI could enhance the antisense effects (cytosolic/nuclear) of different peptide nucleic acid-peptide conjugates (Tat, Arg7, KLA) up to two orders of magnitude [34]. In addition, efficient gene silencing of the *S100A4* gene by PNA delivered by PCI has also been demonstrated [35]. These results emphasize the importance of endosomal release for cellular activity of this type of drug delivery.

siRNA molecules, which are functional mediators of RNA interference, also need to enter the cytoplasm of cells in order to be able to interrupt translation of a specific protein by inducing posttranscriptional gene silencing. PCI has been employed to facilitate the escape of siRNA molecules complexed with lipofectamine from endocytic vesicles [36]. Combining anti-epidermal growth factor receptor (EGFR) siRNA treatment

with PCI induced a 10-fold increased efficiency in knockdown of EGFR compared to siRNA treatment alone. Thus, lower doses of siRNA can be used when PCI is employed to augment its delivery. Lowering the doses of siRNA would prevent saturation of the RNAi machinery and reduce off-target effects. In addition, local light exposure of target tissue would enhance siRNA delivery in the desired cells, only, which further increases the specificity of the treatment.

20.4 EFFECTS OF PCI ON DELIVERY OF GENES *IN VIVO*

Although PCI is a useful tool for *in vitro* drug and gene delivery, the most interesting use of PCI is as a method for site-specific *in vivo* treatment. PCI-studies in Balb/c mice on subcutaneously growing tumors (colon carcinomas and sarcomas) have been performed with the protein toxin gelonin, the cytotoxic agent bleomycin and a plasmid carrying the p53 gene [8,9,37,38]. The *in vivo* studies performed on PCI of gelonin show that the inhibition on tumor growth and the depth of necrosis was much stronger using gelonin in combination with PCI as compared to using gelonin alone or the photochemical treatment alone. PCI of gelonin led to complete tumor regression in 50%–80% of the animals.

PCI with genes is a more complex process than with proteins, as the gene has to be transcribed and translated before it can exhibit a desirable function. However, Ndoye and colleagues [9] performed iterative PCI treatment with a nonviral vector encoding the p53 protein in a head and neck xenograft with mutated p53. Successful tumor cure was achieved in 83% of the mice after seven rounds of PCI treatment. Compared to data reported in the literature, the PCI *in vivo* data are highly promising because in gene therapy several groups report upon tumor regression, while tumor eradication is rarely reported even in the cases where viral vectors have been applied.

20.5 ADVANTAGES AND DRAWBACKS OF PCI

PCI is a versatile method that can be applied to enhance the delivery of a variety of molecules with endocytic uptake mechanism in a site-specific manner, both *in vitro* and *in vivo*. The photochemical treatment substantially enhances the expression of transgenes and the biological effect of PNAs and siRNAs in cells. For example, in some cell lines, 20 times less adenoviral particles can be applied in combination with PCI to obtain similar levels of transduction as with adenovirus infection in the absence of photochemical treatment [17]. Because the concentration of the gene vector drops rapidly from the application point in tissues, this may be an important improvement of gene delivery protocols.

The main drawbacks of the technology are, for certain applications, the limited light penetration through tissue and the cytotoxicity induced by the photochemical treatment itself. The light penetration is tissue dependent and decays approximately (e^{-1}) for every 2–3 mm of depth, and the maximum depth of necrosis observed for PDT is 1 cm [39]. PCI is

expected to improve treatment of additional sublayers of tumors than those killed by PDT because of the additional effect of the transgene or drug delivered into the cells [8,9,37,38]. Nevertheless, in applications where tissue removal is the main goal, the limited light penetration in tissue can be counteracted by performing the treatment several times [9]. The cytotoxicity induced by the photochemical treatment may be a drawback for some gene therapy applications, but it has been successfully exploited in PDT of cancer as well as for the treatment of age-related macular degeneration [1]. It is possible to reduce the toxicity by reducing the photochemical dose, but this would also decrease the effect of the photochemical treatment on gene delivery. Approaches are being made to reduce the cellular toxicity of the treatment. For example, a system for DNA delivery in which the DNA and a novel dendritic photosensitizer (DP) are assembled into one structure has been developed [40]. This is a ternary complex composed of a core containing DNA packaged with cationic peptides and enveloped in the anionic DP. The ternary complex showed significantly enhanced transgene expression *in vitro* and *in vivo* with minimal unfavorable phototoxicity.

20.6 CONCLUSION

The future of gene therapy may rely on approaches that combine various concepts for enhancing the efficiency and specificity of gene transfer. The photochemical internalization technology described is a versatile method that can be applied for enhancing delivery and biological effect of various agents and gene vectors. Moreover, photochemical treatments are already in clinical use for cancer therapy, and they are very specific and have few side effects. On the basis of preclinical studies, we conclude that PCI has a clear potential for improving both the efficiency and the specificity of gene therapy protocols, making it possible to achieve efficient site-specific gene delivery in tissue.

21.1 INTRODUCTION

Designed by nature for information, valued by molecular biologists for manipulation, DNA is also a favorite molecule of physical chemists and physicists [1]. Its mechanical properties [2], interactions with other molecules [3], and modes of packing [4] present tractable but challenging problems whose answers have *in vivo* and *in vitro* consequences. In the context of DNA transfection and gene therapy [5], what has been learned through molecular mechanics, interaction and packing might teach us how to package DNA for more effective gene transfer. Among these modes of *in vitro* packaging are association with proteins, treatment with natural or synthetic cationic “condensing agents,” and combination with synthetic positively charged lipids [6].

In vivo, DNA is tightly held, not at all like the dilute solution form often studied *in vitro* (see Figure 21.1). This tight assembly necessarily incurs huge energetic costs of confinement, which create a tension under which DNA is expected to ravel or to unravel its message. Through direct measurement of forces between DNA molecules [7] and direct observation of its modes of packing [8], we might see not only how to use concomitant energies to design better DNA transfer systems but also to reason better about the sequences of events by which DNA is read in cells.

What binds these structures? To first approximation, for large, flexible biological macromolecules, the relevant interactions resemble those found among colloidal particles [9] where the size of the molecule (such as DNA molecules, lipid membranes, actin bundles) distinguishes it from simpler, smaller species (such as small solutes or salt ions). On the colloidal scale of tens of nanometers ($1\text{ nm} = 10^{-9}\text{ m}$), only the interactions between macromolecules are evaluated explicitly, while

the small molecular species only “dress” the large molecules and drive the interactions between them.

The electrical charge patterns of multivalent ions, such as Mn^{2+} , Co^{3+} , or spermine⁴⁺, with cation binding to negative DNA create attractive electrostatic and solvation forces that move DNA double helices to finite separations despite the steric knock of thermal Brownian motion of the DNA [10]. Solvation patterns about the cation-dressed structures create solvation forces: DNA–DNA repulsion because of water clinging to the surface and attraction from the release of the solvent [11]. Positively charged histones spool DNA into carefully distributed skeins, which are arrayed for systematic unraveling and reading [12]. Viral capsids encase DNA, stuffed against its own DNA–DNA electrostatic and solvation repulsion, to keep it under pressure for release upon infection [13]. In artificial preparations, the glue of positively charged and neutral lipids can lump negative DNA into ordered structures that can move through lipids and through water solutions [14].

Changes in the suspending medium can modulate intermolecular forces. One example is the change in van der Waals charge-fluctuation forces (see Section 21.2.4) between lipid bilayers when small sugars modifying the dielectric dispersion properties of water are added to the solution [15]. More dramatic, the addition of salt to water can substantially reduce electrostatic interactions between charged molecules such as DNA or other charged macromolecules bathed by an aqueous solution [16]. These changes can modify the behavior of macromolecules quantitatively or induce qualitatively new features into their repertoire, the most notable among these being the precipitation of DNA by addition of organic polycations to the solution [10].

Similar observations can be made about the small molecules essential to practically every aspect of interaction between macromolecules. In case of water, a network is built: its dielectric

FIGURE 21.1 *In vivo* DNA is highly compacted. The figure shows *Esheria coli* DNA and T2 bacteriophage DNA after osmotic shock in distilled water has allowed them to expand from their much more compact *in vivo* configurations. constant or dielectric permittivity facilitates electrostatic interactions, its pH enables its interaction in charging equilibria, and its fundamental molecular geometry creates the hydrogen bond network topology around simple solutes. This is, of course, the network of water molecule [17]. In what follows, we will limit ourselves to only three basic properties of macromolecules—charge, polarity (solubility), and conformational flexibility—that appear to govern the plethora of forces encountered in biological milieus. It is no surprise that highly ordered biological structures, such as the quasicrystalline spooling of DNA in viral heads or the multilamellar stacking of lipid membranes in visual receptor cells (Figure 21.2), can, in fact, be explained by the properties of a very small number of fundamental forces acting between macromolecules. Detailed experimental as well as theoretical investigations have identified hydration, electrostatic, van der Waals or dispersion, conformational fluctuation, and polyelectrolyte bridging forces as the most fundamental interactions governing the fate of biological macromolecules.

Our intent here is to sketch the measurements of these operative forces and to dwell upon concepts that rationalize them. It is from these concepts, with their insight into what controls organizing forces, that we expect people to learn to manipulate and to package DNA in more rewarding ways.

21.2 MOLECULAR FORCES

21.2.1 ORIGIN AND MEASUREMENT OF MOLECULAR FORCES

We divide these forces into two broad categories, both of which can be either attractive or repulsive. First, there are interactions that are connected with fields emanating from sources within or on the macromolecules themselves [16]; for example, electrostatic fields pointing from the fixed charge distributions on macromolecules into the surrounding space and fields of connectivity of hydrogen bond networks extending from the macromolecular surfaces into the bulk solution that are seen in hydration interactions. Second, there are the forces due to fluctuations that originate either in thermal Brownian motion or quantum jitter [15]. Consequent interactions include the van der Waals or dispersion forces that originate from thermal as well as quantum mechanical fluctuations of electromagnetic (EM) fields in the space between and within the interacting molecules and conformation–fluctuation forces from thermal gyrations of the macromolecule when thermal agitation pushes against the elastic energy resistance of the molecule and confinement imposed by neighboring macromolecules [16].

FIGURE 21.2 Highly ordered assemblies, ubiquitous among biological structures, can be explained through the properties of a very small number of fundamental forces acting between macromolecules. On the left-hand side, electron micrograph of a part of a human eye rod cell showing multilamellar bilayer aggregate. (From Kessel, R.G. and Kardon, R.H., *Tissues and Organs*, W.H. Freeman and Co., San Francisco, CA, 1979.) In the middle, electron micrograph of an *in vivo* cholesteric phase of a wild type *E. coli* DNA. (Adapted from Frankiel Krispin, D. et al., *EMBO J.*, 2001, 20, 1184.) For comparison, we show the same type of structure for DNA *in vitro* below. (Adapted from Leforestier, A. and Livolant, F., *Biophys. J.*, 1993, 65, 56.) On the right-hand side, cryo-micrographs and computer-processed images of T7 phage heads showing ordered DNA spooling within the viral heads. (From Cerritelli, M.E., Cheng, N., Rosenberg, A.H., McPherson, C.E., Booy, F.P., and Steven, A.C., *Cell*, 91, 271, 1997. With permission.)

FIGURE 21.3 Osmotic pressure in macromolecular arrays. Dissolved polymers such as PEG exert an osmotic pressure on the part of the solution from which they are excluded (shown schematically by the weight). Instead of exerting osmotic pressure directly on the macromolecular subphase such as DNA or lipid arrays (small circles), one can equilibrate it with a solution of PEG at a set concentration and the PEG itself will exert osmotic stress on the macromolecular subphase. Osmotic weighing of polymers one against the other (the one with the known, set osmotic pressure against the unknown one) is the essence of the osmotic stress technique of measuring interactions in macromolecular solutions.

There are many ways to detect interactions between macromolecules. In this chapter, we consider only macromolecules interacting in ordered arrays that are particularly relevant for investigations of the packing and energetics of DNA–lipid complexes.

A fundamental concept in macromolecular arrays is that of osmotic pressure (Figure 21.3). It is equal to the pressure needed to hold a macromolecular array together against the forces acting between its constituent macromolecules. It can be applied either mechanically across a semipermeable membrane or via the osmotic stress of a high molecular weight (e.g., polyethylene glycol [PEG], polyvinyl pyrrolidone [PVP], dextran) polymer solution. At chemical equilibrium, the osmotic pressure of one solution (macromolecular array) balances that of the other (the bathing polymer solution). The chemical equilibrium can be maintained either via a semipermeable membrane or simply because the bathing polymer solution phase separates from the macromolecular array, as is many times the case with PEGs, PVP, and dextran. This osmotic balancing of different molecular solutions is the basis of the “osmotic stress method” to measure the equation of state of macromolecular arrays [18].

The equation of state of a macromolecular solution is defined as the dependence of its osmotic pressure on the density of the array (see Figure 21.4). By equilibrating the macromolecular array versus a solution of high molecular weight polymer with a known osmotic pressure, one can set the osmotic pressure in the macromolecular array itself [18]. If in addition, one measures the concurrent density of the macromolecular array, either via x-ray scattering or direct densitometry, one gets the dependence of the osmotic pressure of the array on its density, i.e., its equation of state. This is the essence of the osmotic stress method.

FIGURE 21.4 (See color insert following blank page 206.) Osmotic stress method. (From Parsegian, V.A., Rand, R.P., Fuller, N.L., and Rau, D.C., *Methods Enzymol.*, 1986, 127, 400.) DNA liquid crystals are equilibrated against solutions of a neutral polymer (such as PEG or PVP, depicted as disordered coils). These solutions are of known osmotic pressure, pH, temperature, and ionic composition. (From Rau, D.C., Lee, B.K., and Parsegian, V.A., *Proc. Natl. Acad. Sci. USA*, 1984, 81, 2621.) Equilibration of DNA under the osmotic stress of external polymer solution is effectively the same as exerting mechanical pressure on the DNA subphase with a piston that passes water and small solutes but not DNA. After equilibration under this known stress, DNA separation is measured either by x-ray scattering, if the DNA subphase is sufficiently ordered, or by densitometry. (From Strey, H.H., Parsegian, V.A., and Podgornik, R., *Phys. Rev. Lett.*, 1997, 78, 895.) DNA density and osmotic stress thus determined immediately provide an equation of state (osmotic pressure as a function of the density of the DNA subphase) to be codified in analytic form over an entire phase diagram.

21.2.2 HYDRATION FORCES

The hydration force is connected with a very simple observation that it takes increasing amounts of work to remove water from between electrically neutral lipids in multilamellar arrays or from between ordered arrays of polymers at large polymer concentrations [18]. Direct measurements of this work show that it increases exponentially with the diminishing separation between colloid surfaces with a decay length that depends as much on the bulk properties of the solvent as on the detailed characteristics of the interacting surfaces. There is nevertheless some profound universality in the interactions between macromolecular surfaces at close distances (see Figure 21.5)—whether they are charged, zwitterionic, or uncharged—that strongly suggest that water is essential to maintaining the stability of biological matter at high densities.

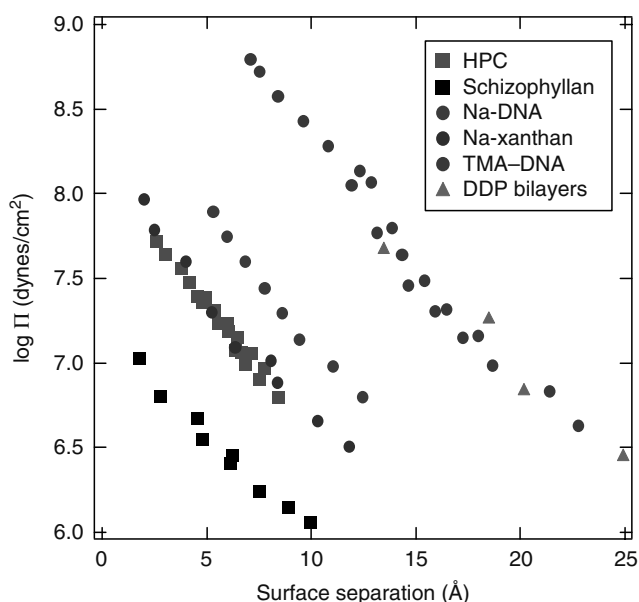

FIGURE 21.5 (See color insert following blank page 206.) Interactions between biological macromolecules show striking universality at close surface-to-surface separations (or equivalently at very large densities). Hydroxypropyl cellulose, schizophyllan, different DNA salts, xanthan, and DDP bilayers at small intermolecular separations (given in terms of the separation between effective molecular surfaces of the interacting molecules) all show a strong repulsive interactions decaying with about the same characteristic decay length. The log-linear plot is thus more or less a straight line. (Composite data, courtesy D.C. Rau.)

Hydration forces can be understood in different terms with no consensus yet on mechanism [11]. Marčelja and Radić [19] first proposed the idea that colloid surfaces perturb the vicinal water and that the exponential decay of the hydration force is due to the weakening of the perturbation of the solvent as a function of the distance between the interacting surfaces (Figure 21.6). They introduced an order parameter $P(z)$ as a function of the transverse coordinate z , between the surfaces located at $z = D/2$ and $z = -D/2$, that would capture the local condition or local ordering of solvent molecules between the surfaces. The detailed physical nature of this order parameter is left unspecified, but since the theory builds on general principles of symmetry and perturbation expansions, molecular details are not needed. All one needs to know about P is that within the bulk water $P = 0$ and close to a macromolecular surface P remains nonzero. As a mnemonic, one can envision P as an arrow associated with each water molecule. In bulk water, the arrows point in all directions with equal probability. Close to a bounding macromolecular surface, they point preferentially toward or away from the surface (Figure 21.6) depending on the surface-orienting fields.

If we envisage solvent molecules between two perturbing surfaces, we can decompose the total free energy F of their configuration into its energy W and entropy S parts via the well-known thermodynamic definition $F = W - TS$, where T is the absolute temperature. Energetically, it would be most favorable for the surface-induced order to persist away from

FIGURE 21.6 The hydration force. Marčelja, S. and Radić, N., *Chem. Phys. Lett.*, 1976, 42, 129, introduced an order parameter P that would capture the local condition, or local ordering, of solvent molecules between the surfaces. We represent it as an arrow (that has magnitude and direction) on each water molecule that is trapped between the two opposing surfaces and is being acted upon by the surface fields, depicted schematically with a bold line below each of the three drawings. Minimizing the energy corresponding to a spatial profile of P leads to a configuration where P points (for example) away from both surfaces and there is thus mismatch at the midplane (the dotted line below the leftmost drawing). The entropy on the other hand would favor completely disordered configurations with no net value of P (the dotted line below the rightmost drawing). The free energy strikes a compromise between the two extrema, leading to a smooth profile of P , varying continuously as one goes from one surface to the other (the dotted line below the bottom drawing). As the two surfaces approach the nonmonotonic profile of the order parameter P , it leads to repulsive forces between them.

the surfaces, but that would create conflict between the opposing surfaces (see Figure 21.3). Entropy fights any type of ordering and wants to eliminate all orderly configurations between the two surfaces, creating a homogeneous state of molecular disorder characterized by $P = 0$. Energy and entropy compromise to create a nonuniform profile of the order parameter between the surfaces; surface-induced order propagates but progressively decreases away from the surfaces.

From the free energy, we can derive the repulsive hydration osmotic pressure p acting between the surfaces because, by definition, it is proportional to the derivative of the free energy with respect to the separation D . Osmotic pressure between two apposed lipid surfaces has been measured extensively for different lipids [20] and has been found to have the form $p = p_0 \exp(-D/\lambda)$. This is consistent with the previous theoretically derived form of the hydration free energy if one assumes that $p_0 \sim P^2$ ($z = D/2$). The corresponding interaction free energy per unit surface area of the interacting surfaces, $F(D)$, would thus behave as $F(D) \sim p_0 \lambda \exp(-D/\lambda)$. From these experiments, one can deduce the magnitude of the prefactor p_0 , which determines the absolute magnitude of the hydration repulsion for a great variety of lipids and lipid mixtures within an interval 10^{12} to 10^{10} dynes/cm² or equivalently in pressures of hundreds of atmospheres.

As already noted, in this simple theoretical approach, the hydration decay length depends only on the bulk properties of the solvent and not on the properties of the surface. In order to generalize this simplification, Kornyshev and Leikin [21] formulated a variant of the hydration force theory also to take into account explicitly the nature of surface ordering. They derived a modified hydration decay length that clearly shows how surface order couples with the bare hydration decay length. Without going too deeply into this theory, we note that if the interacting surfaces have two-dimensional ordering patterns characterized by a wave vector $Q = 2/\lambda$, where λ is the characteristic scale of the spatial variations of these patterns, then the effective hydration force decay length would be $\lambda_{\text{KL}} = 1/2\lambda$. Inserting numbers for the case of DNA, where the “surface” structure has a characteristic scale of 1–2 Å, we realize that the hydration decay length in this case would be almost entirely determined by the surface structure and not the bulk solvent properties. Given the experimentally determined variety of forces between phospholipids [20], it is indeed quite possible that even in the simplest cases, the measured decay lengths are not those of the water solvent itself but instead also include the surface properties in the characteristic scale of the surface ordering.

The other important facet of this theory is that it predicts that in certain circumstances, the hydration forces can become attractive [11]. This is particularly important in the case of interacting DNA molecules where this hydration attraction connected with condensing agents can hold DNAs into an ordered array even though the van der Waals forces themselves would be unable to accomplish [22]. This attraction is always an outcome of nonhomogeneous surface ordering and arises in situations where apposing surfaces have complementary checkerboard like order [11]. Unfortunately, in this situation, many mechanisms can contribute to attractions; it is difficult to argue for one strongest contribution.

21.2.3 ELECTROSTATIC FORCES

Electrostatic forces between charged colloid bodies are among the key components of the force equilibria in (bio)colloid systems [23]. At larger separations, they are the only forces that

can counteract van der Waals attractions and thus stabilize colloid assembly. The crucial role of the electrostatic interactions in (bio)colloid systems is well documented and explored following the seminal realization of Bernal and Fankuchen [24] that electrostatic interaction is the stabilizing force in tobacco mosaic virus (TMV) arrays.

Though the salient features of electrostatic interactions of fixed charges in a sea of mobile countercharges and salt ions are intuitively straightforward to understand, they are difficult to evaluate. These difficulties are clearly displayed by the early ambiguities in the sign of electrostatic interactions between two equally charged bodies that was first claimed to be attractive (Levine), then repulsive (Verwey-Overbeek), and finally realized that it is usually repulsive except if the counterions or the salt ions are of higher valency [25].

In this section, we introduce the electrostatic interaction on an intuitive footing (see Figure 21.7). Assume we have two equally charged bodies with counterions in between. Clearly the minimum of electrostatic energy W_E [28], which for the electrostatic field configuration at the spatial position \mathbf{r} , $\mathbf{E}(\mathbf{r})$, is proportional to the integral of $\mathbf{E}^2(\mathbf{r})$ over the whole space where one has nonzero electrostatic field, would correspond to the adsorption of counterions to the charges, leading to their complete neutralization. The equilibrium electrostatic field would be thus entirely concentrated right next to the surface. However, at a finite temperature, it is not the electrostatic energy but rather the free energy [26], $F = W_E - TS$, containing also the entropy S of the counterion distribution, that should be minimized. The entropy of the mobile particles with the local density $\rho_i(r)$ (we assume there is more than one species of mobile particles, for example, counterions and salt ions, tracked through the index i) is taken as an ideal gas entropy [26], which is proportional to the volume integral of $\sum_i [\rho_i(r) \ln(\rho_i(r)/\rho_{i0}) - \rho_i(r) - \rho_{i0}]$, where ρ_{i0} is the density of the mobile charges in a reservoir that is in chemical equilibrium with the confined system under investigation. Entropy by itself would clearly lead to a uniform distribution of counterions between the charged bodies, $\rho_i(r) = \rho_{i0}$, while together with the electrostatic energy, it obviously leads to a nonmonotonic profile of the mobile charge distribution between the surfaces, minimizing the total free energy of the mobile ions.

The above discussion, though being far from rigorous, contains all the important theoretical underpinnings known under the title of “Poisson–Boltzmann theory” [27]. In order to arrive at the central equation corresponding to the core of this theory, one simply has to formally minimize the free energy $F = W_E - TS$, just as in the case of structural interactions, together with the basic electrostatic equation [28] (the Poisson equation) that connects the sources of the electrostatic field with the charge densities of different ionic species. The standard procedure now is to minimize the free energy, take into account the Poisson equation, and what follows is the well-known Poisson–Boltzmann (PB) equation, the solution of which gives the nonuniform profile of the mobile charges between the surfaces with fixed charges. This equation can be solved explicitly for some particularly simple geometries [27]. For two charged planar surfaces, the solution gives a screened

FIGURE 21.7 Pictorial exposition of the main ideas behind the PB theory of electrostatic interactions between (bio)colloidal surfaces. Electrostatic energy by itself would favor adsorption of counterions (white circles) to the oppositely charged surfaces (black circles). The equilibrium profile of the counterions in this case is presented by the dotted line below the leftmost drawing. Entropy, on the contrary, favors a completely disordered configuration, i.e., a uniform distribution of counterions between the surfaces, presented by the dotted line below the rightmost drawing. The free energy works a compromise between the two principles leading to a nonmonotonic profile of the counterion density (From Verwey, E.J.W. and Overbeek, J.T.G., *Theory of the Stability of Lyophobic Colloids*, Elsevier, New York, 1948), varying smoothly in the intersurface region. As the two surfaces are brought close, the overlapping counterion distributions originating at the fixed charge at the surfaces (the bold line below each of the drawings) create repulsive forces between them.

electrostatic potential that decays exponentially away from the walls. It is thus smallest in the middle of the region between the surfaces and largest at the surfaces. The spatial variation of the electrostatic interaction is just as in the case of structural interactions described with a characteristic decay length, termed the Debye length in this case, which for uni–uni valent salts assumes the value of $\lambda_D = 3 \text{ \AA} / \sqrt{I}$, where I is the ionic strength of the salt in moles per liter. A 0.1 M solution of uni–uni valent salt, such as NaCl, would thus have the characteristic

decay length of about 9.5 Å. Beyond this separation, the charged bodies do not feel each other any more. By adding or removing salt from the bathing solution, we are thus able to regulate the range of electrostatic interactions.

The exponential decay of the electrostatic field away from the charged surfaces with a characteristic length independent (to the lowest order) of the surface charge is one of the most important results of the PB theory.

Obviously as the surfaces come closer together, their decaying electrostatic potentials begin to interpenetrate [25]. The consequence of this interpenetration is a repulsive force between the surfaces that again decays exponentially with the intersurface separation and a characteristic length again equal to the Debye length. For two planar surfaces at a separation D , bearing sufficiently small charges, characterized by the surface charge density σ , so that the ensuing electrostatic potential is never larger than $k_B T/e$, where k_B is the Boltzmann's constant and e is the elementary electron charge, one can derive the expression $F(D) \sim \sigma^2 \lambda \exp(-D/\lambda_D)$ [27] for the interaction free energy per unit surface area $F(D)$. The typical magnitude of the electrostatic interaction in different systems of course depends on the magnitude of the surface charge. It would not be unusual in lipids to have surface charge densities in the range of one elementary charge per 50 to 100 Å² surface area [29]. For this range of surface charge densities, the constant prefactor in the expression for the osmotic pressure would be of the order $0.4\text{--}1.2 \times 10^7 \text{ N/m}$.

The same type of analysis would apply also to two charged cylindrical bodies, e.g., two molecules of DNA, interacting across an electrolyte solution. What one evaluates in this case is the interaction free energy per unit length of the cylinders [30], $g(R)$, where R is the separation between the cylinders, which can be obtained in the approximate form $g(R) = \mu^2 \exp(-R/\lambda_D)$. It is actually possible to get also an explicit form [30] of the interaction energy between two cylinders even if they are skewed by an angle θ between them. In this case, the relevant quantity is the interaction free energy itself (if θ is nonzero, then the interaction energy does not scale with the length of the molecules) that can be obtained in a closed form as $F(R, \theta) \sim \mu^2 \lambda_D R^{1/2} \exp(-R/\lambda_D) / \sin \theta$.

The predictions for the forces between charged colloid bodies have been reasonably well borne out for electrolyte solutions of uni–uni valent salts [31]. In that case, there is near quantitative agreement between theory and experiment. However, for higher valency salts, the PB theory does not only give the wrong numerical values for the strength of the electrostatic interactions, but also misses their sign. In higher valency salts, the correlations among mobile charges between charged colloid bodies due to thermal fluctuations in their mean concentration lead effectively to attractive interactions [32] that are in many respects similar to van der Waals forces that we analyze next.

21.2.4 VAN DER WAALS FORCES

van der Waals charge fluctuation forces are special in the sense that they are a consequence of thermodynamic as well as quan-

tum mechanical fluctuations of the EM fields [15]. They exist even if the average charge, dipole moment, or higher multipole moments on the colloid bodies are zero. This is in stark contrast to electrostatic forces that require a net charge or a net polarization to drive the interaction. This also signifies that van der Waals forces are much more general and ubiquitous than any other force between colloid bodies [9].

There are many different approaches to van der Waals forces [15,33,34]. For small molecules interacting at a relatively large distance, one can distinguish different contributions to the van der Waals force, stemming from thermally averaged dipole-dipole potentials (the Keesom interaction), dipole-induced dipole interactions (the Debye interaction), and induced dipole-induced dipole interactions (the London interaction) [35]. They are all attractive and their respective interaction energy decays as the sixth power of the separation between the interacting molecules. The magnitude of the interaction energy depends on the EM absorption (dispersion) spectrum of interacting bodies, hence also the term dispersion forces.

For large colloidal bodies composed of many molecules, the calculation of the total van der Waals interactions is not trivial [15,34], even if we know the interactions between individual molecules composing the bodies. Hamaker assumed that one can simply add the interactions between composing molecules in a pairwise manner. It turned out that this was a very crude and simplistic approach to van der Waals forces in colloidal systems, as it does not take into account the highly nonlinear nature of the van der Waals interactions in condensed media. Molecules in a condensed body interact among themselves, thus changing their properties, hence their dispersion spectrum, which in turn modifies the van der Waals forces between them.

Lifshitz, following work of Casimir [9,15,34], realized how to circumvent this difficulty and formulated the theory of van der Waals forces in a way that already includes all these nonlinearities. The main assumption of this theory is that the presence of dielectric discontinuities, as in colloid surfaces, modifies the spectrum of EM field modes between these surfaces (see Figure 21.8). As the separation between colloid bodies varies, so do the eigenmode frequencies of the EM field between and within the colloid bodies. It is possible to deduce the change in the free energy of the EM modes due to the changes in the separation between colloid bodies coupled to their dispersion spectral characteristics [36].

Based on the work of Lifshitz, it is now clear that the van der Waals interaction energy is just the change of the free energy of field harmonic oscillators at a particular eigenmode frequency ω as a function of the separation between the interacting bodies D and temperature T , $\omega = \omega(D, T)$. With this equivalence in mind, it is quite straightforward to calculate the van der Waals interaction free energy between two planar surfaces at a separation D and temperature T ; the dielectric permittivity between the two surfaces, ϵ , and within the surfaces, ϵ' , must both be known as a function of the frequency ω of the EM field [36]. This is a consequence of the fact that in general, the dielectric media comprising the surfaces as well as the

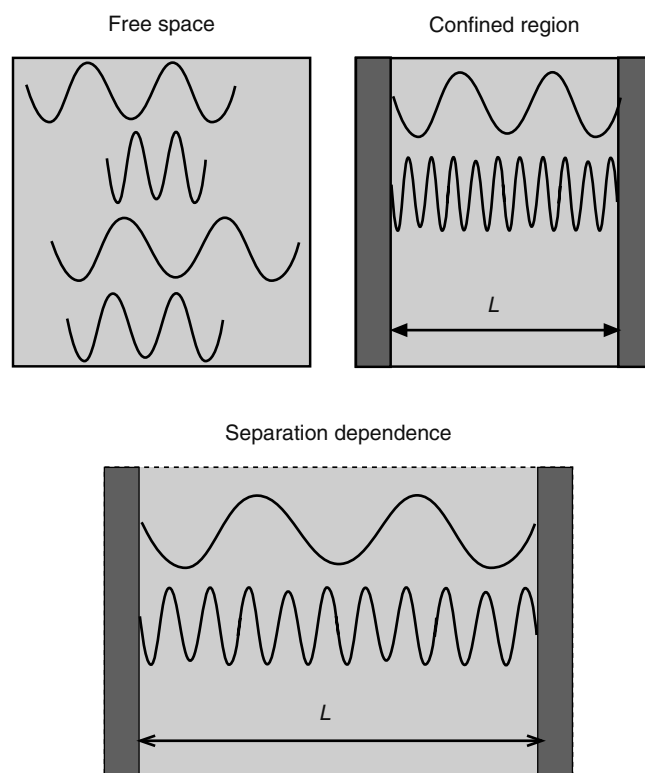

FIGURE 21.8 Pictorial introduction to the theory of Lifshitz-van der Waals forces between colloid bodies. Empty space is alive with EM field modes that are excited by thermal as well as quantum mechanical fluctuations. Their frequency is unconstrained and follows the black body radiation law. Between dielectric bodies only those EM modes survive that can fit into a confined geometry. As the width of the space between the bodies varies, so do the allowed EM mode frequencies. Every mode can be treated as a separate harmonic oscillator, each contributing to the free energy of the system. Since this free energy depends on the frequency of the modes that in turn depend on the separation between the bodies, the total free energy of the EM modes depends on the separation between the bodies. This is an intuitive description of the Lifshitz-van der Waals force. (From Mahanty, J. and Ninham, B.W., *Dispersion Forces*, Academic Press, London, 1976.)

space between them are dispersive, which means that their dielectric permittivities depend on the frequency of the EM field, i.e., $\epsilon = \epsilon(\omega)$. With this in mind, one can derive the interaction free energy per unit surface area of the interacting surfaces in the form $F(D) = A(D)/12\pi D^2$, where the so called Hamaker coefficient A depends on the difference between the dielectric permittivities of the interacting materials at different imaginary frequencies $i\xi$. It can, in general, be split into two terms: the first term in the Hamaker coefficient is due to thermodynamic fluctuations, such as Brownian rotations of the dipoles of the molecules composing the media or the averaged dipole-induced dipole forces and depends on the static ($\omega = 0$) dielectric response of the interacting media, while the second term is purely quantum mechanical in nature [15]. The imaginary argument of the dielectric constants is not that odd since $\epsilon(i\xi)$ is an even function of ξ , which makes $\epsilon(i\xi)$ also a purely real quantity [36].

In order to evaluate the magnitude of the van der Waals forces, one has to know the dielectric dispersion $\epsilon(\omega)$, or more appropriately $\epsilon(\zeta)$, of all the media involved. This is no simple task and can be accomplished only for very few materials [34]. Experiments seem to be a much more straightforward way to proceed. The values for the Hamaker coefficients of different materials interacting across water are between 0.3 and 2.0×10^{-20} J. Specifically for lipids, the Hamaker constants are quite close to theoretical expectations except for the phosphatidylethanolamines that show a much larger attractive interactions probably due to headgroup alignment [31]. Evidence from direct measurements of attractive contact energies as well as direct force measurements suggests that van der Waals forces are more than adequate to provide attraction between bilayers for them to form multilamellar systems [37].

For cylinders, the same type of argument applies except that due to the geometry, the calculations are a bit more tedious [38]. Here the relevant quantity is not the free energy per unit area but the interaction free energy per unit length of the two cylinders of radius a , $g(R)$, considered to be parallel at a separation R . The calculation [39] leads to the following form: $g(R) \sim Aa^4/R^5$ where the constant A again depends on the differences between dielectric permittivities, ϵ_{\parallel} and ϵ_{\perp} , respectively, the parallel and the perpendicular components of the dielectric permittivity of the dielectric material of the cylinders, and ϵ_m , the dielectric permittivity of the bathing medium.

If, however, the two interacting cylinders are skewed at an angle θ , then the interaction free energy $G(R, \theta)$, this time not per length, is obtained [39] in the form $G(R, \theta) \sim (A + B \cos^2 \theta)(a^4/R^4 \sin \theta)$. The constants A and B describe the dielectric mismatch between the cylinder and the bathing medium at different imaginary frequencies. The same correspondence between the thermodynamic and quantum mechanical parts of the interactions as for two parallel cylinders applies also to this case. Clearly the van der Waals force between two cylinders has a profound angular dependence that, in general, creates torques between the two interacting molecules.

Taking the numerical values of the dielectric permittivities for two interacting DNA molecules, one can calculate that the van der Waals forces are quite small, typically one to two orders of magnitude smaller than the electrostatic repulsions between them, and in general cannot hold the DNAs together in an ordered array. Other forces, leading to condensation phenomena in DNA [10], clearly have to be added to the total force balance in order to get a stable array. There is as yet still no consensus on the exact nature of these additional attractions. It seems that they are due to the fluctuations of counterions atmosphere close to the molecules.

21.2.5 DLVO MODEL

The popular Derjaguin–Landau–Verwey–Overbeek (DLVO) [9,25] model assumes that electrostatic double layer and van der Waals interactions govern colloid stability. Applied with a piety not anticipated by its founders, this model actually does surprisingly work rather well in many cases. Direct osmotic stress measurements of forces between lipid bilayers show

that at separations less than ~ 10 Å, there are qualitative deviations from the DLVO thinking [40]. For micron-sized objects and for macromolecules at greater separations, electrostatic double-layer forces and sometimes van der Waals forces tell us what we need to know about interactions governing movement and packing.

21.2.6 GEOMETRIC EFFECTS

Forces between macromolecular surfaces are most easily analyzed in plane-parallel geometry. Because most of the interacting colloid surfaces are not planar, one must either evaluate molecular interactions for each particular geometry or devise a way to connect the forces between planar surfaces with forces between surfaces of a more general shape. The Derjaguin approximation [9] assumes that interactions between curved bodies can be decomposed into interactions between small plane-parallel sections of the curved bodies (see Figure 21.9). The total interaction between curved bodies would be thus equal to a sum where each term corresponds to a partial interaction between quasilplane-parallel sections of the two bodies.

FIGURE 21.9 The Derjaguin approximation. Formulating forces between oppositely curved bodies (e.g., cylinders, spheres, etc.) is very difficult. But it is often possible to use an approximate procedure. Two curved bodies (two spheres of unequal radii in this case) are approximated by a succession of planar sections, interactions between which can be calculated relatively easily. The total interaction between curved bodies is obtained through a summation over these planar sections.

This idea can be given a completely rigorous form and leads to a connection between the interaction free energy per unit area of two interacting planar surfaces, $F(D)$, and the force acting between two spheres at minimal separation D , $f(D)$, one with the mean radius of curvature R_1 and the other one with R_2 . The formal equivalence can be written as follows: $f(D) = 2\pi(R_1R_2/(R_1 + R_2))F(D)$. A similar equation can also be obtained for two cylinders in the form, $f(D) = 2\pi(R_1R_2)^{1/2}F(D)$.

These approximate relations clearly make the problem of calculating interactions between bodies of general shape tractable. The only caveat here is that the radii of curvature should be much larger than the proximal separation between the two interacting bodies, effectively limiting the Derjaguin approximation to sufficiently small separations.

Using the Derjaguin formula or evaluating the interaction energy explicitly for those geometries for which it is not an insurmountable task, one can now obtain a whole range of DLVO expressions for different interaction geometries (see Figure 21.10). The salient features of all these expressions are that the total interaction free energy always has a primary minimum that can only be eliminated by strong short-range

hydration forces and a secondary minimum due to the compensation of screened electrostatic repulsion and van der Waals–Lifshitz attraction. The position of the secondary minimum depends as much on the parameters of the forces (Hamaker constant, fixed charges, and ionic strength) as well as on the interaction geometry. One can state generally that the range of interaction between the bodies of different shapes is inversely proportional to their radii of curvature.

Thus the longest-range forces are observed between planar bodies, and the shortest between small (point-like) bodies. What we have not indicated on Figure 21.7 is that the interaction energy between two cylindrical bodies, skewed at a general angle θ and not just for parallel or crossed configurations, can be obtained in an explicit form. It follows simply from these results that the configuration of two interacting rods with minimal interaction energy is the one corresponding to $\theta = \pi/2$, i.e., corresponding to crossed rods.

21.2.7 FLUCTUATION FORCES

The term “fluctuation forces” is a bit misleading in this context because clearly van der Waals forces already are fluctuation

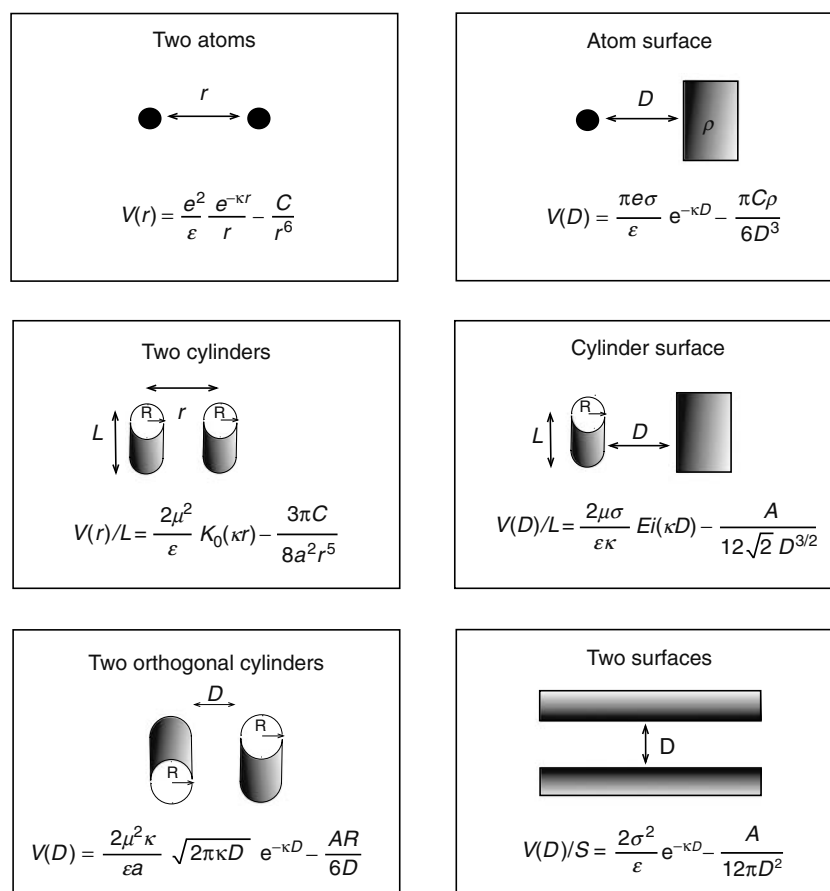

FIGURE 21.10 A representative set of DLVO interaction expressions for different geometries most commonly encountered in biological milieus: Two small particles, a particle and a wall, two parallel cylinders, a cylinder close to a wall, two skewed cylinders, and two walls. The DLVO interaction free energy is always composed of a repulsive electrostatic part (calculated from a linearized PB theory) and an attractive van der Waals part. Charge: e , charge per unit length of a cylinder: μ , charge per unit surface area of a wall: σ , C are geometry-dependent constants, ϵ the dielectric constant, κ the inverse Debye length, and ρ the density of the wall material. The functions $K_0(x)$ (the Bessel function K_0) and $Ei(x)$ (the exponential integral function) both depend essentially exponentially on their respective argument.

forces. What we have in mind is thus a generalization of the van der Waals forces to situations where the fluctuating quantities are not EM fields but other quantities subject to thermal fluctuations. No general observation as to the sign of these interactions can be made; they can be either repulsive or attractive and are as a rule of thumb comparable in magnitude to the van der Waals forces.

The most important and ubiquitous force in this category is the undulation or Helfrich force [41]. It has a very simple origin and operates among any type of deformable bodies as long as their curvature moduli are small enough (comparable to thermal energies). It was shown to be important for multilamellar lipid arrays [42] as well as in hexagonal polyelectrolyte arrays [43] (see Figure 21.11).

FIGURE 21.11 (See color insert following blank page 206.) Thermally excited conformational fluctuations in a multilamellar membrane array (small molecules are waters and long chain molecules are phospholipids) or in a tightly packed polyelectrolyte chain array (the figure represents a hexagonally packed DNA array) leading to collisions between membranes or polyelectrolyte chains. These collisions contribute an additional repulsive contribution to the total osmotic pressure in the array, a repulsion that depends on the average spacing between the fluctuating objects. (Graphics courtesy of B.B. Brooks and M. Hodoscek, NIH)

The mechanism is simple. The shape of deformable bodies fluctuates because of thermal agitation (Brownian motion) [26]. If the bodies are close to each other, the conformational fluctuations of one will be constrained by the fluctuations of its neighbors. Thermal motion makes the bodies bump into each other, which creates spikes of repulsive force between them. The average of this force is smooth and decays continuously with the mean separation between the bodies.

One can estimate this steric interaction for multilamellar lipid systems and for condensed arrays of cylindrical polymers (Figure 21.11). The only quantity entering this calculation is the elastic energy of a single bilayer that can be written as the square of the average curvature of the surface, summed over the whole area of the surface, multiplied by the elastic modulus of the membrane, K_C . K_C is usually between 10 and $50 k_B T$ [44] for different lipid membranes. If the instantaneous deviation of the membrane from its overall planar shape in the plane is now introduced as u , the presence of neighboring membranes introduces a constraint on the fluctuations of u that basically demands that the average of the square of u must be proportional to D^2 , where D is the average separation between the membranes in a multilamellar stack. Thus we should have $u^2 \sim D^2$. The free energy associated with this constraint can now be derived in the form $F(D) \sim (k_B T)^2 (K_C D^2)$, and is seen to decay in inverse proportion to the separation between bilayers squared [41].

It has thus obviously the same dependence on D as the van der Waals force. This is, however, not a general feature of undulation interactions as the next example clearly shows. Also we only indicated the general proportionality of the interaction energy. The calculation of the prefactors can be a difficult [45] especially because the elastic bodies usually do not interact with idealized hard repulsions but rather through soft potentials that have both attractive as well as repulsive regimes.

The same line of thought can now be applied to flexible polymers in a condensed array [43]. This system is a one-dimensional analog of the multilamellar membrane system. For polymers, the elastic energy can be written similarly to the membrane case as the square of the local curvature of the polymer, multiplied by the elastic modulus of the polymer, integrated over its whole length. The elastic modulus K_C is usually expressed through a persistence length $L_p = K_C / (k_B T)$. The value of the persistence length tells us how long a polymer can be before the thermal motion forces it to fluctuate wildly. For DNA, this length is about 50 nm. It spans, however, the whole range of values between about 10 nm for hyaluronic acid and all the way to 3 mm for microtubules. Using now the same constraint for the average fluctuations of the polymer away from the straight axis, one derives the relationship for the free energy change due to this constraint, $F(D) \sim (k_B T)(L_p^{1/3} D^{2/3})$ [43].

Clearly the D dependence for this geometry is very much different from the one for van der Waals force, which would be D^{-5} . There is thus no general connection between the van der Waals force and the undulation fluctuation force. Here again one has to indicate that if the interaction potential between fluctuating bodies is described by a soft potential, with no discernible hard core, the fluctuation interaction can have a profoundly different dependence on the mean separation [43].

Apart from the undulation fluctuation force, there are other fluctuation forces. The most important among them appears to be the monopolar charge fluctuation force [46], recently investigated in the context of DNA condensation. It arises from transient charge fluctuations along the DNA molecule due to constant statistical redistributions of the counterion atmosphere.

The theory of charge fluctuation forces is quite intricate and mathematically demanding [47]. Let us just quote a rather interesting result: if two point charges interact via a “bare” potential $V_0(R)$, where R is the separation between them, then the effect of the thermal fluctuations in the number of counterions surrounding these charges would lead to an effective interaction of the form $V(R) \sim k_B T (V_0(R))^2$. The fluctuation interaction in this case would thus be attractive and proportional to the square of the bare interaction.

This simple result already shows one of the salient features of the interaction potential for monopolar charge fluctuation forces, i.e., it is screened with half the Debye screening length (because of $V^2(R)$). If there is no screening, however, the monopolar charge fluctuation force becomes the strongest and longest ranged among all the fluctuation forces. It is, however, much less general than the related van der Waals force and at present, it is still not clear what the detailed conditions should be for its appearance, the main difficulty being the question whether charge fluctuations in the counterion atmosphere are constrained or not.

21.2.8 ATTRACTIVE ELECTROSTATIC FORCES: STRONG COUPLING AND POLYELECTROLYTE BRIDGING

As we pointed out in the section on the electrostatic forces, the predictions of the PB theory for interactions between charged

macroions in electrolyte solutions of univalent salts conform well with osmotic stress experiments on ordered DNA arrays to the extent of a near quantitative agreement between theory and experiment [43]. The effective surface charge on DNA obtained from osmotic stress experiments is close, but nevertheless consistently somewhat smaller from the theoretical predictions based on the Manning counterion condensation theory. Theoretical arguments based on the more detailed analysis of the counterion condensation in the presence of salt [48] generally agree that the effective charge on DNA in an ionic solution should be smaller than the one based on the estimate of Manning condensation theory.

When the same analysis of the osmotic stress experiments is furthermore applied to salts containing at least one higher valency counterion, such as Mn^{2+} , $\text{Co}(\text{NH}_3)_6^{3+}$, or various polyamines, the theoretical predictions based on the PB theory tend to lose agreement with experiment. Not only does the PB theory give the wrong numerical values for the strength of the electrostatic interactions, but also and more importantly misses their sign since experiments point to the existence of electrostatic attractions [22]. This attraction is deduced from the shape of the osmotic pressure as a function of density of DNA, i.e., there are regions of DNA density where the corresponding osmotic pressure in a DNA array remains constant [49] (see left panel of Figure 21.12 for $\text{Co}(\text{NH}_3)_6^{3+}$ concentrations of 12 and 6 mM).

This is quite similar to the pressure versus volume isotherms in the case of a liquid–gas transition [50] (see right panel of Figure 21.12). In that case due to attractive van der Waals interactions between gas molecules, the gaseous phase condenses into a liquid phase at a certain condensation pressure that depends on the temperature. As we reduce the volume in the region of liquid–gas coexistence, more of the gas condenses

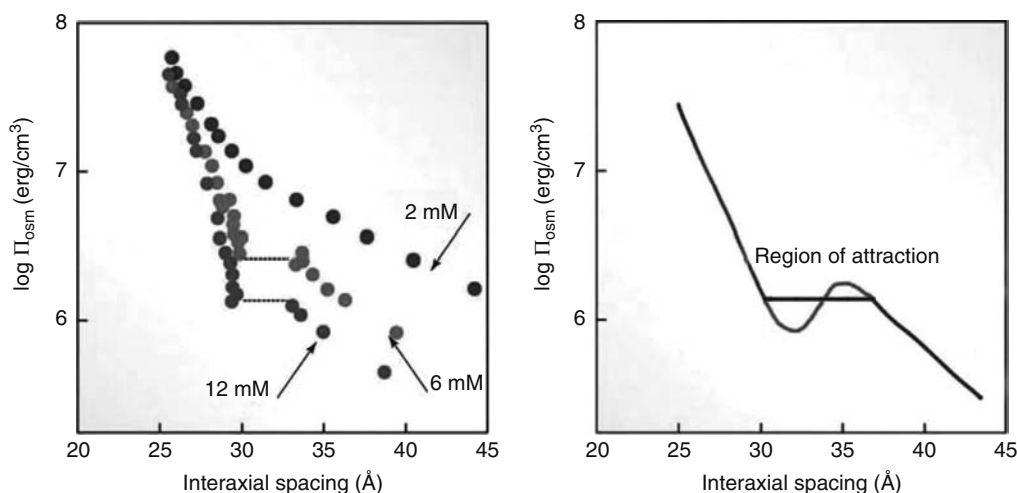

FIGURE 21.12 Left-hand side: Osmotic pressure as a function of DNA concentration in a DNA array with monovalent salt (0.25 M NaCl) with added trivalent counterion CoHex ($\text{Co}(\text{NH}_3)_6^{3+}$) at concentration from 0 to 20 mM. Above a sufficiently large value of CoHex concentration (17 mM), DNA spontaneously precipitates. For smaller values of CoHex concentration, e.g., 6 mM, the osmotic pressure dependence on the interaxial spacing shows a horizontal transition line between two regimes of repulsive forces. Right-hand side: A schematic explanation of the 6 mM CoHex concentration line. The dependence of the osmotic pressure on the interaxial spacing is in fact nonmonotonic due to the presence of attractive interactions in the region depicted in red. Because of the condition of stability, just as in the case of the van der Waals isotherm, the regions of attraction can only be traversed via a horizontal transition line.

into liquid, while the applied force required to keep the gas in place is unchanged. As a result, the part of the isotherm between the start and the end of the condensation process is flat (see right panel of Figure 21.12). In the DNA case, the role of inverse temperature is played (roughly) by the concentration of the polyvalent counterion. For sufficiently large concentration, for example, of $\text{Co}(\text{NH}_3)_6^{3+}$, the DNA array spontaneously precipitates or condenses into an ordered high density phase. One thus concludes that the polyvalent counterion should confer some kind of attractive interactions between nominally equally charged DNA molecules. What is so special about multivalent counterions, such as Mn^{2+} , $\text{Co}(\text{NH}_3)_6^{3+}$, or various polyamines, that leads to a complete breakdown of the simple PB framework?

In order to understand this anomaly, we should first relinquish a seemingly obvious explanation—that we are dealing with the effects of DNA–DNA van der Waals interactions as is the case in condensation of gases (see Section 21.2.4). These forces are much too small to account for the strong attractions seen with polyvalent counterions [34]. So how are we to rationalize the polyvalent counterion-mediated DNA attractions?

When dealing with small univalent counterions in the PB framework, we actually assume that they can be described collectively, via their number or charge density, without acknowledging that we have individual charges (see, for example, the chapter by Andelman in Ref. [27]). This approach is usually referred to as the mean-field approach in statistical thermodynamics and is used in a plethora of contexts. It works only if the concentration of the counterions or salt ions, in general, is high enough. PB theory is, in fact, a mean-field theory. When we go to polyvalent counterions of valency Z , and for the sake of the argument, assume that $Z \gg 1$, we have fewer counterions to satisfy the overall electroneutrality of the system. In an extreme case, we would be dealing with just a few of them as represented schematically in Figure 21.13. In this case, the mean-field description would break down miserably. Why? Because there is no proper “mean-field” to speak of. We have to deal with each of the counterions individually. This demands a completely different approach that has to be set apart and formulated in a completely different language than the popular PB (mean-field) theory. This alternative approach has been formulated by various people and goes under the strong-coupling approach [51] or the strong-correlation approach [52].

Let us try to describe this alternative approach without invoking the heavy analytical machinery on which it relies. For instance, assume that we have only one giant polyvalent counterion between two fixed charges of opposite sign (see right panel of Figure 21.13). The charge of this giant counterion would have to be large indeed in order to neutralize the two surfaces with fixed charge of opposite sign, but this is the assumption. The overall force between the fixed charges is composed of direct repulsion between the fixed charges, since they are assumed to be equally charged plus the attraction between the left fixed charge and the counterion (remember, they bear charges of opposite sign), assumed

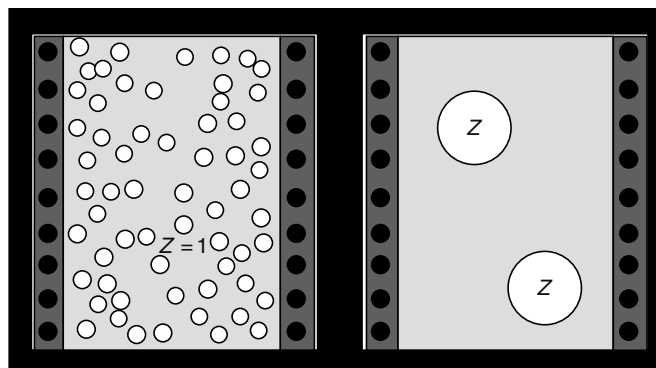

FIGURE 21.13 Monovalent counterions (small white circles) assumed to be positive between two oppositely charged surfaces (small black circles) versus polyvalent positive counterions (large white circles) in the same geometry. In the idealized case when the valency (Z) of the counterion is assumed to be very large ($Z \gg 1$), we can treat just a single counterion (of the two depicted in the right panel) in the space between the two surfaces bearing fixed charges. Direct electrostatic interactions between negatively charged surfaces are repulsive, but the interactions between the (single) counterion and the surfaces are attractive since the counterion bears a charge opposite in sign to those on the surfaces. The sum of the two is also net attractive. This is the physical origin of the correlation attraction in polyvalent counterion systems such as DNA with trivalent $\text{Co}(\text{NH}_3)_6^{3+}$ counterion.

to be in the middle of the space between the fixed charges and the attraction between the right fixed charge and the counterion (again remember, they bear charges of opposite sign). Summing together all these contribution, we get an overall attraction. Thus in this case, like-charged surfaces do not repel as goes the common wisdom, in fact they attract. This intuitive argument can be made exact within the strong-coupling approximation that supersedes the PB description in the case of polyvalent counterions. The strong coupling approach can be formulated also in an alternative form of the s.c. correlated Coulomb fluid theory [52], but is always reduced to the assumption that polyvalent counterions interact with the fixed charges individually and not collectively as in the PB framework. The attraction usually outweighs repulsion only at small separation between the surfaces bearing fixed charges, and as the separation increases the idealization invoked above becomes increasingly less realistic, we move smoothly from the strong-coupling attraction to the standard PB repulsion.

An alternative interpretation of the same effect [22] would be that the polyvalent counterion adsorbs onto the charged surface and thus changes its hydration pattern by interacting much more strongly with the water molecules in its vicinity than with the fixed charges on the surface. This modulation of the hydration pattern on both of the apposed surfaces could also induce structural attractions, qualitatively similar to the strong coupling electrostatic interactions. Both effects are short-ranged and are thus difficult to disentangle. Strong counterion specificity in the magnitude of attractive

interactions shows that at least a part of it has an origin in counterion properties other than its valency.

Until now, when invoking polyvalent counterions what we had in mind were relatively small charged particles without any inherent structure. We now move forward. By increasing the valency of the counterions, thus adding more and more charge to them, ions do not only grow in size but in fact usually become more and more polymer-like. Their inherent chemical structure becomes increasingly chain-like. In fact, we refer to them as polyelectrolytes [53], which in this context means long, usually positively charged polymer chains. Typical examples include polyamines, such as spermine (Sp), and polypeptides such as poly-L-lysine (PL) and poly-L-arginine (PA). Mixing these long flexible polycations with DNA in an ionic solution leads again to ordered DNA arrays that allow the application of the osmotic stress technique, resulting in equation of state, i.e., osmotic pressure as a function of the DNA density, just as in the case of simple salts [54]. Strong attractions between DNA molecules have been measured also in solutions containing such polycations. In this case, however, it would be difficult to invoke the previous argument based on the strong-coupling picture, since the charged polymer chains have very extended configurations that do not allow us to use gedanken experiments based on point charge models as we did before, where the total interaction was composed of direct repulsion between the fixed charges plus the attraction between the fixed charges and the counterion. So what would be an appropriate conceptual picture to explain attractions between surfaces with fixed negative charges mediated by these long polycations?

We again give a simple description of what is going on without going into complicated mathematical details [55]. Imagine the situation of two cylindrical macroions with fixed negative charge together with a polycation chain and possibly simple salt and counterions (as depicted in Figure 21.14). Because the polyelectrolyte chain is oppositely charged from

the macroions, it would like to neutralize them due to electrostatic attraction. In the case of sufficiently long polycations, the flexible chain can wrap around both macroions with fixed charges, creating a polyelectrolyte bridge between them (see the schematic representation on the left panel of Figure 21.14). This bridge is trying to pull the two fixed charges together by an entropic elastic force due to a tendency to maximize the possible number of polymer conformations, thus creating an attractive force between them. However, in this case, there is no strong-coupling or correlation effect. The chain draws the two macroions together simply because of its connectivity [56]. The total force in this case is composed of the direct electrostatic repulsion between the macroions with partially neutralized charges and the elastic term corresponding to the part of the polyelectrolyte chain between the macroions. Note the difference, however. In the strong coupling viewpoint, the attraction is still electrostatic in origin, stemming from the sharing of the simple polyvalent counterion between the two fixed charges. In the case of polyelectrolyte bridging on the other hand, the attraction is only distantly electrostatic in origin, stemming more directly from the elasticity, connectivity, and conformational flexibility of the polycation chain. Similar to the situation with simple, not polymeric, counterions, the polyelectrolyte bridging attraction is also usually short-ranged except in arrays of macromolecules where it can be also long(er) ranged [57].

Both mechanisms, strong coupling attraction as well as polyelectrolyte bridging, have a profound effect on the balance of forces in DNA arrays as well as for conformations of a single DNA in a very dilute solution. In the former case, they have been observed directly in the DNA-polycation complexes analyzed by the osmotic stress technique that we will describe in more detail later [54], whereas in the latter case, they are responsible for the phenomenon of DNA condensation that we will not deal with specifically in this chapter.

FIGURE 21.14 A schematic presentation of two cylindrical macroions with fixed (negative) charges (cylinders) with a polycation chain (wires) and explicit salt and counterions (small spheres) in between. The polycation chain tends to neutralize the fixed charges and thus wraps around both cylindrical macroions in a bridging configuration. Left-hand side: For small enough separation between the counterions, the polycation can bridge the space between them resulting in attractive bridging interactions. Right-hand side: For larger separations, the polycation cannot bridge the space between macroions and the bridging attraction is not present. This polycation-mediated bridging attraction is usually of short range but much stronger than the van der Waals interaction.

21.2.9 LESSONS

Molecular forces apparently convey a variety that is surprising considering the fact that they are all to some extent or another just a variant of electrostatic interactions. Quantum and thermal fluctuations apparently modify the underlying electrostatics, leading to qualitatively novel and unexpected features. Electrostatic interactions mediated by polyvalent counterions show a quite surprising feature of being actually attractive even between nominally equally charged macroions such as two DNA molecules. These attractions can be due to either complicated correlation or hydration effects, or polyelectrolyte bridging attractions if the counterions have long flexible charged chains. The menagerie of forces obtained in this way is what one has to deal with and understand when trying to make them work for us.

21.3 DNA MESOPHASES

21.3.1 POLYELECTROLYTE PROPERTIES OF DNA

We can define several levels of DNA organization similar to Ref. [1]. Its primary structure is the sequence of base pairs. Its secondary structure is the famous double helix that can exist in several conformations. In solution, the B-helical structure dominates [58]. The bases are perpendicular to the axis of the molecule and are 0.34 nm apart, and 10 of them make one turn of the helix. These parameters can vary for DNA in solution where up to 10.5 base pairs can make a whole turn of the double helix [59]. In the A structure, the bases are tilted with respect to the direction of the helix and this arrangement yields an internal hole, wider diameter, and closer packing (see Figure 21.15). Other conformations, such as the left-handed Z form, are rare. In solution, DNA's tertiary structure includes the many bent and twisted conformations in three dimensions.

DNA lengths can reach macroscopic dimensions. For instance, the human genome is coded in approximately 3 billion base pairs with a collective linear stretch on the order of a meter. Obviously, this molecule must undergo extensive compaction in order to fit in the cell nucleus. In natural environments, DNA is packaged by basic proteins, which form chromatin structures to keep DNA organized. In the test tube, DNA can be packaged into very tight and dense structures as well, primarily by various “condensing” agents. Their addition typically induces a random coil to globule transition. At large concentrations, DNA molecules, like lipids, form ordered liquid crystalline phases [10] that have been studied extensively at different solution conditions [8].

In vitro, at concentrations above a critical value [60], polyelectrolyte DNA self-organizes in highly ordered mesophases [8]. In this respect, it is a lyotropic liquid crystal. But contrary to the case of lipid mesophases, where the shape of constituent molecules plays a determining role, the organization of DNA in condensed phases is primarily a consequence of its relatively large stiffness [8]. The orientational ordering of DNA at high concentrations is promoted mostly by the interplay between entropically favored disorder or misalignment and the consequent price in terms of the high interaction

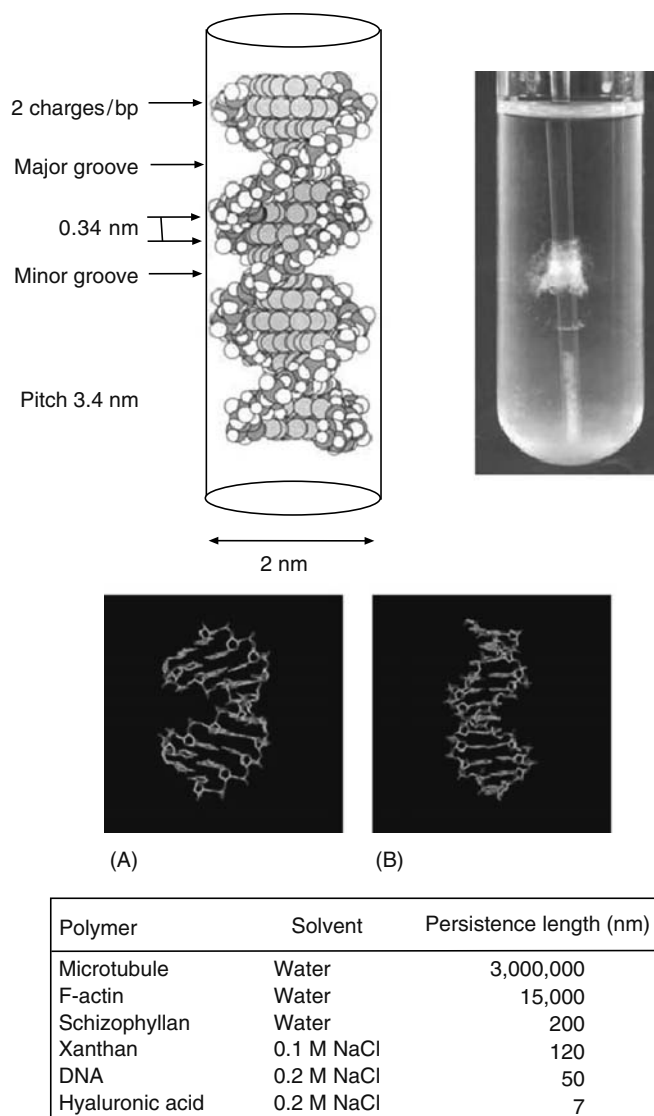

FIGURE 21.15 Structural parameters of a DNA molecule. The two relevant configurations of the DNA backbone. (A) DNA, common at small hydrations or high DNA densities. (B) DNA, common in solution at large hydrations and lower DNA densities. The test tube holds ethanol-precipitated DNA in solution. Its milky color is due to the light scattering by thermal conformational fluctuations in the hexatic phase (see main text). Box: Typical persistence lengths for different (bio)polymer chains in nanometers. DNA persistence length was first inferred from light scattering experiments in 1953 by Peterlin. (From Peterlin, A., *Nature*, 171, 259, 1953.)

energy. The mechanism of orientational ordering is thus the same as in standard short nematogens [61], with the main difference arising from the extended length of the polymeric chains. The discussion that follows will concentrate mostly on very long, on the order of 1000 persistence lengths, microns long, DNA molecules.

21.3.2 FLEXIBILITY OF DNA MOLECULES IN SOLUTION

In isotropic solutions, DNA can be in one of the several forms. For linear DNA, individual molecules are effectively straight over the span of a persistence length that can be defined also

as the exponential decay length for the loss of angular correlation between two positions along the molecule, while for longer lengths they form a worm-like random coil. The persistence length of DNA is about 50 nm [1]. The persistence length has been determined by measuring the diffusion coefficient of different-length DNA molecules using dynamic light scattering and by enzymatic cyclization reactions [62]. It depends only weakly on the base-pair sequence and ionic strength.

DNA can also be circular as in the case of a plasmid. The closed form of a plasmid introduces an additional topological constraint on the conformation that is given by the linking number Lk [2]. The linking number gives the number of helical turns along a circular DNA molecule. Because plasmid DNA is closed, Lk has to be an integer number. By convention, Lk of a closed right-handed DNA helix is positive. The most frequent DNA conformation for plasmids in cells is negatively supercoiled. This means that for such plasmids, Lk is less than it would be for a torsionally relaxed DNA circle; negatively supercoiled DNA is underwound. This is a general phenomenon with important biological consequences. It seems that free energy of negative supercoiling catalyzes processes that depend on DNA untwisting such as DNA replication and transcription, which rely on DNA [63]. While the sequence of bases in exons determines the nature of proteins synthesized, it is possible that such structural features dictate the temporal and spatial evolution of DNA-encoded information.

21.3.3 LIQUID CRYSTALS

The fact that DNA is intrinsically stiff makes it form liquid crystals at high concentration [8]. Known for about 100 years, the simplest liquid crystals are formed by rodlike molecules. Solutions of rods exhibit a transition from an isotropic phase with no preferential orientation to a nematic phase, a fluid in which the axes of all molecules point on average in one direction (see Figure 21.11). The unit vector in which the molecules point is called the nematic director \mathbf{n} . Nematic order is orientational order [61], in contrast to positional order that distinguishes between fluid and crystalline phases. Polymers with intrinsic stiffness can also form liquid crystals. This is because a long polymer with persistence length L_p acts much like a solution of individual rods that are all one persistence length long, thus the term “polymer nematics” [64].

If the molecules that comprise the liquid crystal are chiral, have a natural twist such as double helical DNA, then their orientational order tends to twist. This twist originates from the interaction between two molecules that are both of the same handedness. This chiral interaction is illustrated in Figure 21.16 for two helical or screw-like molecules. For steric reasons, two helices pack best when tilted with respect to each other. Instead of a nematic phase, chiral molecules form a cholesteric phase [61]. The cholesteric phase is a twisted nematic phase in which the nematic director twists continuously around the so-called cholesteric axis as shown in Figure 21.16. Using the same arguments as for plain polymers, chiral polymers form polymer cholesterics.

FIGURE 21.16 “Chiral” interaction for two helical or screw-like molecules. For steric reasons, two helices just as two screws (depicted on the figure) pack best when slightly tilted with respect to each other. Since DNA because of its double-stranded, helical nature is a type of molecular screw, it too exhibits chiral interactions. Instead of a nematic phase depicted in Figure 21.11, characterized by the average constant direction of molecules, chiral molecules form a cholesteric phase. (From De Gennes, P.G. and Prost, J., *The Physics of Liquid Crystals*, 2nd ed., Oxford University Press, Oxford, 1993.) The cholesteric phase is a twisted nematic phase in which the nematic director twists continuously around a “cholesteric axis” depicted on the middle drawing. Under crossed polarizers (bottom), the DNA cholesteric phase creates a characteristic striated texture. For long DNA molecules, the striations appear disordered.

Both cholesteric and hexagonal liquid crystalline DNA phases were identified in the 1960s. This discovery was especially exciting because both phases were also found in biological systems. The hexagonal liquid crystalline phase can be seen in bacterial phages and the cholesteric phase can be seen in cell nuclei of dinoflagellates [8].

21.3.4 MEASUREMENTS OF FORCES BETWEEN DNA MOLECULES

Liquid crystalline order lets us measure intermolecular forces directly. With the osmotic stress method, DNA liquid crystals are equilibrated against neutral polymer (such as PEG or PVP) solutions of known osmotic pressure, pH, temperature, and ionic composition [65]. Equilibration of DNA under osmotic stress of external polymer solution is effectively the same as exerting mechanical pressure on the DNA subphase with a piston (see Figure 21.4). In this respect, the osmotic stress technique is formally very much similar to the Boyle experiment

where one compresses a gas with mechanical pistons and measures the ensuing pressure. After equilibration under this known stress, DNA separation is measured either by x-ray scattering, if the DNA subphase is sufficiently ordered, or by straightforward densitometry [66]. Known DNA density and osmotic stress immediately provide an equation of state (osmotic pressure as a function of the density of the DNA subphase) to be codified in analytic form for the entire phase diagram. Then, with the local packing symmetry derived from x-ray scattering [7,65], and sometimes to correct for DNA motion [42], it is possible to extract the bare interaxial forces between molecules which can be compared with theoretical predictions as developed in Chapter 2. *In vivo* observation of DNA liquid crystals [67] shows that the amount of stress needed for compaction and liquid crystalline ordering is the same as for DNA *in vitro*.

21.3.5 INTERACTIONS BETWEEN DNA MOLECULES

Direct force measurements performed on DNA in univalent salt solutions reveal two types of purely repulsive interactions between DNA double helices [4]:

1. At interaxial separations less than ~ 3 nm (surface separation ~ 1 nm), an exponentially varying “hydration” repulsion is thought to originate from partially ordered water near the DNA surface.
2. At surface separations greater than 1 nm, measured interactions reveal electrostatic double layer repulsion presumably from negative phosphates along the DNA backbone.

Measurements give no evidence for a significant DNA–DNA attraction expected on theoretical grounds [68]. Though charge fluctuation forces must certainly occur, they appear to be negligible at least for liquid crystal formation in monovalent-ion solutions. At these larger separations, the double layer repulsion often couples with configurational fluctuations to create exponentially decaying forces whose decay length is significantly larger than the expected Debye screening length [42].

Bare short-range molecular interactions between DNA molecules appear to be insensitive to the amount of added salt. This has been taken as evidence that they are not electrostatic in origin, as attested also by similar interactions between completely uncharged polymers such as schizophyllan (Figure 21.5). The term “hydration force” associates these forces with perturbations of the water structure around the DNA surface [65]. Alternatively, short-range repulsion has been viewed as a consequence of the electrostatic force specific to high DNA density and counterion concentration [69].

21.3.6 HIGH-DENSITY DNA MESOPHASES

Ordering of DNA can be induced by two alternative mechanisms. First of all, attractive interactions between different DNA segments can be enhanced by adding multivalent

counterions thought to promote either counterion-correlation forces [70] or electrostatic [71] and hydration attraction [22]. In these cases, DNA aggregates spontaneously. Alternatively, one can add neutral crowding polymers to the bathing solution that phase separate from DNA and exert osmotic stress on the DNA subphase [72]. In this case, the intersegment repulsions in DNA are simply counteracted by the large externally applied osmotic pressure. DNA is forced in this case to condense under externally imposed constraints. This latter case is formally (but only formally) analogous to a Boyle gas pressure experiment but with osmotic pressure playing the role of ordinary pressure. The main difference being that ordinary pressure is set mechanically while osmotic pressure has to be set through the chemical potential of water, which is in turn controlled by the amount of neutral crowding polymers (such as PEG, PVP, or dextran) in the bathing solution [66].

At very high DNA densities, where the osmotic pressure exceeds 160 atm, DNA can exist only in a (poly)crystalline state [73]. Nearest neighbors in such an array are all oriented in parallel and show correlated (nucleotide) base stacking between neighboring duplexes (see Figures 21.11 and 21.17). This means that there is a long-range correlation in the positions of the backbone phosphates between different DNA molecules in the crystal. The local symmetry of the lattice is monoclinic. Because of the high osmotic pressure, DNA is actually forced to be in an A conformation characterized by a somewhat larger outer diameter as well as a somewhat smaller pitch than in the canonical B conformation (see Figure 21.15), which persists at smaller densities. If the osmotic pressure of such a crystal is increased above 400 atm, the helix begins to crack and the sample loses structural homogeneity [73].

Lowering the osmotic pressure does not have a pronounced effect on the DNA crystal until it is down to ~ 160 atm. Then the crystal as a whole simultaneously expands while individual DNA molecules undergo an A to B conformational transition (see Figure 21.17) [73]. This phase transformation is thus first order, and besides being a conformational transition for single DNA, is connected also with the melting of the base stacking as well as positional order of the helices in the lattice. The ensuing low-density mesophase, where DNA is in the B conformation, is therefore characterized by short-range base stacking order, short-range 2D positional order, and long-range bond orientational order (see Figure 21.18) [74]. This order is connected with the spatial direction of the nearest neighbors [75]. It is for this reason that the phase has been termed a “line hexatic” phase. Hexatics usually occur only in 2D systems. They have crystalline bond orientational order but liquid-like positional order. There might be a hexatic to hexagonal columnar transition somewhere along the hexatic line though a direct experimental proof is lacking.

The difference between the two phases is that the hexagonal columnar phase has also a crystalline positional order and is thus a real 2D crystal (see Figure 21.18) [76]. It is the long-range bond orientational order that gives the line hexatic

FIGURE 21.17 Schematic phase diagrams for DNA (left) and lipids (right). In both cases, the arrow indicates increasing density in both cases. DNA starts (bottom) as a completely disordered solution. It progresses through a sequence of “blue” phases characterized by cholesteric pitch in two perpendicular directions (From Leforestier, A. and Livolant, F., *Mol. Cryst. Liquid Cryst.*, 1994, 17, 651.) and then to a cholesteric phase with pitch in only one direction. At still larger densities, this second cholesteric phase is succeeded by a hexatic phase, characterized by short-range liquid-like positional order and long-range crystal-like bond orientational (or hexatic order, indicated by lines). At highest densities, there is a crystalline phase, characterized by long-range positional order of the molecules and long-range base stacking order in the direction of the long axes of the molecules. Between the hexatic and the crystalline forms, there might exist a hexagonal columnar liquid-crystalline phase that is similar to a crystal, but with base stacking order only on short scales. The lipid phase diagram (From Small, D.M., *The Physical Chemistry of Lipids: From Alkanes to Phospholipids*, Plenum Press, New York, 1986.) is a composite of results obtained for different lipids. It starts from a micellar solution and progresses through a phase of lipid tubes to a multilamellar phase of lipid bilayers. This is followed by an inverted hexagonal columnar phase of water cylinders and possibly goes to an inverted micellar phase. Most lipids show only a subset of these possibilities. Boundaries between the phases shown here might contain exotic cubic phases not included in this picture.

phase some crystalline character [77]. The DNA duplexes are still packed in parallel, while the local symmetry perpendicular to the long axes of the molecules is changed to hexagonal. The directions of the nearest neighbors persist through mac-

FIGURE 21.18 Bond orientational or hexatic order. With a real crystal, if one translates part of the crystal by a lattice vector, the new position of the atoms completely coincides with those already there. (Adapted from Chaikin, P.M. and Lubensky, T.C., *Principles of Condensed Matter Physics*, Cambridge University Press, Cambridge, MA, 1995.) In a hexatic phase, the directions to the nearest neighbors (bond orientations) coincide (after rotation by 60°), but the positions of the atoms do not coincide after displacement in one of the six directions. Consequently, a real crystal gives a series of very sharp Bragg peaks in x-ray scattering (upper half of box) whereas a hexatic gives hexagonally positioned broad spots. The pattern of x-ray scattering by high-density DNA samples gives a fingerprint of a hexatic phase. The densitogram of the scattering intensity (right half of figure) shows six pronounced peaks that can be Fourier decomposed with a marked sixth-order Fourier coefficient, another sign that that the scattering is due to long-range bond orientational order. (From Podgornik, R., Strey, H.H., Gawrisch, K., Rau, D.C., Rupprecht, A., and Parsegian, V.A., *Proc. Natl. Acad. Sci. USA*, 1996, 93, 4261.)

roscopic dimensions (on the order of mm) while their positions tend to become disordered already after several (typically 5 to 10) lattice spacings. This mesophase has a characteristic x-ray scattering fingerprint (see Figure 21.18). If the x-ray beam is directed parallel to the long axis of the molecules, it shows a hexagonally symmetric diffraction pattern of broad liquid-like peaks [78].

Typical lattice spacings in the line hexatic phase are between 25 and 35 Å (i.e., between 600 and 300 mg/mL of DNA) [74]. The free energy in this mesophase is mostly a consequence of the large hydration forces stemming from removal of water from the phosphates of the DNA backbone. Typically independent of the ionic strength of the bathing solution, these hydration forces [65] depend exponentially on the interhelical separation and decay with a decay length of about 3 Å [11] at these large densities. This value of the hydration decay length seems to indicate that it is determined solely by the bulk properties of the solvent, i.e., water.

It is interesting to note that the behavior of short-fragment DNA in this range of concentrations is different from the long DNA [76]. The short-fragment DNA, typically the nucleosomal DNA fragment of 146 bp, forms a two-dimensional hexagonal phase at interaxial spacing of ~ 30 Å, which progressively orders into a three-dimensional hexagonal phase on decrease of the interaxial spacing to ~ 23 Å [76].

At still larger concentrations, the short-fragment DNA forms a three-dimensional orthorhombic crystal, with a deformed hexagonal unit cell perpendicular to the c -axis. Concurrently to this symmetry transformation, the helical pitch of the condensed phase decreases continuously from 34.6 to 30.2 Å [76]. The reasons for this fundamental difference between the behaviors of long as opposed to short-fragment DNA are still not well understood.

When the osmotic pressure is lowered to about 10 atm (corresponding to interaxial spacing of about 35 Å or DNA density of about 300 mg/mL), the characteristic hexagonal x-ray diffraction fingerprint of the line hexatic mesophase disappears continuously. This disappearance suggests the presence of a continuous, second-order transition into a low-density cholesteric [74]. It is characterized by short-range (or effectively no) base stacking order, short-range positional order, short-range bond orientational order, but long-range

cholesteric order, manifested in a continuing rotation of the long axis of the molecules in a preferred direction. In this sense, the cholesteric DNA mesophase would retain the symmetry of a one-dimensional crystal. X-ray diffraction pattern of the DNA in the cholesteric phase is isotropic and has the form of a ring. Crossed polarizers, however, reveal the existence of long-range cholesteric order just as in the case of short chiral molecules. The texture of small drops of DNA cholesteric phase (spherulites) under crossed polarizers (see Figure 21.19) reveals the intricacies of orientational packing of DNA where its local orientation is set by a compromise between interaction forces and macroscopic geometry of a spherulite. It is thus only at these low densities that the chiral character of the DNA finally makes an impact on the symmetry of the mesophase. It is not yet fully understood why the chiral order is effectively screened from the high-density DNA mesophases.

At still smaller DNA densities, the predominance of the chiral interactions in the behavior of the system remains. Recent work on the behavior of low-density DNA mesophases indicates [79] that the cholesteric part of the phase diagram might end with a sequence of blue phases that would emerge as a consequence of the loosened packing constraints coupled to the chiral character of the DNA molecule. At DNA density of about 10 mg/mL, the cholesteric phase line would end with DNA reentering the isotropic liquid solution where it remains at all subsequent densities except perhaps at very small ionic strengths [80].

FIGURE 21.19 Texture of small drops of DNA cholesteric phase (spherulites) in a PEG solution under crossed polarizers. These patterns reveal the intricacies of DNA orientational packing when its local orientation is set by a compromise between interaction forces and the macroscopic geometry of a spherulite. The change from a bright to a dark stripe indicates that the orientation of the DNA molecule has changed by 90°.

21.3.7 DNA EQUATION OF STATE

The free energy of the DNA cholesteric mesophase appears to be dominated by the large elastic shape fluctuations of its constituent DNA molecules [81] that leave their imprint in the very broad x-ray diffraction peak [66]. Instead of showing the expected exponential decay characteristic of screened electrostatic interactions [82], where the decay length is equal to the Debye length, it shows a fluctuation-enhanced repulsion similar to the Helfrich force existing in the flexible smectic multilamellar arrays [41]. Fluctuations not only boost the magnitude of the existing screened electrostatic repulsion but also extend its range through a modified decay length equal to four times the Debye length. The factor-of-four enhancement in the range of the repulsive force is a consequence of the coupling between the bare electrostatic repulsions of exponential type and the thermally driven elastic shape fluctuations described through elastic curvature energy that is proportional to the square of the second derivative of the local helix position [42]. In the last instance, it is a consequence of the fact that DNAs in the array interact via an extended, soft-screened electrostatic potential and not through hard bumps as assumed in the simple derivation in Section 21.2.7.

The similarity of the free energy behavior of the smectic arrays with repulsive interactions of Helfrich type and the DNA arrays in the cholesteric phase, which can as well be understood in the framework of the Helfrich-type enhanced repulsion, satisfies a consistency test for our understanding of flexible supermolecular arrays.

21.4 LIPID MESOPHASES

21.4.1 AGGREGATION OF LIPIDS IN AQUEOUS SOLUTIONS

Single-molecule solutions of biological lipids exist only over a negligible range of concentrations; virtually all interesting lipid properties are those of aggregate mesophases such as bilayers and micelles. Lipid molecules cluster into ordered structures to maximize hydrophilic and minimize hydrophobic interactions [83,84]. These interactions include negative free energy contribution from the solvation of polar heads and van der Waals interactions of hydrocarbon chains, competing with positive contributions such as steric, hydration, and electrostatic repulsions between polar heads. The “hydrophobic effect,” which causes segregation of polar and nonpolar groups, is said to be driven by the increase of the entropy of the surrounding medium.

Intrinsic to the identity of surfactant lipids is the tension between water-soluble polar groups and lipid-soluble hydrocarbon chains. There is no surprise then that the amount of water available to an amphiphile is a parameter pertinent to its modes of packing and to its ability to incorporate foreign bodies.

These interactions therefore force lipid molecules to self-assemble into different ordered microscopic structures, such as bilayers, micelles (spherical, ellipsoidal, rodlike, or disk-like), which can, especially at higher concentrations, pack into macroscopically ordered phases such as lamellar, hexagonal, inverted hexagonal, and cubic. The morphology of these macroscopic phases changes with the balance between attractive van der Waals and ion correlation forces versus electrostatic, steric, hydration, and undulation repulsion [85].

21.4.2 LIPID BILAYER

The workhorse of all lipid aggregates is the bilayer (see Figure 21.20) [84]. This sandwich of two monolayers, with nonpolar hydrocarbon chains tucked in toward each other and polar groups facing water solution, is only about 20 to 30 Å thick. Yet it has the physical resilience and the electrical resistance to form the “plasma” membrane that divides “in” from “out” in all biological cells. Its mechanical properties have been measured in terms of bending and stretching moduli. These strengths together with measured interactions between bilayers in multilamellar stacks have taught us to think quantitatively about the ways in which bilayers are formed and maintain their remarkable stability.

With some lipids, such as double-chain phospholipids, when there is the need to encompass voluminous hydrocarbon components compared with the size of polar groups, the small surface-to-volume ratio of spheres, ellipsoids, or even cylinders cannot suffice even at extreme dilution. Bilayers in this case are the aggregate form of choice. These may occur as single “unilamellar” vesicles, as onion-like multilayer vesicles, or multilamellar phases of indefinite extent. *In vivo*, bilayer-forming phospholipids create the flexible but tightly sealed plasma-membrane matrix that defines the inside from the outside of a cell. *In vitro*, multilayers are often chosen as a

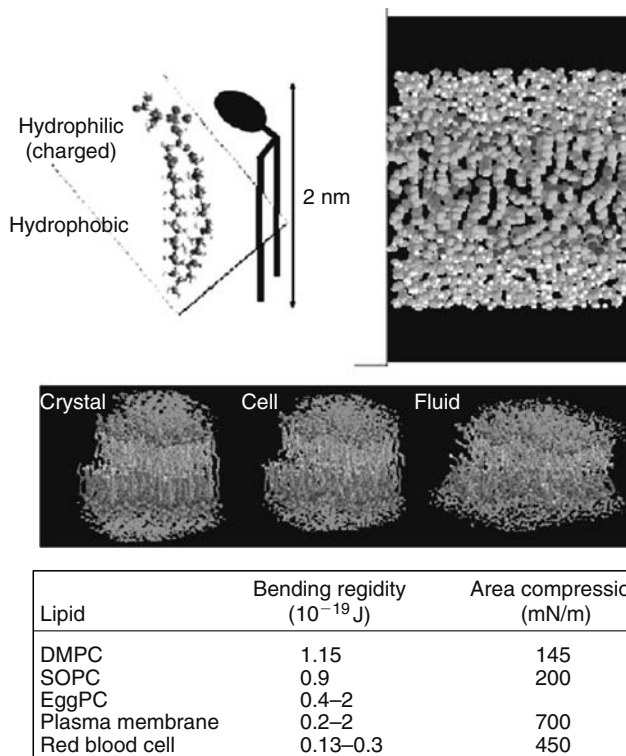

FIGURE 21.20 (See color insert following blank page 206.) The lipid bilayer. A lipid molecule has a hydrophilic and a hydrophobic part (here shown is the phosphatidylserine molecule that has a charged headgroup). At high enough densities, lipid molecules assemble into a lipid bilayer. Together with membrane proteins as its most important component, the lipid bilayer is the underlying structural component of biological membranes. The degree of order of the lipids in a bilayer depends drastically on temperature and goes through a sequence of phases (see main text): Crystalline, gel, and fluid, as depicted in the middle drawing. The box at the bottom gives sample values of bilayer bending rigidity and area compressibility for some biologically relevant lipids and one well-studied cell membrane. (Graphics courtesy of B.B Brooks, and M. Hodoseck, NIH).

matrix of choice for the incorporation of polymers. Specifically, there are tight associations between positively charged lipids that merge with negatively charged DNA in a variety of forms (see Section 21.5.1).

The organization of lipid molecules in the bilayer itself can vary [84]. At low enough temperatures or dry enough conditions, the lipid tails are frozen in an all-*trans* conformation that minimizes the energy of molecular bonds in the alkyl tails of the lipids. Also the positions of the lipid heads along the surface of the bilayer are frozen in 2D positional order, making the overall conformation of the lipids in the bilayer crystal (L_C). The chains can either be oriented perpendicular to the bilayer surface (L_β and L_β') or be tilted (crystalline phase L_C or ripple phase P_β). Such a crystalline bilayer cannot exist by itself but assembles with others to make a real 3D crystal.

Upon heating, various rearrangements in the 2D crystalline bilayers occur, first the positional order of the headgroups melts leading to a loss of 2D order (L_β) and tilt (L_β') and then

at the gel–liquid crystal phase transition, the untilted or rippled (P_β phase) bilayer changes into a bilayer membrane with disordered polar heads in two dimensions and conformationally frozen hydrocarbon chains, allowing them to spin around the long axes of the molecules, the so-called L_α phase. At still higher temperatures, the thermal disorder finally destroys also the ordered configuration of the alkyl chains, leading to a fluidlike bilayer phase. The fluid bilayer phase creates the fundamental matrix that according to the fluid mosaic model [83] contains different ingredients of biological membranes, e.g., membrane proteins, channels, etc.

Not only bilayers in multilamellar arrays but also liposome bilayers can also undergo such phase transitions; electron microscopy has revealed fluid phase, rippled and crystalline phase in which spherical liposomes transform into polyhedra due to very high values of bending elasticity of crystallized bilayers [86].

The fluid phase of the lipid bilayer is highly flexible. This flexibility makes it prone to pronounced thermal fluctuations resulting in large excursions away from a planar shape. This flexibility of the bilayer is essential for understanding the range of equilibrium shapes that can arise in closed bilayer (vesicles) systems [87]. Also, just as in the case of flexible DNA, it eventually leads to configurational entropic interactions between bilayers that have been crammed together [41]. Bilayers and linear polyelectrolytes thus share a substantial amount of fundamentally similar physics that allows us to analyze their behavior in the same framework.

21.4.3 LIPID POLYMORPHISM

Low-temperature phases [88] are normally lamellar with frozen hydrocarbon chains tilted (crystalline phase L_C or ripple phase P_β) or untilted (L_β and L_β' , form 3D, 2D, or 1D crystalline or gel phases) with respect to the plane of the lipid bilayers. Terminology from thermotropic liquid crystals phenomenology [61] can be used efficiently in this context: these phases are smectic, and SmA describes 2D fluid with no tilt while a variety of SmC phases with various indices encompass tilted phases with various degrees of 2D order. Upon melting, liquid crystalline phases with 1D (lamellar L_α), 2D (hexagonal II), or 3D (cubic) positional order can form.

The most frequently formed phases are micellar, lamellar, and hexagonal (Figure 21.17). Normal hexagonal phase consists of long cylindrical micelles ordered in a hexagonal array, while in the inverse hexagonal II (H_{II}) phase, water channels of inverse micelles are packed hexagonally with lipid tails filling the interstices. In excess water, such arrays are coated by a lipid monolayer. The morphology of these phases can be maintained upon their (mechanical) dispersal into colloidal dispersions. Despite the requirement that energy has to be used to generate dispersed mesophases, relatively stable colloidal dispersions of particles with lamellar, hexagonal, or cubic symmetry can be formed.

Many phospholipids found in lamellar cell membranes after extraction, purification, and resuspension prefer an inverted hexagonal geometry (Figure 21.21) [88]. Under

FIGURE 21.21 Different lipids are strained to different degrees when forced into lamellar packing. Relaxation of this strain contributes to the conditions for lamellar-to-inverted hexagonal phase transitions that depend on temperature, hydration, and salt concentration (for charged lipids).

excess-water conditions, different lipids assume different most-favored spontaneous radii for the water cylinder of this inverted phase [89]. An immediate implication is that different lipids are strained to different degrees when forced into lamellar packing. There are lamellar-inverted hexagonal phase transitions that occur with varied temperature, hydration, and salt concentration (for charged lipids) that form in order to alleviate this strain (see Figure 21.21).

In the presence of an immiscible organic phase, emulsion droplets can assemble [90]. In regions of phase diagram, which are rich in water, oil-in-water emulsions and microemulsions ($c > 0$) can be formed, while in oil-rich regions, these spherical particles have negative curvature and are therefore water-in-oil emulsions. The intermediate phase between the two is a bicontinuous emulsion that has zero average curvature and an anomalously low value of the surface tension (usually brought about the use of different cosurfactants) between the two immiscible components. Only microemulsions can form spontaneously (analogously to micelle formation) while for the formation of a homogeneous emulsion, some energy has to be dissipated into the system.

The detailed structure of these phases as well as the size and shape of colloidal particles are probably dominated by

- Average molecular geometry of lipid molecules
- Their aqueous solubility and effective charge
- Weaker interactions such as intra- and intermolecular hydrogen bonds
- Stereoisomerism as well as interactions within the medium

All depend on the temperature, lipid concentration, and electrostatic and van der Waals interactions with the solvent and solutes. With charged lipids, counterions, especially anions,

may also be important. Ionotropic transitions have been observed with negatively charged phospholipids in the presence of metal ions leading to aggregation and fusion [91]. In cationic amphiphiles, it was shown that simple exchange of counterions can induce micelle-vesicle transition. Lipid polymorphism is very rich and even single-component lipid systems can form a variety of other phases, including ribbon-like phases, coexisting regions and various stacks of micelles of different shapes.

21.4.4 FORCES IN MULTILAMELLAR BILAYER ARRAYS

Except for differences in dimensionality, forces between bilayers are remarkably similar to those between DNA. At very great separations between lamellae, the sheet-like structures flex and “crumple” because of (thermal) Brownian motion [41]. Just as an isolated flexible linear polymer can escape from its one linear dimension into the three dimensions of the volume in which it is bathed, so can two-dimensional flexible sheets. In the most dilute solution, biological phospholipids typically form huge floppy closed vesicles; these vesicles enjoy flexibility while satisfying the need to keep all greasy nonpolar chains comfortably covered by polar groups rather than exposed at open edges. For this reason, in very dilute solution, the interactions between phospholipid bilayers are usually space wars of collision and volume occupation. This steric competition is always seen for neutral lipids; it is not always true for charged lipids [85].

Especially in the absence of any added salt, planar surfaces emit far-ranging electrostatic fields [27] that couple to thermally excited elastic excursions to create very long-range repulsion [44,92]. As with DNA, this repulsion is a mixture of direct electrostatic forces and soft collisions mediated by electrostatic forces rather than by actual bilayer contact. In some cases, electrostatic repulsion is strong enough to snuff out bilayer bending when bilayers form ordered arrays with periodicities as high as hundreds of angstroms [93].

Almost always bilayers align into well-formed stacks when their concentration approaches ~50 to 60 wt.% and their separation is brought down to a few tens of angstroms. In this region, charged layers are quite orderly with little lamellar undulation. In fact, bilayers of many neutral phospholipids often spontaneously fall out of dilute suspension to form arrays with bilayer separations between 20 and 30 Å. These spontaneous spacings are thought to reflect a balance between van der Waals attraction and undulation-enhanced hydration repulsion [85]. One way to test for the presence of van der Waals forces has been to add solutes such as ethylene glycol, glucose, or sucrose to the bathing solutions. It is possible then to correlate the changes in spacing with changes in van der Waals forces due to the changes in dielectric susceptibility as described above [94]. More convincing, there have been direct measurements of the work to pull apart bilayers that sit at spontaneously assumed spacings. This work of separation is of the magnitude expected for van der Waals attraction [95].

Similar to DNA, multilayers of charged or neutral lipids, subjected to strong osmotic stress, reveal exponential variation

in osmotic pressure versus bilayer separation [85]. Typically at separations between dry “contact” and 20 Å, exponential decay lengths are 2–3 Å in distilled water or in salt solution, whether phospholipids are charged or neutral. Lipid bilayer repulsion in this range is thought to be due to the work of polar group dehydration sometimes enhanced by lamellar collisions from thermal agitation [96]. Normalized per area of interacting surface, the strength of hydration force acting in lamellar lipid arrays and DNA arrays is directly comparable.

Given excess water, neutral lipids usually find the above-mentioned separation of 20 to 30 Å at which this hydration repulsion is balanced by van der Waals attraction. Charged lipids, unless placed in solutions of high salt concentration, swell to take up indefinitely high amounts of water. Stiff charged bilayers repel with exponentially varying electrostatic double layer interactions, but most charged bilayers undulate at separations where direct electrostatic repulsion has weakened. In that case, similar to what has been described for DNA, electrostatic repulsion is enhanced by thermal undulations [97].

21.4.5 EQUATION OF STATE OF LIPID MESOPHASES

Lipid polymorphism shows much less universality than DNA. This is of course expected since lipid molecules come in many different varieties [84] with strong idiosyncrasies in terms of the detailed nature of their phase diagrams. One thus cannot achieve the same degree of generality and universality in the description of lipid phase diagram and consequent equations of state as was the case for DNA.

Nevertheless, recent extremely careful and detailed work on PCs by Nagle and his group [98] points strongly to the conclusion that at least in the lamellar part of the phase diagram of neutral lipids, the main features of the DNA and lipid membrane assembly physics indeed is the same [96]. This statement, however, demands qualification. The physics is the same provided one first disregards the dimensionality of the aggregates—one dimensional in the case of DNA and two dimensional in the case of lipid membranes—and takes into account the fact that while van der Waals forces in DNA arrays are negligible, they are essential in lipid membrane force equilibria. One of the reasons for this state of affairs is the large difference, unlike in the case of DNA, between the static dielectric constant of hydrophobic bilayer interior, composed of alkyl lipid tails, and the aqueous solution bathing the aggregate.

We have already pointed out that in the case of DNA arrays, quantitative agreement between theory, based on hydration and electrostatic forces augmented by thermal undulation forces, and experiment has been obtained and extensively tested [7,42]. The work on neutral lipids [96] claims that the same level of quantitative accuracy can also be achieved in lipid membrane assemblies if one takes into account hydration and van der Waals forces again augmented by thermal undulations. Of course, the nature of the fluctuations in the two systems is different and is set by the

dimensionality of the fluctuating aggregates: one-versus two-dimensional.

The case of lipids adds an additional twist to the quantitative link between theory and experiments. DNA in the line hexatic as well as cholesteric phases (where reliable data for the equation of state exist) is essentially fluid as far as positional order is concerned and thus has unbounded positional fluctuations. Lipid membranes in the smectic multilamellar phase on the other hand are quite different in this respect. They are not really fluid as far as positional order is concerned but show something called quasilong range (QLR) order, meaning that they are in certain respects somewhere between a crystal and a fluid [61,78]. The QLR positional order makes itself recognizable through the shape of the x-ray diffraction peaks in the form of persistent (Caille) tails [78].

In a crystal, one would ideally expect infinitely sharp peaks with Gaussian broadening only because of finite accuracy of the experimental setup. Lipid multilamellar phases, however, show peaks with very broad, non-Gaussian, and extended tails that are one of the consequences of QLR positional order. The thickness of these peaks for different orders of x-ray reflections varies in a characteristic way with the order of the reflection [78]. It is this property that allows us to measure not only the average spacing between the molecules but also the amount of fluctuation around this average spacing. Luckily the theory predicts this property also and without any free parameters (all of them being already determined from the equation of state), the comparison between predicted and measured magnitude in positional fluctuations of membranes in a multilamellar assembly is more than satisfactory [96].

In summing up, the level of understanding of the equation of state reached for DNA and neutral lipid membrane arrays is pleasing.

21.5 DNA-LIPID INTERACTIONS

Mixed in solution with cationic lipids (CLs), DNA spontaneously forms CL-DNA aggregates of submicron size. These DNA-lipid aggregates, sometimes called “lipoplexes,” [99] are routinely used for cell transfection *in vitro*. More important, they are used primarily as potential gene delivery vehicles for *in vivo* gene therapy (for recent reviews, see Refs. [100–105] and references therein). Under appropriate conditions, these aggregates reveal complex underlying thermodynamic phase behavior. There is a practical paradox here. We use stable equilibrium structures to reveal the forces that cause aggregation and assembly; we use this knowledge of forces to create the unstable preparations likely to be most efficient in transfection.

Lipoplexes for transfection were first proposed by Felgner and coworkers [106,107]. The guiding idea was to overcome the electrostatic repulsion between cell membranes (containing negatively charged lipids) and negative DNA by complexing DNA with positively charged CL. Preliminary experimental data showed that at least some lipoplexes deliver

DNA through direct fusion with the cell membrane [108,109]. More often, however, lipoplex internalization probably proceeds through endocytosis after initial interaction with the cell's membrane.

Prior to the attempts to utilize lipoplexes for transfection, studies of DNA aggregated with multivalent cations and coated with negatively charged liposomes were also explored as possible vectors. It was hoped that CL-DNA complexes would no longer require an additional complexing agent, and that also, the transfection efficiency would be higher. The complex's lipid coating could protect the tightly packed DNA cargo during its passage to the target cells. In recent years, this strategy has been slightly modified to complex DNA and anionic (or even neutral) membranes in ordered lamellar phases that should have lower cytotoxicity than the alternative CLs. An unresolved problem of this approach is the inefficient association between the ALs and DNA molecules, which is attributed to their like-charge electrostatic repulsion [110–114].

While not confronted with the immunological response, risked by the alternative viral vector strategy, the use of lipoplexes in gene therapy is still hampered by toxicity of the CL and low *in vivo* transfection efficiency despite the *in vitro* efficiency of some CL formulations. This discrepancy can be attributed to the multistage and multibarrier process the complexes must endure before transfection is achieved. These steps typically include passage in the serum, interaction with target and other cells, internalization, complex disintegration in the cytoplasm, transport of DNA into the nucleus, and ultimately expression.

In the search for increasingly more potent gene delivery vectors, the intimate relationship between the lipoplex's phase structure (or morphology) and its transfection efficiency probably serves as the greatest motivation for their study. How is transfection affected by lipoplex morphology? How may this structure be controlled? Experiment and theory of the past decade shed some light on such fundamental questions. They may give perspective for future strategies to design CL-based nonviral vectors.

To this end, we present here our current understanding of the structure and phase behavior of CL-DNA complexes. We review the relation of structure to transfection efficiency, and more specifically, to the way the complex formation overcomes one barrier to DNA release into the cytoplasm.

21.5.1 STRUCTURE OF CL-DNA COMPLEXES

In general, the structures of CL-DNA composite phases can be viewed as morphological hybrids of familiar pure-lipid and pure-DNA phases. A first example is the lamellar-like structure initially proposed by Lasic et al. [115,116]. The first comprehensive and unambiguous evidence for this structure came from a series of studies by Rädler et al. [117–121]. From high-resolution synchrotron x-ray diffraction and optical microscopy, they reported the existence of novel lamellar CL-DNA phase morphologies. In particular, one complex structure was shown to consist of lamellar multilayer. In this case,

FIGURE 21.22 Schematic illustration of some possible structures of DNA–mixed lipid (cationic/nonionic) complexes. (A) The sandwich-like (L_{α}^c) lamellar complex composed of parallel DNA molecules intercalated between lipid bilayers. (B) The honeycomb-like (H_{II}^c) hexagonal complex, composed of a hexagonally packed bundle of monolayer-coated DNA strands. (C) Two interpenetrating hexagonal lattices, one of DNA, the other of micelles. (D) Spaghetti-like complex, composed of bilayer-coated DNA. (From May, S., Harries, D., and Ben-Shaul, A., *Biophys. J.*, 79, 1747, 2000. With permission.)

smectic-like stacks of mixed bilayers, each composed of a mixture of CL (e.g., dioleoyltrimethylammonium propane (DOTAP)) and neutral “helper” lipid (e.g., dioleoylphosphatidylcholine (DOPC)), with monolayers of DNA strands intercalated within the intervening water gaps (see Figure 21.22A) like a multilipid bilayer L_{α} phase [122]. Helper lipids (HLs) are often added for their fusogenic properties. Dioleoylphosphatidylethanol amine (DOPE), for example, is conjectured to promote transfection. In addition, because pure (synthetically derived) CLs often tend to form micelles in solution, HLs facilitate the formation of membranes.

In this L_{α}^c complex geometry, the DNA strands within each gallery are parallel to each other, exhibiting a well-defined repeat distance d . While d depends on the CL/DNA and CL/HL concentration ratios, the spacing between two apposed lipid monolayers is nearly constant at $\sim 26 \text{ \AA}$ corresponding to the diameter of double stranded B-DNA, ca. 20 \AA , surrounded by a thin hydration shell. This L_{α}^c lamellar (sandwich) complex is stabilized by the electrostatic attraction between the negatively charged DNA and the CL bilayer. Because of strong electrostatic repulsion between the charged bilayers (particularly at low salt conditions), the lamellar lipid phase is unstable without DNA.

Quite different equilibrium ordered phase morphologies were found to occur from other choices of neutral HL. In the case of DOPE, or lecithin, for example, inverted hexagonal (“honeycomb” or H_{II}^c) organization of the lipid, with stretches of double-stranded DNA laying in the aqueous solution regions, were found to form (see Figure 21.22B) [106,118,123]. The H_{II}^c structure may be regarded as the inverse-hexagonal (H_{II}) lipid phase, with DNA strands wrapped within its water tubes. Here too, the diameter of the water tubes is only slightly larger than the diameter of the DNA “rods.” The presence of DNA is crucial for stabilizing the hexagonal structure. Without it, strong electrostatic repulsion will generally drive the lipids to organize themselves into planar bilayers. In fact, the most abundant aggregate structure of pure CL and HL mixtures,

from which hexagonal complexes are subsequently formed, is single-bilayer liposomes.

Other CL–DNA phases have also been observed. One of the earliest studies probing the structure of lipoplexes showed some evidence for a hexagonal arrangement of rodlike micelles intercalated between hexagonally packed DNA (Figure 21.22C) [124,125]. More recently, such structures have been unambiguously characterized in complexes composed of lipids that possess large, typically polyvalently charged headgroups [126]. There is also evidence that some lipid mixtures promote the formation of cubic phases that are also able to transfect [127].

The number of possibilities is even larger if one also considers metastable intermediates. The “spaghetti” structure (see Figure 21.22D), observed using freeze-fracture electron microscopy, has been predicted by theory to probably be one such metastable morphology [128,129]. In this structure, each (possibly supercoiled) DNA strand is coated by a cylindrical bilayer of the CL/HL lipid mixture [130,131]. Early proposed models of the CL–DNA complexes suggested a “beads on a string” type complex, in which the DNA is wrapped around or in between lipid vesicles (and even spherical micelles). While this may not turn out to be an equilibrium structure, such aggregates are sometimes found and may also serve as unstable intermediates [132–134]. Other structures, such as the bilamellar invaginated liposomes (BIV) made of DOTAP-Chol, have been proposed and demonstrated to be efficient vectors [108,135]. These structures resemble to some degree the L_{α}^c phase. However, formed from extruded liposomes, the BIVs are most probably metastable.

What factors determine which of these phases (or possibly several coexisting structures) actually form in solution? To what degree can we control and predict them? Control can first be achieved through the choice of type of CL and HL, and the ratio between the two used in forming liposomes. This in turn will determine such basic properties as the lipid bilayer’s bending rigidity, spontaneous curvature, and surface

charge density of the water–lipid aggregate interface. An additional experimentally controllable parameter is the ratio between the lipid and DNA content in solution. We show that both these parameters have significant effects on the phases that are formed.

21.5.2 COUNTERION RELEASE

From the start, it was realized that the expected condensation of DNA with oppositely charged lipids could be used to package and send DNA to transfect targeted cells. The expectation that the DNA and lipids would aggregate was intuitively based on the notion that oppositely charged bodies attract. Early experiments confirmed the aggregation of DNA and lipids. However, the mechanism by which CL and DNA were found to associate—previously termed in the context of macromolecular association “counterion release” [136]—is more intricate than the “opposites attract” mechanism that may be naively expected.

Prior to association, DNA and lipids are bathed in the aqueous solutions containing their respective counterions, so that the solutions are overall electrostatically neutral. The counterions are attracted to the oppositely charged macromolecules, thus gaining electrostatic energy. Here, in addition to DNA, we shall also refer to the preformed CL liposomes as a “macromolecules” since they typically retain their integrity in solution, even upon association with other charged macromolecules. The counterions are therefore confined to the vicinity of the oppositely charged macromolecules at the compromise of greater translational entropy in solution.

Upon association, the two oppositely charged macromolecules condense to form CL–DNA complexes (see Figure 21.23). Many (possibly all) previously confined counterions

can now be expelled into the bulk solution from the lipoplex interior, thus gaining translational entropy. While the translational entropy of the paired macromolecules is reduced by (typically) only a few $k_B T$ s, due to loss of conformational and translational entropy, many released counterions can now favorably contribute to a gain in entropy, each by a comparable amount. For this reason, it is sometimes stated that the DNA–lipid condensation is “entropically driven.” The electrostatic energy can also contribute somewhat to stabilizing the lipoplexes. However, it has been well argued, both experimentally and theoretically, that the cardinal contribution to the association free energy of CL–DNA complexes is the entropy gain associated with counterion release [137–139].

Further support was given by counting released ions using conductivity measurements of the supernatant. It was possible to determine that a maximal number of counterions were released when the number of “fixed” charges on the DNA and lipid was exactly equal.

Calorimetric measurements confirm this finding and furthermore reveal that the association could in fact be endothermic so that it is only favorable for entropic reasons [140,141]. The special point at which the number of positive and negative fixed charges is equal has been termed the “isoelectric point.” At this point, the (charging) free energy of the complex is minimal: the fixed charges of opposite signs fully compensate each other, thus allowing essentially *all* the counterions to be released into solution. Note, that by “counterions,” we do not refer here to added salt ions. Ions of added salt will span the entire solution including the lipoplex interior. Thus, the salt content changes the thermodynamic phase behavior and the value of the adsorption free energy, mainly because a high ambient salt concentration lowers the entropic gain associated with releasing a counterion.

Theoretical predictions and estimates from calorimetry show that for a salt solution of concentration $n^0 = 4$ mM, and a 1:1 CL/HL mole ratio, the gain in free energy upon adsorption at the isoelectric point is a bemusingly large $\sim 7.5 k_B T$ per fixed charge pair (DNA and CL) [138–141]. This value translates to over $2000 k_B T$ when considering the energy per persistence length of DNA (about 50 nm), carrying approximately 300 charges.

21.5.3 LAMELLAR DNA–LIPID COMPLEXES AND OVERCHARGING

Many degrees of freedom with competing contributions are expected to ultimately determine the free energy minimum for equilibrium DNA/membrane structures. Typically these include (but are not limited to) electrostatic energy, elastic bending, solvation, van der Waals, ion mixing, and lipid mixing. Therefore, considering the lipoplex phase behavior, we begin, for simplicity, by discussing systems where only L_α^c complexes are found. This can be expected when the lipid membranes are rather rigid, such as in the case of mixtures of DOTAP/DOPC [100,118] or DMPC (dimyristoyl phosphatidylcholine)/DC-Chol [142]. The main structural parameter for the L_α^c phase is the DNA–DNA distance, reflecting the DNA packing density within the complex. A series of x-ray measurements by Rädler et al. revealed

FIGURE 21.23 Schematic illustration of the condensation of DNA and lipid bilayers (liposomes) into CL–DNA complexes. In the process, the previously confined counterions are released into the bathing solution, thereby gaining translational entropy.

how the DNA–DNA spacings d vary with the ratio ρ of the number of lipid charges to the total number of charges on DNA. The measurements were repeated for each of several different lipid compositions defined by the ratio of charged to overall number of lipids, ϕ . It was found that for a lipid mixture of a given composition ϕ , the spacings are constant throughout the low ρ range where the complex coexists with excess DNA. In the high ρ range, where the complex coexists with excess lipid, the spacings are also nearly constant. In between these limits, there exists a “single-phase” region, where all the DNA and lipids participate in forming lipoplexes. This region is generally found to include the isoelectric point where, by definition, $\rho = 1$ (see Figure 21.24).

Several theoretical studies have been proposed to account for this phase behavior [137,143,144]. It was found that it is possible to account for most of the experimental observations within the scope of the nonlinear PB equation [144]. In this theoretical model, elastic deformations of the DNA and lipid bilayers were neglected, treating them as rigid macromolecules. On the other hand, the lipid’s lateral (in plane) mobility in the membrane layer was explicitly taken into account. This turns out to be an important degree of freedom in mixed fluid bilayers, enabling the system to greatly enhance the free energy gain upon complexation, with respect to the case where no lipid mobility is allowed. This adds to the stability of the L_{α}^c complex. Generally, it was found that lipid mobility favors optimal (local) charge matching of the apposed DNA and lipid membrane. This is the state in which a maximal number of mobile counterions are expelled from the interaction zone, implying a maximal gain in free energy upon complex formation [145]. However, the tendency for charge matching (hence migration of lipid to and from the region of proximity) is opposed by an unfavorable local lipid demixing entropy loss. This entropic penalty will somewhat suppress the membrane’s tendency to polarize in the vicinity of the DNA molecule. The extent to which the membrane will polarize is determined by the intricate balance between the

FIGURE 21.24 Schematic illustration of the phase evolution of the L_{α}^c complexes, for a constant lipid composition (cationic to non-ionic lipid ratio). As lipid is added (ρ increases), the system evolves from a two-phase (complex and excess DNA) region through a one-phase (complex only) region, and finally to a two-phase (complex and excess lipid) region. The isoelectric point is generally contained within the one-phase region.

electrostatic and lipid mixing entropy contributions to the free energy of the complex. The contribution of lipid demixing to the stabilization of the complex is most pronounced when the membrane’s average composition is far from that of the DNA, namely for low ϕ . Here, the system can gain most out of the polarization so as to come close to local charge matching.

The tendency of charged lipids to segregate in the vicinity of adsorbed rigid macromolecules has gained some experimental support from nuclear magnetic resonance (NMR) studies [146] although many systems may display a more complex behavior. Molecular dynamic simulations of L_{α}^c complexes, for a lipid mixture of DMTAP and DMPC, showed evidence for a favorable pairing of DMPC and DMTAP lipid molecules through the (partial) negative charge on DOPC and an interaction of the (remaining) positive charge of the zwitterionic DOPC with the DNA. In contrast to the model discussed above, this implies a nonideal lipid demixing: these lipid molecules preferentially move in pairs [147]. This may be anticipated since it is well known that lipids do not generally mix ideally even in free (unassociated) membranes [148]. Furthermore, there is evidence that to some extent neutral lipids also interact directly with DNA [149].

Figure 21.25 shows the experimental results and theoretical calculations for the dependence of d on ρ for several values of ϕ . For a specific value of ϕ (say $\phi = 0.5$), the three-phase

FIGURE 21.25 DNA–DNA spacing as a function of ρ in a series of theoretical and experimental results. The theoretical results correspond to (top to bottom) $\phi = 0.3, 0.4, 0.5, 0.6, 0.8$; all results are presented for a screening length of 50 Å (corresponding to ca. 4 nm of bathing salt solution). The experimental results correspond to $\phi = 0.3$ (squares), 0.5 (circles), 0.7 (triangles), and were performed with no added salt. (Theoretical results adapted from Harries, D., May, S., Gelbart, W.M., and Ben-Shaul, A., *Biophys. J.*, 1998, 75, 159 and Harries, D., PhD dissertation, The Hebrew University, Jerusalem, Israel, 2001; experimental results adapted from Rädler, J.O., Koltover, I., Salditt, T. et al., *Science*, 275, 810, 1997.)

regimes can clearly be seen. As ρ increases, d changes from $\approx 35 \text{ \AA}$ (in the excess DNA regime, $\rho \ll 1$) to $\approx 47 \text{ \AA}$ (in the excess lipid regime, $\rho \gg 1$). Both theory and experiment show that for a wide range of lipid composition, ϕ , there exists a one-phase, complex-only region at ρ values somewhat larger and smaller than the isoelectric point. This implies that complexes may become either negatively or positively “overcharged” so that the total number of fixed positive and negative charges is not equal. Hence, the complex accommodates either an excess number of lipids or else an excess amount of DNA. The complex’s free energy is thus not at its minimum, which occurs at isoelectricity ($\rho = 1$). The interplay between possible phases to minimize the total system’s free energy dictates that the complex moves away from its minimal free energy. The alternative would be to expel the excess lipid ($\rho > 1$) or excess DNA ($\rho < 1$) into solution. The charge densities on these “free” unneutralized macromolecules would be very large, rendering this scenario highly unfavorable. Using a simple model based on this overcharging phenomenon, it was possible to account for the considerable extent of this one-phase region [144]. Within this model, only the uncompensated charges on apposed (DNA–DNA or bilayer–bilayer) surfaces of a L_{α}^c unit cell (“box”) were considered in estimating the complex’s free energy. Figure 21.25 also shows that as the membrane becomes enriched in CL (ϕ increases) the DNA–DNA distance is systematically reduced, reflecting the fact that smaller amounts of lipid membrane are needed to achieve isoelectricity.

Salt has a significant effect on the phase behavior. In general, added salt causes a significant decrease in d , presumably due to a screening of the repulsive DNA–DNA interaction. This effect is most pronounced when divalent salts are added in increasing amounts. A sharp decrease in the d value is observed for a certain salt molar concentration, resulting in very highly condensed DNA in each gallery [89,130]. Another interesting observation is that the identity of the CL’s counterion used changes the (endothermic) association enthalpy considerably, particularly in the excess DNA region [140]. This probably reflects the nonelectrostatic interaction energies of different ions with membranes, which may influence the thermotropic behavior of the lipid membranes [150,151].

21.5.4 DNA ADSORPTION ON LIPID MEMBRANES

Further insight into the in-plane DNA ordering in L_{α}^c complexes has been gained through the atomic force microscopy (AFM) study by Fang and Yang [152,153] of DNA adsorption on supported lipid bilayers. In these experiments, DNA was first adsorbed on dipalmitoyldimethylammoniumylpropane (DPDAP) or distearoyl-DAP (DSDAP) CL bilayers, assumed to be in the gel phase. After equilibration and saturation of the surface, the DNA bulk solution was removed, and the surface was put in contact with solution of various concentrations of NaCl. After further equilibration, the salt solution was removed and the surface imaged by AFM. Plasmid and linear DNA similarly treated showed similar results.

FIGURE 21.26 AFM images of DNA from different sources (see figure for details) condensed on DPDAP bilayers at room temperature in 20 mM NaCl. Striking fingerprint-like order is apparent, with a domain size of the order of the persistence length (ca. 50 nm). (Courtesy of J. Yang, University Vermont.)

Striking, fingerprint-like images of DNA adsorbed on the surface were revealed (Figure 21.26). The typical domain size for the aligned, smectic-like order is usually several hundred angstroms, reflecting the DNA’s intrinsic persistence length. These structures are expected to be like those found in L_{α}^c complexes: the domain size, inferred from x-ray scattering is quite similar [119,120]. Furthermore, it was found that the surfaces are often overcharged when DNA is adsorbed, i.e., the number of DNA fixed charges exceeds the number of lipid charges. This can be anticipated on the basis of theoretical studies of a similar problem: adsorption of charged globular proteins (yet another macroion) on oppositely charged membranes [154]. In both cases the driving force for adsorption is similar to that driving lipoplex formation, namely counterion release. In L_{α}^c complex formation, much of the DNA can interact with the two sandwiching bilayers. In contrast, topology dictates that adsorbates on a single lipid bilayer will always possess a part proximal and a part distal to the interaction zone. If both parts are charged, as is the case with DNA, complete counterion release cannot be achieved since the distal part does not interact significantly with the underlying bilayer. Therefore, although charges on the lipid membrane are fully

cancelled by charges on adsorbed DNA macroions, still the portion of DNA away from the contact zone imparts a net surface charge, i.e., overcharging of the DNA-covered membrane.

Yet another interesting feature is the dependence of the DNA–DNA distance on salt concentration. As the NaCl concentration was varied between 20 and 1000 mM, this distance grew from around 45 Å to almost 60 Å. At first this may seem baffling: adding salt should be expected to decrease the DNA–DNA electrostatic repulsion, and hence lower the distance between neighboring interacting strands. This is indeed the general trend that has been observed in L_{α}^c complexes [117,144]. However, because the DNA was primarily allowed to saturate the surface, and only subsequently treated with the salt solution (which was later also washed away), adsorption here was not at equilibrium. In fact, when faced with a neat salt solution, the adsorbed DNA can only detach and will not generally re-adsorb onto the surface. It is therefore hard to give full theoretical reasoning for the trend.

Theoretical explanations have previously been offered to account for this salt-dependent behavior based on a balance between membrane-mediated effective attraction (that may be the result of the DNA perturbation of the lipid bilayer) and electrostatic repulsion between DNA strands [155]. The predicted DNA–DNA spacing as a function of screening length is nonmonotonic: increasing first for low screening lengths and decreasing for high values. An alternative to this approach is related to the free energy gain upon adsorption and how it changes with the addition of salt. In the presence of added salt, the adsorption free energy can be expected to be lower since the gain in entropy upon release of counterions becomes very small when releasing an ion from an adsorbed layer into a bathing solution with a comparable concentration. Assuming that unbinding would occur when the free energy gain per persistence length is $\approx k_B T$, we can estimate from a simple model that the thickness of the confined layer is $l_{\text{eff}} \approx 5 \text{ \AA}$, rather close to the screening length in solution (3–4 Å) [138–141]. Thus, the lower binding free energy may cause some of the DNA strands to dissociate from the lipid surface once the system is exposed to salt. Allowing DNA to rearrange on the surface would then lead to an increase in the average DNA–DNA distance.

When multivalent salt is used, a crowding of DNA molecules is first observed as salt is added (in accordance with the observations in the L^c complexes), and then starts to grow for higher concentrations [100,156]. This may be a manifestation of the two competing forces as salt is added: lessened repulsion between strands versus weakened adsorption energy.

21.5.5 FROM LAMELLAR TO HEXAGONAL COMPLEXES

So far, we have discussed the L_{α}^c lipoplexes formed from lipid membranes that are rigid (bending rigidity much greater than $k_B T$) and tend to a planar geometry. Other lipoplex structures may ensue when the lipids possess a spontaneous curvature which is nonplanar, or when the membranes are soft enough to be deformed under the influence of the apposed macroion.

The lipid membrane thus responds to the presence of DNA by deforming elastically and by locally changing its composition ϕ .

Membrane elasticity may be varied substantially either by changing the lipid CL/HL composition, changing the lipid species, or by adding other agents, such as alcohols, to the membrane [157,158]. In contrast, double-stranded DNA generally remains rather stiff, with a typical persistence length of $\approx 500 \text{ \AA}$. Hence, the lipoplex geometries are restricted to structures in which DNA remains linear on these large length scales. Usually, it is the interplay between the elastic (spontaneous curvature and bending rigidity) and electrostatic (charge density) properties of the membrane that will determine the optimum lipoplex geometry at equilibrium.

Often, the membrane elasticity and electrostatic contribution to the free energy display opposing tendencies. For example, the hexagonal H_{II}^c complex is electrostatically favored due to the cylindrical wrapping of the DNA by the lipid monolayer. This allows better contact between the two macromolecular charged surfaces. However, the highly curved lipid geometry may incur substantial elastic (curvature deformation) energy. The price to pay will be lower when the lipid (monolayer's) spontaneous curvature matches closely the DNA intrinsic (negative) curvature or when it has low bending rigidity. Under such conditions, the H_{II}^c complex may become more stable than the L_{α}^c phase. Usually, a neutral HL is used for adjusting the spontaneous curvature to the required negative curvature, since pure CLs typically tend to form uncurved or positively curved aggregates. Use of more HL in the mixed membranes may, on one hand, lower the elastic penalty, while, on the other hand, lower the monolayer's charge density, compromising the electrostatic energy gain upon association.

These qualitative notions were elegantly demonstrated by experiments in which the elastic properties of the lipid monolayers were controlled by changing the nature of the lipid mixture. The spontaneous curvature of the lipid bilayer was modified by changing the identity of HL. It was found that when using a mixture of DOTAP/DOPE, H_{II}^c was the preferred structure, while DOTAP/DOPC mixtures promoted the formation of the L_{α}^c phase. This is consistent with the fact that pure DOPE forms the inverted hexagonal phase, H_{II} , due to its high negative spontaneous curvature [159–161], while DOPC self-assembles into planar bilayer. In addition, by adding hexanol to the DOTAP/DOPC–DNA lipid mixture, the bending rigidity could be diminished by about one order of magnitude [157,158]. This induced a clear first-order $L_{\alpha}^c \rightarrow H_{II}^c$ phase transition [118].

Additional complexity can be expected when accounting for the coexistence of more than one phase in solution. A theoretical study of the phase equilibrium took into account the bare lipid phases L_{α} and H_{II} , the naked DNA and the complex L_{α}^c and H_{II}^c phases [162]. The phase diagram of the system was evaluated by minimization of the total free energy, which included electrostatic, elastic, and lipid demixing contributions. Several systems of different compositions were considered. Figure 21.27 shows the predicted phase coexistence corresponding to the simplest case already discussed of rigid

FIGURE 21.27 Phase diagram of a lipid–DNA mixture for lipids, which self-assemble into rigid planar membranes. The phase diagram was calculated for membranes characterized by a bending rigidity in the range of $4 < \kappa < \infty k_B T$ and a spontaneous curvature of $c = 0 \text{ \AA}^{-1}$ for both helper and CLs. The symbols S, B, and D denote, respectively, the L_α^c , L_α , and uncomplexed (naked) DNA phases. (From May, S., Harries, D., and Ben-Shaul, A., *Biophys. J.* 2000, 79, 1747. Reprinted by permission from Biophysical Society.)

FIGURE 21.28 Phase diagram of a lipid–DNA mixture involving “curvature-loving” helper lipid: the spontaneous curvature of the helper lipid is $c = -1/25 \text{ \AA}^{-1}$. For the CL the spontaneous curvature taken is $c = 0 \text{ \AA}^{-1}$. The bending rigidity for both lipids is $\kappa = 10 k_B T$. The symbols S, H, B, I, and D denote, respectively, the L_α^c , H_{II}^c , L_α , H_{II} , and uncomplexed (naked) DNA phases. The broken line marks the single H_{II}^c phase. (From May, S., Harries, D., and Ben-Shaul, A., *Biophys. J.*, 79, 1747, 2000. Reprinted by permission from Biophysical Society.)

planar membranes. Results are presented for lipid membranes with a bending rigidity of $\kappa = 10 k_B T$ per monolayer and spontaneous curvature $c = 0 \text{ \AA}^{-1}$ (typical for many bilayer forming lipids [122]) for which only lamellar complexes are expected to form. As the overall lipid composition is enriched in CL (higher ϕ) the one phase persists over a wider range of ρ . This indicates that for higher CL content, the complex may be expected to be more stable toward addition of either DNA or lipid (hence moving away from the isoelectric point).

The Gibbs phase rule allows for up to three phases to coexist concomitantly for this three-component (DNA, HL, and CL) system. Figure 21.28 shows the theoretical prediction for the phase diagram for a system in which the HL has a strong negative spontaneous curvature ($\kappa = 10 k_B T$ and $c = 1/25 \text{ \AA}^{-1}$) [162]. For high ϕ values, the phase behavior resembles that of the previously discussed system. However, for lower values of ϕ , a multitude of regions of (up to three) different phases coexisting together can be found. In some regions, lamellar and hexagonal complexes appear coexisting side by side. A similarly complex diagram results when the membranes are soft (bending rigidity of $\approx k_B T$) as might be expected for membranes with added alcohols [162].

A more subtle demonstration of the underlying balance of forces can be found within the realm of the L_α^c complex. Thus far, the theoretical models considered for the lipid membranes in this lamellar phase assumed them to be perfectly planar slabs. However, this need not be so. When membranes are sufficiently soft (yet not soft enough to favor the H_{II}^c phase) or if one of the CL/HL has a propensity to form curved surfaces, the membrane may corrugate so as to

optimize its contact with DNA (see Figure 21.22A). If the membrane is further softened, finally, a transition may occur to the H_{II}^c phase. In this respect, the membrane corrugation in the L_α^c complex may be regarded as a further stabilization of the lamellar complex, and a delay to the onset of the $L_\alpha^c \rightarrow H_{II}^c$ transition.

A possible consequence of membrane corrugation in the L_α^c phase is an induced locking between neighboring galleries. This follows the formation of “troughs” in a gallery, induced by the interaction of the membrane with DNA in adjacent galleries. This imposes “adsorption sites” for the DNA in the two neighboring galleries, which propagates the order on. The formation of these troughs, as well as a very weak electrostatic interaction between galleries, may thus correlate between the positions of DNA in different galleries [147,163,164]. Limited experimental evidence supports this notion. In cryo-transmission electron microscopy (cryo-TEM) studies of the L_α^c phase, spatial correlations were found between DNA strands in different galleries [165]. In another series of x-ray studies, the corrugation and charge density modulation in an L_α^c -like complex, in which the membranes are in the gel phase, were measured [166]. Further support for the possible formation of corrugations is gained from computer simulations of lipid–DNA complexes [147].

In order to assess the extent of membrane corrugation, a balance of forces between many degrees of freedom should be taken into account. The free energy minimum now depends on the local membrane composition—dictating membrane properties such as local charge density, spontaneous curvature, and bending elasticity—and the extent of local deformation around the DNA. Theoretical predictions show that for

a wide range of conditions, both stiff and soft membranes can show corrugations that are stable with respect to thermal undulations of the membranes [164]. The spacings between galleries and between DNA molecules are also predicted to change somewhat with respect to the case where no corrugations are allowed [163]. For the conditions in which the troughs are shallow, or absent altogether, one may anticipate the formation of phases where DNA in different galleries are positionally uncorrelated, while orientational order is preserved. These structures were predicted theoretically and termed "sliding phases" [119,120,165,167–169].

21.5.6 LIPOPLEX STRUCTURE AND TRANSFECTION EFFICIENCY

In recent years, a large number of CL–DNA formulations have been proposed as vectors. However, the fate of the CL–DNA complex once administered, its interaction with the cell membrane, and entry into the cell and subsequently into the cell nucleus, is likely complex and largely unresolved. The poorly understood [170–172] process of DNA release once in the cell interior must be important. For example, it has been shown from action in the nucleus that DNA expression is diminished when it is tightly complexed with lipids [175]. Hints to the mechanism of the intracellular release of lipoplexes come from experimental evidence *in vitro* showing that other added polyelectrolytes may compete with DNA and subsequently replace it in the complex [173]. This kind of replacement, by natural polyelectrolytes, may be one way in which DNA is released in cells [174]. Another possible mechanism is the fusion of complex lipids with lipid membranes in the cell [100,120].

Only a limited number of experiments have probed the relationship between the structure of CL–DNA complexes and the transfection efficiency. One emergent theme attributes an important role to complex frustration and destabilization in promoting transfection.

Experimental studies show that the two ordered complex structures, L_{α}^c and H_{II}^c , behave differently inside living cells. Furthermore, a correlation was found between the structure of the lipoplexes formed and the transfection efficiency. The structure formed depends in turn on the specific choice and relative amount of HL, CL, and DNA. The H_{II}^c complex was found (in the studied cases) to be a more potent vector than L_{α}^c [176,177]. Further information is gained from fluorescence studies of cell cultures with both complex types internalized in fibroblast L-cells. These indicate that the L_{α}^c complex is more stable inside the cells, while the H_{II}^c more readily disintegrates—its lipids fusing with the cell's own (endosomal or plasma) membranes—resulting in DNA release. This is in accord with the theoretical findings that the L_{α}^c complex structure is rather flexible toward changes in the system's compositional parameters due to its ability to tune both the membrane composition and the DNA–DNA spacing, while this tuning is more limited in the H_{II}^c phase.

The picture is further substantiated by a series of studies by Barenholtz and coworkers [101,171,172,178]. In general, it was shown that maximal transfection efficiency could be

achieved in complexes that were formed in the excess lipid regime (with ρ in the range of 2–5). This correlated well with the point of maximal size heterogeneity of the complexes. These instabilities were shown to occur concomitantly with an increase in the amount of membrane defects that were in turn mainly attributed to the appearance of several coexisting structures in solution (e.g., H_{II}^c and L_{α}^c in DOTAP/DOPE lipoplexes, or micellar and lamellar phases in DOSPA/DOPE-based lipoplexes). This is in accordance with the theoretical prediction that the regions of most phase diversity and the largest number of coexisting phases occurs at high ρ (and low ϕ) values (see Figure 21.28 [101,132,159]).

Other evidence seems to agree with these notions. For example, some successful formulations, such as BIV, are also probably metastable [108,115,128]. This may suggest that it is in fact their instability, which helps them in releasing their DNA cargo once they are inside the cell. Attempts have also been made to destabilize lipoplexes more specifically once they are already internalized in the cells (rather than en route in the serum). Reduction-sensitive CLs were designed, and the subsequent lipoplexes that are formed were shown to undergo large structural changes when exposed to the cytoplasmic reductive systems. The lipoplexes are thus destabilized and the previously packaged DNA is released into the cytosol [103,179–181]. A decrease in the toxicity of the CL and increased transfection efficiency are thus achieved [182].

Recent experiments have shed additional light on the relation between complex structure and transfection efficiency. These studies concentrate on lamellar L_{α}^c complexes that are the ones most often encountered. It has been shown that the membrane charge density of the CL vector, rather than, say, the large valency of the CL is an important parameter that governs transfection efficiency. Specifically, the path for complex uptake is distinctly different for high versus low lipid charge density. While at both high and low charge densities, complexes are found to enter through endocytosis, at low lipid charge density, DNA was trapped in complexes, and those in turn were trapped inside endosomes, while at high density, endosomal entrapment does not seem to be a significant limiting factor. At very high lipid charge density, the transfection efficiency is again reduced. These findings have led to a new model of the intracellular release of DNA from lamellar complexes, through activated fusion with endosomal membranes. It has been suggested that complexes escape the endosome by fusion with the endosomal membrane. This fusion is favored by (attractive) electrostatic interaction energy that is higher for highly charged membranes [183–186].

In contrast, the transfection efficiency of the H_{II}^c complexes does not seem to depend on lipid charge density, perhaps because their structure leads to a distinctly different mechanism of cell entry. It seems that these complexes undergo rapid fusion with cellular membranes. The curvature-loving properties of the hexagonal complexes favor rapid fusion and escape of DNA from the endosome, and this process no longer limits the transfection rate.

Destabilizing lipoplexes is not the only barrier to transfection. For example, entry of DNA into the nucleus through the

nuclear pore complex is inefficient for large pieces of DNA. It has been shown that the cell's own nuclear import machinery may be utilized to increase transfection efficiency dramatically by attaching a peptide containing a nuclear localization signal (NLS) to the DNA [187,188]. Furthermore, the size of the complexes also seems to play a crucial role in determining transfection efficiencies [101,102,108,115]. Here, the repulsive interaction between like-surface charge of the complex due to over/under charging (excess lipid or DNA) can aid in stabilizing the complexes, once they are formed, from fusing further.

Another strategy to controlling the interaction between aggregates and the stability of the aggregate *in vivo* is to modify the composition of the outer wrapping sheath of the lipoplex. The caveat is that the lipoplexes are not stabilized to such a degree that they can no longer disintegrate once inside the cells. For example, short-chain lipids possessing a PEG headgroup (or a derivative thereof) have been used to increase the stability of the lipoplexes in the blood stream due to repulsive steric interactions, while not interfering with the endosomal unwrapping once the lipoplexes are internalized in cells. These "PEGylated" lipids can reduce the transfection efficiency, but also increase the stability of complexes en route to their targets [189–191]. The PEG chains that are attached to the lipids are present inside as well as at the surface of CL–DNA complexes. This gives rise to polymer-mediated forces, such as depletion attraction between DNA strands that arises because polymer disfavors confinement of its degrees of freedom when it is between DNA rods.

More generally, we can expect that understanding how to control and manipulate the formation of specific phases on the one hand, while better understanding the multistage transfection mechanism, and the parameters (conditions) affecting it on the other, should aid in the design of more potent lipid-based gene delivery vectors in the future. These, together with control over the coating and targeting of the complexes, may render these vectors as useful vehicles in gene therapy.

21.6 DNA–POLYCATION INTERACTIONS

Stiff polyelectrolytes like DNA are readily capable of spontaneously forming complexes with various oppositely charged macromolecules to form submicron-sized complexes [53]. It is primarily thought that the formation of these self-assemblies is driven by Coulombic electrostatic and polyelectrolyte bridging interactions as well as the entropic gains derived upon the release of bound water and counterions. These forces compensate for the entropic loss resulting from a close packing of the stiff polyelectrolyte chains. Due to their potential for protecting and delivering genetic information, condensation of DNA with polycations is of particular interest. The polycation–DNA complex, often called "polyplex" [99], forms spontaneously upon mixing positively charged polymers with negatively charged nucleic acids. The advantage of polymer formulations lies in their ability to be generated economically in large quantities while offering versatility of synthetic chemistry and allowing easy tailoring of various chemical structures, molecular weights, and topologies with low immunogenicity [192].

Similar to lipoplexes, the primary goal of polycation research is the condensation of DNA into particles of virus-like dimensions that can migrate through the blood stream and into target tissue, overcome the electrostatic repulsions of the cell membrane, yet protect the nucleic acid from degradation and undesired interactions [193]. A wide variety of natural and synthetic polycations have been investigated, most of them based on amine chemistry. Factors influencing DNA compaction include the number of charges per chain, the type of charge (e.g., primary, secondary), charge spacing along the chain, chain architecture (linear, branched, dendritic), and chain hydrophobicity. External conditions such as solution ionic strength, concentration, positive-to-negative charge ratio of polycations to DNA, and mixing conditions also are observed to influence how polyplexes form. Observed differences in transfection efficiency to date are not easily correlated to polycation chemistry or structure. Large transfection differences are observed between various polycations as well as with the same polycation but of varied molecular weight or polymer chain architecture. Aggregation is generally diffusion limited upon mixing. Depending on the technical process of mixing one can form fibers; large micron-sized aggregates; or small rod, toroidal, or spherical aggregates [194–197]. Critical to increasing binding to the negatively charged cell membrane, polyplexes are usually overcharged by the polycation resulting in a net-positive colloidal aggregate.

In an ideal polyplex-mediated gene delivery, the polycations must not only compact DNA but also be able to overcome a wide variety of multibarrier processes to achieve successful transfection. Similar to a virus capsid, vector delivery would occur in a highly cell-specific manner, facilitate cellular uptake as well as endosomal release, and be able to maneuver through the cytoplasmic environment, disassociate, and then localize the desired nucleic acid vector into the cell nucleus ready for transcription. In addition, this ideal polycation would also be nontoxic, nonimmunogenic, and biodegradable. Obviously, this is a large list; in reality, no one polycation is likely to satisfy all these conditions. Consequently, a variety of additional functional elements have also been included in polyplex formulation to try to improve delivery, efficiency, targeting, and lower cytotoxicity. To date, no predictions of the correlation between polyplex structure and transfection efficiency can be made without extensive experiments. Clearly a balance of the molecular forces within and between the polyplexes is needed to create particles stable enough to carry the DNA to the nucleus yet sufficiently unstable to release the DNA when needed. In this chapter, we introduce our current understanding of the internal structure, phase behavior, and compressibility of polyplexes. We end with a brief discussion of recent advances in the understanding of polyplex gene delivery.

21.6.1 STRUCTURE OF POLYPLEXES

Early work investigating the internal packing and ordering of DNA–polycation complexes used small-angle x-ray scattering (SAXS) to look at pulled DNA fibers kept at

FIGURE 21.29 (A) Synchrotron small-angle x-ray intensity profiles for five different polycation–DNA complexes shifted in intensity for clarity. All samples were made with an excess of cationic charge to DNA phosphate and equilibrated in TE buffer without additional salt. (B) Schematic drawing of a close-packed hexagonal ordering of DNA rods held together by electrostatically bound polycations chains.

constant humidity levels [198–200]. More recent work has used SAXS to look at the internal packing and ordering of DNA–polycation complexes in buffered solutions [22,54]. Figure 21.29 shows a series of high-resolution synchrotron SAXS intensity profiles, shifted in intensity for clarity, for calf thymus DNA packaged with PL, PA, Sp, and linear and branched polyethylene imine (IPEI and bPEI, respectively) in TE buffer. Here, all samples are made with an excess of polycations and then washed to remove unreacted polycations.

All systems show a similar hexagonal close-packing of rods. A simple schematic view of this hexagonal ordering is shown in Figure 21.29. For simplicity, we represent DNA as a stiff rod to emphasize that on small length scales, such as those observable via SAXS, DNA behaves as a rigid polymer with a large persistence length ($L_p \sim 50$ nm) in stark contrast to the highly flexible polycation chains ($L_p \sim 1$ nm). Here, the flexible polycations act as a simple, electrostatically driven linker molecule, which can both wrap around a single DNA as well as bridge between DNA strands. The DNA packing dominates the scattering profiles here as DNA is significantly higher in electron density compared to the polycations. A dependence of the $d_{\text{DNA-DNA}}$ spacing, as well as small effects on the DNA pitch, is observed to depend on the chemical nature of the complexed polycation. Interhelical distances in buffer or low salt are typically of the order of 26–30 Å, equivalent to ~ 6 –10 Å space between DNA rod surfaces. Due to the

kinetic nature of polyplex formation, sample preparation is also observed to affect the polyplex internal structure. Typical conditions used to form gene therapy vectors (dilute solutions mixed under low salt conditions) were observed to give similar hexagonal packaging of the DNA as shown in Figure 21.29, but with significantly poorer long-range order in the DNA array. These particles were found to be kinetically trapped in nonequilibrium structures. Once formed, they equilibrate extremely slowly with significant, internal spacing rearrangements ($\sim 5\%$) observed on the timescale of several months as the chains try to rearrange themselves to reach their thermodynamic equilibrium spacing. Qualitatively, samples with natural amino acids, lysine and arginine, show a higher degree of long-range order compared to the short natural polyamine (Sp) and the synthetic PEI samples. This loss of long-range order may be due to the shortness of the chain for Sp and charge mismatching in the synthetic PEI polycations. Better ordering is observed for linear compared to branched PEI. This suggests that the chain architecture as well as the chemical nature of the polycations plays some role in determining the internal packing of the polyplexes. Only small effects in interaxial spacings (1–3%) are seen upon changing polycation molecular weight to significantly higher molecular weights, increased nitrogen to phosphate (N/P) charge ratio (above charge neutrality), or changing pH after polyplex formation. An exception is that d spacings were observed to change some 10% with increasing N/P ratio for the PEI samples. However,

as PEI is not a fully charged chain at neutral pH, the calculated N/P charge ratio does not reflect the true N/P ratio such that N/P significantly higher than one is necessary to achieve charge neutrality in the complex, consistent with known PEI behavior. Estimates for PEI place neutrality at N/P ~2.5 [201].

21.6.2 POLYPLEX PHASE BEHAVIOR

The structure and phase behavior of lipoplexes have been investigated in some detail showing a wealth of possibilities tuned by varying intermolecular forces through changing lipid chemistry or chain shape. In contrast, polyplexes have not shown much variability and have not been explored in as much detail. To understand the phase behavior, polyplexes of calf thymus DNA condensed with Sp, polylysine, polyarginine, and linear and branched PEI were investigated as a function of external monovalent salt concentration [54]. The addition of monovalent salt can weaken the molecular interactions of the polycations with DNA through screening of the electrostatic and bridging interactions, displacement of bound multivalents, and/or chloride binding to multivalent ions (see Figure 21.30).

In this work, universal phase behavior was observed for all polyplexes with increasing salt concentration. Initially all samples are observed to form a “tight bundle” phase of hexagonally close-packed DNA rods as depicted in Figure 21.29. The Bragg reflection in the SAXS curves not only gives information about the interaxial spacing between the rods in the array but also the peak width indicates the long-range in-plane ordering of the array through a correlation length ξ . ξ is seen to depend on the polycations and sample preparation; at low salt concentrations, ξ is observed to be on the order of 15–30 DNA repeats for the various polyplexes studied. At low salt concentrations, this hexagonal packing shows simple linear swelling behavior with the observed scattering while maintaining the in-plane correlations. At a critical salt concentration, c_s^* , dependent on polycation, the onset of a coexistence regime is observed (shaded regions in Figure 21.30). The coexistence regime occurs over a relatively narrow range of salt concentrations and is characterized by an overlapping of the initial sharp Bragg reflection with a new broad peak at lower q spacings in the SAXS measurements. In this phase, a significant fraction of the polycations has been displaced from the DNA, and a salt-induced melting transition is observed. Here, the polycations are more loosely associated with the DNA. This results in a phase with a wider distribution of interaxial spacings and a poor in-plane packing of the DNA and identified as a “loose bundle” phase. A high local concentration of the DNA is maintained through the bridging interactions of the polycations.

Due to the intrinsic stiffness or persistence length of DNA, it maintains some order similar in nature to the liquid crystalline phases observed in pure DNA phases at high concentration [8]. For an intuition on the strength of these interactions, c_s^* ranged from ~300 mM for Sp to as much as 1.6 M NaCl for polyarginine. With still more added salt, this broad

peak of the loose bundle phase is observed simultaneously to shift to smaller q , or larger d spacings, and to broaden significantly, corresponding to decreasing in-plane correlations of the DNA arrays. Interestingly, if all the polyplexes are normalized with respect to c_s^* , the swelling behavior in both regimes and ξ above c_s^* is observed to collapse to a single curve (see Figure 21.30). At c_s^* , ξ is observed to drop sharply to ~6–7 DNA repeats, independent of polycations; ξ continues to decrease to ~3 DNA repeats at the highest observed salt concentrations. At large polymer/DNA concentrations, a network phase is observed to form and to grow at the expense of the loose bundle phase. At still higher salt, or lower polymer–DNA concentrations, this network dissociates completely.

A simple model [54] was proposed using a free energy function balancing only the electrostatic attraction and entropic repulsion between the polymer chains for a hexagonal bundle and a network phase. In the bundle phase, condensation is driven by attractive electrostatic interactions. The entropic gains from releasing the bound counterions and water from the DNA compensate for the entropic loss from a close packing of the polymer chains parallel. The network phase, in contrast, is stabilized by highly localized bridge points between polymers and dominates at high salt concentration or low polymer densities. Building on established theory, the potentials for the electrostatic interactions and entropic repulsions can be used to estimate the free energy expressions for both the bundle and network phases [202,203]. This simple balance of electrostatic attraction and entropic repulsion quantitatively and qualitatively describes the transition from a hexagonal loose bundle to a network phase at high salt concentrations on the order of 1 M NaCl, where the network phase grows at the expense of the bundle phase. To induce a phase separation between loose and tight bundles, additional non-electrostatic attractive forces have to be invoked. Furthermore, this model does not include short-ranged specific interactions, which must arise from chemically distinct polycations as observed experimentally.

21.6.3 EQUATION OF STATE FOR POLYPLEXES

Insight into the intermolecular forces within condensed DNA arrays can be obtained through osmotic stress experiments. Stressing solutions of PEG exert a known osmotic pressure that is balanced by the intermolecular repulsion between helices. Measurement of the interhelical spacing at each osmotic pressure furnishes the DNA equation of state. Very few data have been collected on polyplexes, but we expect many similarities with the more extensively studied short condensing agents. Various condensing agents, ranging from divalent Mn salt to longer polycations such as spermidine and protamine, show many common features [22,48]. Equilibrium spacings, at zero osmotic pressure, depend on the polycations inducing assembly and do not change significantly at low pressures. The equilibrium spacing is typically 8–12 Å between DNA surfaces, indicating a balance of attraction and repulsion between helices. These surfaces can be brought

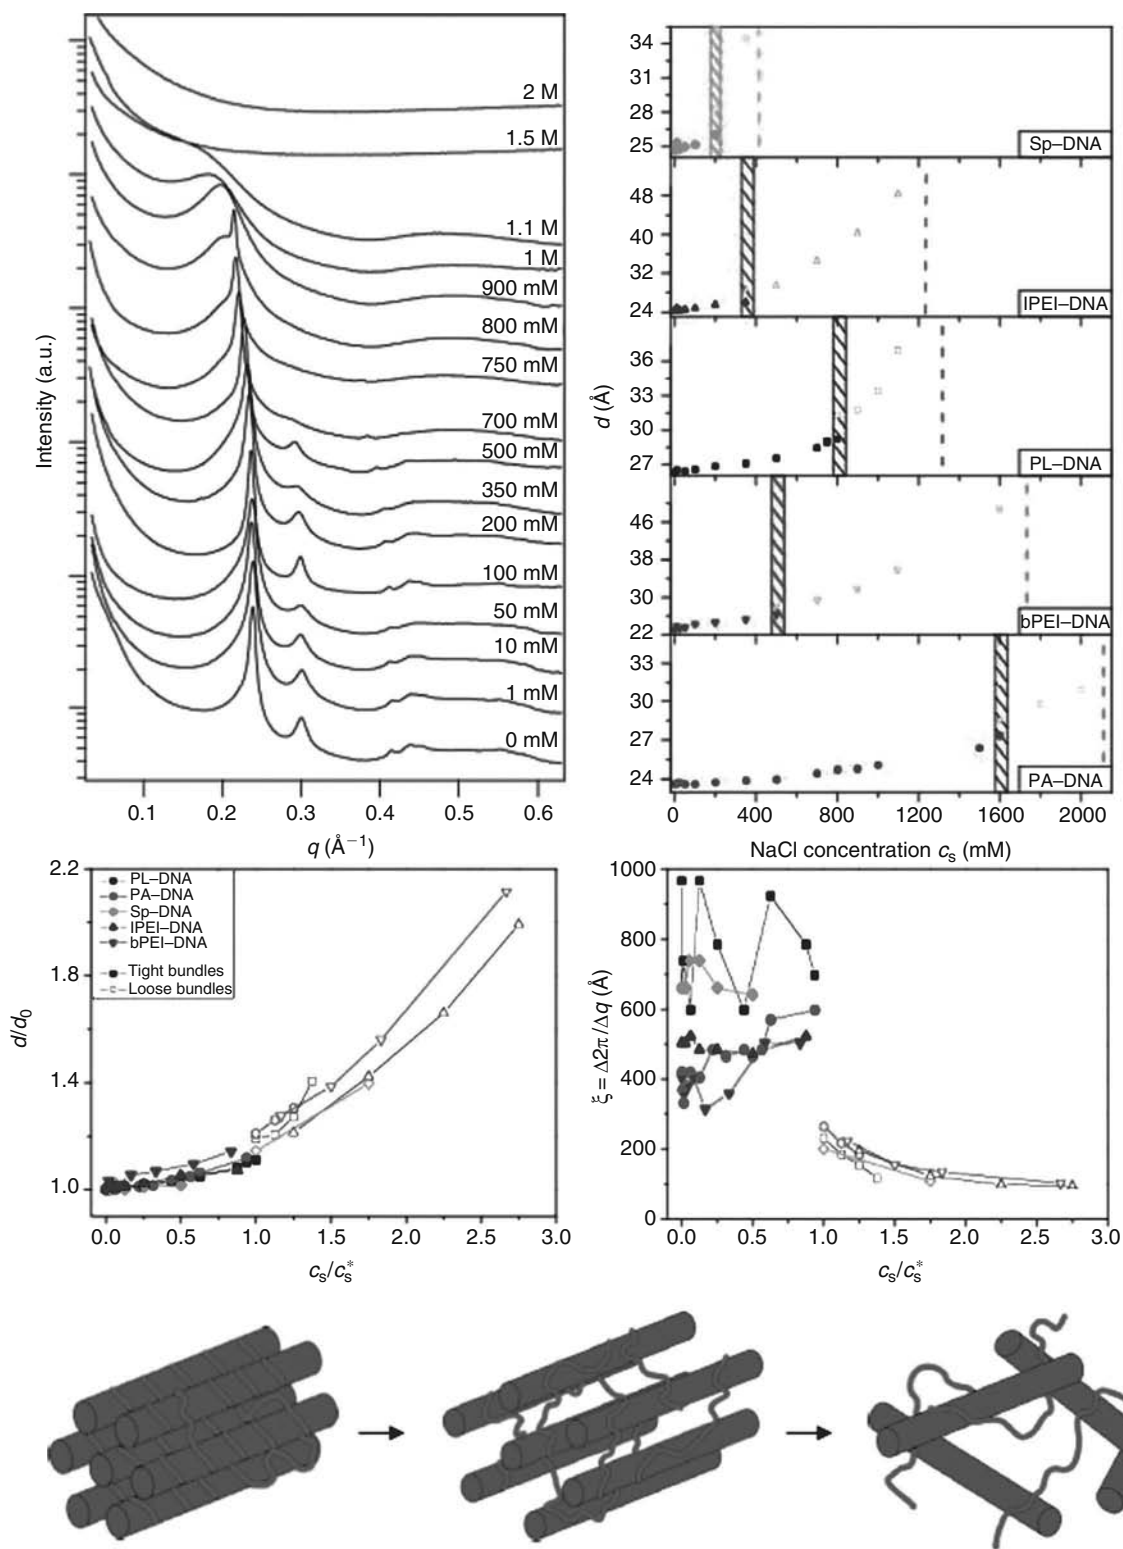

FIGURE 21.30 (See color insert following blank page 206.) Phase behavior of polyplexes with increasing monovalent salt concentration. Universal phase behavior is observed for all systems with an initial swelling of a tightly packed hexagonal array of DNA rods. As a critical salt concentration, c_s^* , dependent on polycation, the onset of a coexistence regime is observed between tight and loose bundles. In-plane correlation lengths, ξ , representative of long-range order within the arrays show a sharp decrease upon crossing c_s^* . When scaled with respect to c_s^* , both swelling ratio (d/d_0) and ξ collapse onto universal behavior. With increasing salt, the loose bundles lose both positional and orientational order with an increase in a network structure at the expense of the loose bundle regime. At sufficiently high salt concentration, or dilute polymer concentration, all Coulombic interactions are screened and the samples disassociate completely into the dilute phase.

FIGURE 21.31 SAXS intensity curves of the osmotic stress induced reordering of PLL–DNA at 900 mM NaCl. With increasing pressure, the broad diffuse peak indicative of liquid crystalline–like “loose bundle” ordering is forced to reorder showing clear coexistence and then finally scattering from a purely tight-bundled phase is observed. Compression at low osmotic pressure in this loose bundle phase was predicted to scale as $1/d$ using a simple calculated energy balance of long-range electrostatic attraction against entropic repulsion. This $1/d$ scaling is shown in the inset and is found to agree well with the experimental results. (From DeRouchey, J., Netz, R.R., and Rädler, J.O., *Eur. Phys. J. E.*, 16, 17, 2005.)

closer together with osmotic pressure and show net hydration repulsion modulated by the presence of the polycations. The force needed to push helices closer than the equilibrium spacing depends on the polyvalent ion identity. At high pressures, however, all samples show exponentially increasing forces with decay lengths of $1.5\text{--}2\text{ \AA}$ independent of the counterion species. The decay lengths of these repulsive interactions are approximately half that for an overall net hydration repulsion observed in pure DNA arrays and are insensitive to external salt concentrations. While decay length is only weakly cation dependent, there are significant differences in the magnitudes of the forces. The exact nature of these forces is not completely understood. The data do set limits that show inconsistency with several proposed ionic fluctuating models such as direct ionic bridging, ionic fluctuation, and van der Waals attraction balanced against hydration/electrostatic repulsion.

Available data for polyplexes show similar osmotic stress force curves. Equilibrium spacings for polylysine or polyarginine polyplexes are similar to spacings of DNA condensed with small cations and curves appear to converge to similar exponential limits. Osmotic stress was used to investigate a complex phase diagram for PL–DNA involving two coexisting phases [54]. Using high salt concentrations, where at $\Pi = 0$, the samples are found to be in a pure loose bundle phase, osmotic stress was applied using a high molecular weight PEG. Initially, simple compression of the loose bundles is observed with the average interaxial spacing between DNA inside the array getting smaller. With increasing osmotic

pressure, the system rearranges and the characteristic scattering for the coexistence regime is observed. Increasing the osmotic pressure further still results in the sample passing through the coexistence regime until scattering due solely to a tight bundle regime is observed. SAXS curves showing PLL–DNA at 900 mM NaCl, corresponding to loose bundles at $\Pi_{\text{osm}} = 0$, with increasing osmotic pressure are shown in Figure 21.31. Using osmotic pressure to stress from a loose bundle to a tight bundle phase showed that these two phases are in equilibrium.

21.6.4 POLYPLEX TRANSFECTION

Typical transfection formulations are mixed in low salt conditions with an excess of positive to negative charge ratio of polymer to DNA to limit aggregation, resulting in uniform nanometer-sized particles (hydrodynamic radii of the order of $20\text{--}50\text{ nm}$). Unfortunately, free polycations, typically amines, are toxic because they destabilize cellular membranes. Optimal charge ratios for gene therapy are a balance between achieving small, stable aggregates while minimizing the toxic effects. Incorporation of uncharged hydrophilic polymers, such as PEG, has proven to be an effective method to shield polyplexes, lower particle surface charge, and reduce unspecific interactions with salt and blood components [204]. However, shielding typically results in reduced transfection efficiency. This reduction can, in part, be overcome by incorporation of targeting ligands or bioreversible shielding into the particles [205,206].

Cellular uptake and delivery is not well understood but is known to depend strongly on particle size. Polyplex nanoparticles are small enough to be brought into the cell through clathrin- and caveolae-dependent endocytosis [207,208]. However, clathrin- and caveolae-independent endocytosis has also been observed including macropinocytosis and phagocytosis [209,210]. Once inside the cell, single-particle tracking techniques suggest that polyplexes are actively transported to the perinuclear region by microtubule transport [211]. More recently, new single-particle tracking results suggest that polyplexes of poly(ethylene imine) (PEI/DNA) have many diffusive behaviors. Interestingly, in early stages, these polyplexes are seen to bind to the cell membrane and freely diffuse on the cell surface while inducing a progressive accumulation of syndecans, resulting in an actin cytoskeleton-mediated endocytosis. Once endocytosed, the active transport of polyplexes inside vesicles by molecular motors along microtubules filaments was observed [212].

One of the primary causes of poor gene delivery with synthetic formulations is believed to be inefficient endosomal release. PEI, one of the most frequently studied systems due to its low cost and excellent transfection efficiencies *in vitro* and significant transfections *in vivo*, shows significant improvement in endosomal release over other common polycations [213,214]. Endosomal escape is believed to proceed through the “proton sponge” effect where charges along the chain with a pK_a slightly below physiological pH gets activated upon acidification in the endosome, resulting in an influx of both protons and charge neutralizing Cl^- ions, inducing an osmotic stress that swells and destabilizes the endosome, releasing its contents into the cytoplasm [215,216]. These studies strongly suggest that the high transfection activity of PEI vectors is due to their unique ability to avoid acidic lysosomes. The subsequent steps, complex disassociation, and final nuclear transport of the plasmid are still not mechanistically well understood. While improved active transport across the nuclear membrane has been reported through the incorporation of NLS [217], clear evidence has also shown that passive DNA entry into the nucleus during cell division when the nuclear membrane is temporarily disrupted is important. Highest efficiencies are reported in dividing populations of cells [218]. While new techniques and studies are beginning to shed light on the complicated multiple barriers, both thermodynamic and kinetic, involved in successful gene delivery, clearly more work must be done to understand, balance, and use the molecular forces involved for improved delivery vectors.

21.7 RETROSPECT AND PROSPECT

Structural elucidation of the DNA–CL and DNA–polycation complexes and realization of the extent to which they share the structural features of pure-DNA or pure-lipid polymorphism have advanced notably in the past few years. Some old questions have been answered and new questions raised. It is these new questions that challenge our knowledge of the intricacies of interactions between macromolecules.

The DNA–lipid and DNA–polycation complexes found so far are only a sample of the much wider set of structures that will be seen on a full DNA–complex phase diagram. We argue that this larger set of possibilities be approached by firmly established methods to measure the energies of these structures at the same time that they are determined and located on a phase diagram. Built on principles of direct molecular interactions, recognizing the consequences of thermal agitation, this line of observation and analysis can lead to an understanding of the energetic “whys” and preparative “hows” of complex structures.

Forces so delineated are already knowledgeably applied in new preparations. Precisely how the structure of DNA–lipid and DNA–polycation aggregates will affect their efficacy in transfection remains to be seen. So far, the ideas we have are too general and have been learned from studying analytically tractable but technically inadequate preparations. General principles do not lead to specific results. Molecules are too interesting to allow easy success in clinical design. Still there is little doubt of a practical link between the energy and structure of these complexes and their viability in a technological application.

Even the present general understanding of forces, even the cartoon ideas of the directions in which forces act in macromolecular complexes, can tutor the bench scientist on how to improve preparations. There is enough known for a healthy iteration between experimental attempt and theoretical reason. Experimental successes and failures become the data for molecular force analyses. Various DNA–lipid and DNA–polycation assemblies reflect the various actions of competing forces. Molecular theorists can define and delineate these forces as they act to create each form; they can provide a logic to design variations in preparation. Basic scientists and clinicians are already in a position to help each other to improve their ways.

ACKNOWLEDGMENTS

We would like to thank Milan Hodoscek and Matjaz Licer for their help with molecular graphics in preparing some of the figures, and John Nagle and Stephanie Tristram-Nagle for their comments on an earlier version of this chapter. We would like to thank Don Rau for instructive discussions. R.P. and D.H. thank the support of the Israeli and Slovenian ministries of science and technology through a joint Slovenian–Israeli research grant. This research was supported by the Intramural Research Program of the NICHD, NIH.

22.1 INTRODUCTION

The first demonstration that gene expression could be suppressed in a specific manner by targeting a messenger RNA (mRNA) using complementary hybridizing DNA sequences was done in 1978 [1,2]. However, several technical obstacles needed to be overcome to develop therapeutic applications based on this discovery. Unmodified oligonucleotides are sensitive to enzymatic degradation *in vivo*, and their negative charge limits their entry into target cells without use of a vehicle to transport them across the plasma membrane. Several chemical modifications of the phosphodiester-deoxyribose backbone have been made to increase the stability of antisense oligonucleotides. One of these involves replacement of the deoxyribose moiety with a substituted morpholine, which maintains the base-specific hybridization of the parent oligonucleotide (Figure 22.1) [3,4]. Phosphorodiamidate morpholino oligonucleotides (morpholinos) are neutral antisense oligomers of this class that have become widely used as a research tool in developmental biology.

Morpholinos are currently the standard reagent to temporarily but efficiently suppress expression of target genes in developing zebrafish embryos [5–7]. Similar applications are emerging for developmental analysis of gene function in other animals for which transgenic technologies are not currently

available. In mice and other animals where transgenesis is available, morpholinos are also useful to complement transgenic approaches to study the function of embryonic lethal genes at specific stages of oocyte and embryo differentiation.

Morpholinos are designed to hybridize with complementary nucleotide sequences in the mRNA of a target gene, but unlike RNA interference approaches, morpholinos do not generally induce RNA degradation [8]. Rather, they can be designed to prevent gene expression by two mechanisms (Figure 22.2). Translation-blocking morpholinos are designed to hybridize with the 5' region of mature mRNA to prevent its efficient translation [9]. Splice-blocking morpholinos are designed to hybridize with an exon–intron junction in a specific nuclear pre-mRNA to prevent the splicing required to generate a mature functional mRNA [10]. The latter approach can be used to inhibit expression if the junction is chosen judiciously so that alternative splicing of the nuclear transcript cannot bypass the targeted splice junction to generate a functional mRNA. Conversely, splice-blocking morpholinos have also found use to force generation of alternatively spliced mRNAs that can rescue function of certain mutated genes.

The stability of these synthetic oligonucleotides and the duration of their activity to suppress gene expression have prompted attempts to apply morpholinos to therapeutically

FIGURE 22.1 General structure of morpholinos. In morpholinos, the 3',5'-phosphodiester linkage of DNA is replaced by the enzymatically stable phosphorodiamidate and the deoxyribose is replaced by a substituted morpholino.

suppress gene expression in adult animals [11,12]. We will review the results to date from these efforts and discuss the advantages of morpholinos for *in vivo* control of gene expression as well as the barriers that must be overcome to bring this approach to broad clinical use.

One of the central theoretical advantages of a morpholino-based therapeutic is its ability to specifically target the gene responsible for a specific pathology or disease state. The morpholino, because it is an electrostatically neutral molecule that engages the target RNA via Watson-Crick base pairing, may have very few if any off-target effects [13]. Some off-target activities can occur and could involve interactions of the morpholino oligonucleotide and various extracellular, membrane, and intracellular structures whose function could be perturbed by such binding. The current generation of morpholino oligonucleotides replaces the five-membered sugar ring backbone of natural DNA with an uncharged phosphorodiamidate linkage. The advantages of this derivative include better biologic stability, water solubility, excellent hybridization with RNA, and complete resistance to enzymatic

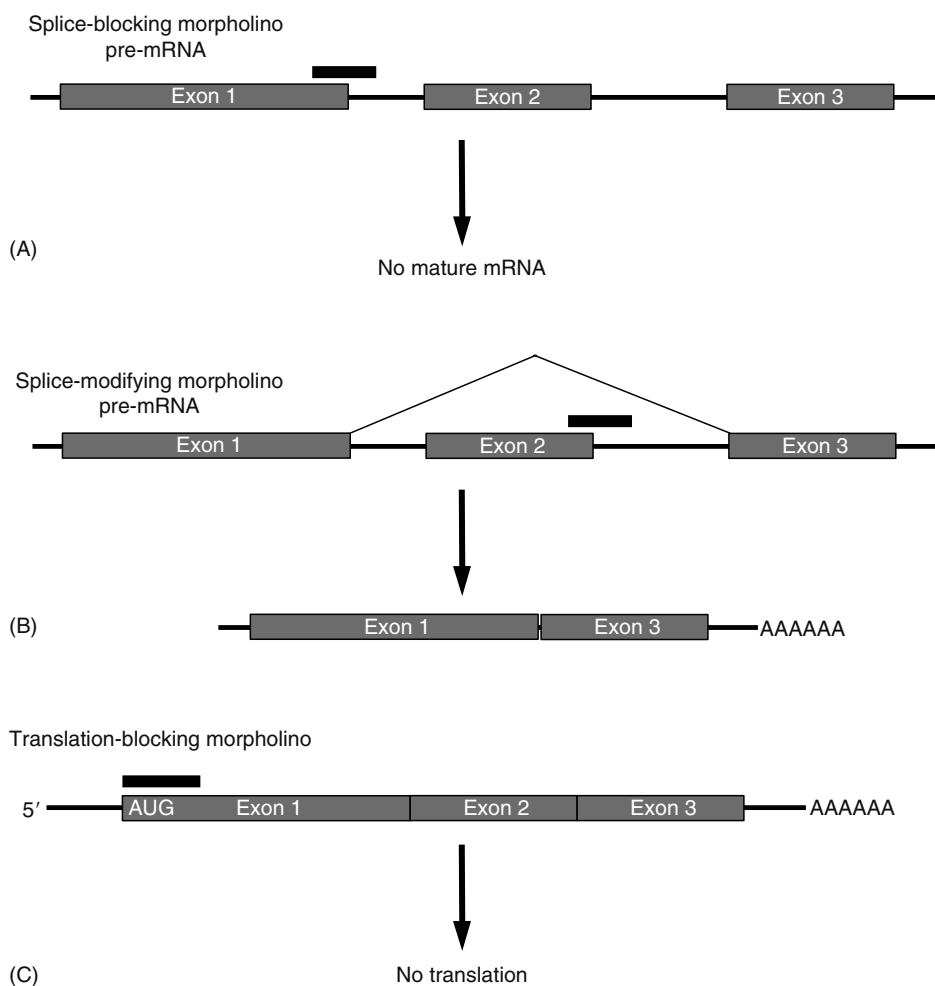

FIGURE 22.2 Strategies to control gene expression using morpholinos. Splicing of nuclear pre-mRNA can be prevented using a morpholino complementary to a splice donor sequence (A), which prevents generation of the mature processed mRNA. In some cases, splicing to generate an alternative mature mRNA can be forced by using a morpholino complementary to an internal exon (B). Translation-blocking morpholinos are typically designed to hybridize near the translation initiation sequence in a mature mRNA (C).

degradation. These agents also provide some advantages over other products used in gene silencing such as S-DNA and small-interfering RNA (siRNA), which were found to have some characteristic off-target effects, multiple protein interactions, and could stimulate both coagulation and immune system effects due their net negative charge, some being lethal in animal models [13–15].

The minimum effective length of the present generation morpholinos for target inhibition has been found to be 14 to 15 bases. This is true of both splice- and translation-blocking morpholinos. As such, once within the cell, the morpholino has free access to both the cytosol and nucleus, increasing the target pool of mRNAs upon which it can exert its therapeutic effects [13].

22.2 DELIVERY TECHNIQUES

22.2.1 IN VITRO DELIVERY

The current phosphorodiamidate morpholinos are very effective at gene silencing, preventing protein production in at least 80%–95% of reported targets. However, such success is clearly dependent upon adequate delivery of the agent to the intracellular space. Most experience to date and research into drug delivery with morpholinos has employed cell culture systems [16,17]. In two-dimensional mammalian cell cultures, efficient delivery has been obtained using physical means to temporarily disrupt integrity of the plasma membrane. The two most effective physical methods are cell scraping and cell trituration [17].

Two nonphysical methods of cell delivery of morpholinos into cultured cells are available from Gene Tools, LLC. One is an ethoxylated polyethylenimine solution [18]. For this purpose, morpholinos are first complexed with a complementary conventional oligonucleotide, which creates an anionic heteroduplex. Then, this heteroduplex is complexed with positively charged polyethyleneimine to form a delivery complex. As has been reported for polyethyleneimine complexes with plasmids [19], these complexes deliver well to certain types of cultured cells including PC3, HT-29, U20S, HL-60, and U937 cells and primary endothelial, vascular smooth muscle, and B cells, but not to some other cell types [20–31].

The second commercial delivery reagent consists of a cell-penetrating peptide (CPP) (Endoport), which does not directly associate with the morpholino but effectively delivers morpholinos or other macromolecules in a nonspecific manner into cells by inducing endocytosis and subsequent release of the endocytic contents into the cytoplasm [32]. Unlike the polyethyleneimine delivery vehicle, the CPP can be used in the presence of serum [16,33]. As described in the manufacturer's patent, the active component is a 19- to 37-residue two-face amphiphilic peptide, with one face composed predominantly (80%–100%) of aliphatic lipophilic amino acids, and the other face composed predominantly (80%–100%) of basic amino acids, with at least 70% of the amino acids of the weak-base face being histidines [34]. Following endocytosis, acidification of the endocytic vesicle by the cell induces a

conformation change that causes the peptide to disrupt the membrane of the vesicle and release the morpholino into the cytoplasm. The commercial delivery vehicle contains 1 mM of this peptide in dimethylsulfoxide and results in efficient delivery of morpholinos into many types of cultured mammalian cells with suppression of target gene expression [35–47].

22.2.2 IN VIVO DELIVERY

22.2.2.1 Nontargeted *in Vivo* Delivery Vehicles

In vivo delivery of morpholinos remains an area of evolving technology and therapeutic development. Local/regional infiltrative injection, central administration via intravenous injection of morpholinos, and topical application have been reported [48–51]. Topical delivery to the skin has been found to be safe and demonstrated tissue localization of the oligonucleotide [48,49]. The vehicle for delivery was a mixture of water, propylene glycol, and linoleic acid. Analysis of the underlying skin demonstrated the morpholino both at the site of application, but morpholino was also detected distantly in the liver. Target protein suppression was found after topical delivery.

Morpholinos have also been delivered locally to disease sites via direct injection with therapeutic effect [52–55]. This approach was especially useful in suppressing solid tumor growth in tumor xenograft models in nude mice [55,56]. Tumors were injected multiple times over several weeks. Intracranial injection of a morpholino was found to alter neuroendocrine responses in a rat model of stress-driven hyperprolactinemia [53]. In this application, a single intracerebroventricular injection was employed. Direct injection of a morpholino intramuscularly, again as a single injection, was found to suppress abnormal muscle cell protein production at the site of injection in a murine model of muscular dystrophy [57]. In these reports, the specific morpholino was delivered in phosphate-buffered saline (PBS) or normal saline and through direct deposition of the morpholino in the region of the site of pathology, enhancing target delivery of the morpholino and most likely increasing concentration of the morpholino at the disease site. Nonetheless, local delivery of morpholinos was associated with demonstration of the morpholino in distant tissue sites. Presumably the hydrostatic pressure of injection and the physical trauma of the needle transecting the tissues facilitate the local uptake of the morpholino at the cellular level, but the mechanism of uptake at distant sites remains a mystery.

Nontargeted administration of morpholinos has also been accomplished by systemic injection either through intravenous injection [58,59] or intraperitoneal (i.p.) injection [60–62]. Studies using i.p. injection dosage schedules have varied from a single dose [60] to inhibit Ebola viral infection to 30 doses over 5 weeks in a murine model of colonic neoplasia [61] to multiple-dose schedules in combination or concurrently with chemotherapy in a Lewis lung cancer model [63]. In these *in vivo* models, the morpholino was delivered in PBS or saline vehicle. Tail vein injection of a morpholino targeting the hepatitis C virus

(HCV) internal ribosome entry site, once more suspended in PBS, was given to mice with a xenotransplant of human HCV, and viral translation was monitored *in vivo* by a luciferase gene reporter assay [59]. Alter et al. also evaluated systemic delivery via tail vein injection once per week over three consecutive weeks and demonstrated systemic alterations in target protein [58]. Though other delivery modalities have been reported in experimental models including via gastrointestinal instillation and through the lungs by inhalation with other types of oligonucleotides, application of these approaches to morpholinos has not been reported.

Significant empirical experience has been gained in using morpholinos *in vitro* to suppress protein production. However, systematic *in vivo* pharmacokinetic data for morpholinos in mammals, regardless of the method of delivery, remain quite limited [13,64]. Tissue distribution may be determined by the means of delivery of the morpholino, with serum concentration and systemic distribution faster via intravenous injection as compared to other delivery methods [65]. Regardless of the *in vivo* delivery method, morpholinos are distributed to essentially all tissues in a manner that is not sequence-dependent [4,33]. However, the ability to find morpholinos in tissues following local or systemic administration does not equate with intracellular delivery of the drug [65]. Various cell types including hepatocytes, macrophages, vascular cells, and splenocytes have been found to take up morpholinos following *in vivo* administration, though intracellular distribution remains nonuniform following uptake similar to *in vitro* results.

22.2.2.2 Peptide-Mediated and Targeted *in Vivo* Delivery Vehicles

To enhance specificity and cell uptake of morpholinos, several novel delivery methods have been described [11,52,57,65–67]. In a model of intracranial glioblastoma, morpholinos were injected in a complex with Polycefin, reportedly to target a specific tumor cell surface protein [66]. Given the number of variables in the experimental design of this report, clear conclusions could not be made. Others have recently reported encouraging results to enhance *in vivo* responses by complexing the morpholino with a CPP [67,68]. Targeting an essential bacterial gene, morpholino-CPP complexes given via i.p. injection significantly decreased bacteremia in mice [67,68]. However, the general effectiveness of CPP for delivery of morpholinos is not clear. Recent reports from the same investigators showed that the peptide, particularly if the peptide had aminohexanoic residues, was subject to rapid degradation. Also, the entire complex of CPP-PMO localized to endosomes and lysosomes, and it remains unclear the manner by which such complexes escape these intracellular compartments to gain access to the nucleus [16].

In a novel approach to achieve a higher local concentration of morpholino with less systemic distribution, morpholinos were complexed to perfluorocarbon microbubbles and given intravenously at the time of coronary artery stent placement

[69]. This morpholino complex was found to localize to the vessel site of injury and suppress the target protein with minimal systemic presence.

22.3 *IN VIVO* THERAPEUTIC APPLICATIONS

Morpholinos have demonstrated therapeutic effects in a number of animal models of disease processes. Local and diffuse systemic diseases have been treated by either local or central routes of administration, although no general guidelines or standards are yet in place. This section reviews the results reported to date for several disease models in animals.

22.3.1 MUSCULAR DYSTROPHY

A morpholino targeting the dystrophin exon 23 donor splice site was given via injection in saline into the skeletal muscle. This treatment was associated with an increase in normal protein in an *mdx* mouse model of Duchene muscular dystrophy [52]. In this report, the oligonucleotide was annealed to a sense strand leash, creating a heteroduplex to facilitate cell penetration. The agents were then dissolved in normal saline and delivered via direct intramuscular injection in single doses or via i.p. injection as a single dose or multiple doses. Regardless of the agent or delivery method, target protein alteration was demonstrated.

Alter et al. [58] injected 2 μ g of a morpholino targeting the sequence M23D + 07–18, specific for removal of exon 23 of the mouse dystrophin gene, into the tibialis anterior skeletal muscle of dystrophic mice. They found an increase in dystrophin-positive muscle fibers. They also administered 2 mg of morpholino via tail vein injection and found mRNA changes in muscle after 2 weeks. Given the temporary effects of morpholinos on cell culture protein levels, it is not clear how changes were sustained after 2 weeks, although the slower proliferation of cells *in vivo* may extend the duration of suppression.

22.3.2 ANTIVIRAL ACTIVITY

Burrer et al. [11] reported the minimization of hepatitis infection in mice treated with a morpholino targeting the 5' terminus of coronavirus mRNA or murine hepatitis virus. Several formulations of these agents were employed including morpholino alone and morpholino covalently complexed by a thioether or an amide linkage to an arginine-rich peptide sequence. Both peptide-bound and unbound phosphorodiamidate morpholinos reduced viral titers in animals and reduced viral tissue damage. However, in a group inoculated with a high viral dose, several animals demonstrated toxicity that was absent in control uninfected animals who received the same treatment.

Peptide-conjugated morpholinos targeting the 5' terminus of the viral genome or an essential 3' RNA element required for genome cyclization displayed a broad spectrum of antinflavivirus

activity, suppressing West Nile virus, Japanese encephalitis virus, and St. Louis encephalitis virus by 3–5 log units in cell culture [70]. Both of the conjugated morpholinos at 100 and 200 µg/day partially protected mice from West Nile virus disease with minimal to no toxicity. However, a higher treatment dose (300 µg/day) caused toxicity. In contrast to some other *in vivo* applications, unconjugated morpholinos at 3 mg/day showed neither efficacy nor toxicity, suggesting the importance of the peptide-conjugate for the observed antiviral activity.

Similar activity in mice was observed using a CPP-conjugated morpholino targeting a sequence in the 3' portion of the Coxsackievirus B3 internal ribosomal entry site [65]. Coxsackievirus B3 is a primary cause of viral myocarditis. A/J mice received intravenous administration of the CPP-morpholino once prior to and once after Coxsackievirus B3 infection and showed an approximately 100-fold decreased viral titer in the myocardium at 7 days postinfection and a significantly less cardiac tissue damage, compared to the controls.

The same CPP conjugation strategy proved effective for protecting mice from Ebola virus infection [60]. A 22-mer CPP-morpholino complementary to the translation start site region of Ebola virus VP35 positive-sense RNA inhibited viral amplification in cell culture and provided complete protection to mice when administered before or after an otherwise lethal infection of Ebola virus. In this prophylaxis model, three nonconjugated morpholinos targeting the same VP35 sequence also protected the mice from Ebola virus challenge.

22.3.3 CANCER

Recently, attempts to combine morpholino delivery with increased uptake and specificity following intravenous administration have been applied to several cancer models. Ljubimova et al. [71] described a new polymer-derived drug delivery system. The scaffold incorporates antibodies specific for the target tumor tissue, the morpholino, and a fluorescent marker to track localization. In two murine xenograft models of cancer, the agent localized to the tumors in greater concentrations than other tissues. However, no therapeutic results were reported. Liu et al. [64,72] also reported relative specificity of drug delivery to tumors. However, they used the morpholino as a targeting agent (not as a primary therapeutic) to concentrate radioactivity in tumor tissue. A morpholino conjugated to the anti-CEA IgG antibody MN14 was injected via tail vein into mice bearing a colon cancer xenograft. This was then followed by a radiolabeled complementary morpholino. Tumor growth rates were markedly inhibited compared to controls. The MN14–morpholino complex localized to the tumor cells and allowed for site specific delivery of the radiotherapy via the complementary morpholino. Here the tissue specificity appears to depend on the localization of the bound antitumor antibody. This study supports the specificity of morpholino-antibody targeting but does not add new insight into the ability of morpholinos to enter tissues or cells *in vivo* to control gene expression.

22.3.4 CARDIOVASCULAR DISEASE

Morpholino oligonucleotides have also been employed in cardiovascular disease models in higher mammals including pigs [69,73] and rabbits [74] with some reported therapeutic success. In a porcine model of the coronary artery disease, several studies have employed a c-myc antisense morpholino in an effort to reduce intimal hyperplasia secondary to vascular smooth muscle cells (VSMC) proliferation [12,69,75]. The agents were locally delivered through catheters and/or implanted stents. Both delivery techniques resulted in decreased coronary lesion size in response to injury.

22.3.5 ISCHEMIC INJURY

Recently, we have developed a morpholino targeting a conserved sequence in human and murine CD47 to treat ischemic injuries. CD47, also known as integrin-associated protein, is a cell surface receptor for the secreted protein thrombospondin-1 [76]. Thrombospondin-1 is a potent inhibitor of nitric oxide/cGMP signaling in vascular cells [77,78]. The nitric oxide signaling pathway acutely controls blood flow into tissues by promoting vasodilation, and in the longer term promotes angiogenic remodeling of the vasculature (Figure 22.3). Transgenic mice lacking either thrombospondin-1 or CD47 show enhanced angiogenic responses as well as superior acute maintenance of blood flow and tissue oxygenation in ischemic tissues and improved long-term survival of ischemic injuries in cutaneous skin flap and hindlimb models [35,79]. These studies established that thrombospondin-1/CD47 signaling plays a critical role in acutely limiting blood flow and the long-term inhibition of angiogenic remodeling in ischemic tissues. Therefore, we sought therapeutic approaches to selectively block this pathway to treat ischemic injuries.

One effective approach to treat fixed tissue ischemia in several murine models, including random dorsal myocutaneous flaps and hind limb vascular occlusion, was to temporarily suppress CD47 expression using morpholinos [35]. The morpholino used here was first shown to be effective to suppress CD47 expression in cultured VSMC. Immunohistochemistry of tissue sections from treated mice also demonstrated a substantial reduction in CD47 protein expression *in vivo* following morpholino treatment. Local morpholino injection into the flaps and wound bed markedly improved survival of ischemic tissues in McFarland dorsal skin flaps (Figure 22.4A). Remarkably, the morpholino was equally effective at improving survival in ischemic hindlimb models (Figure 22.4B). The loss of target expression and clinical responses to these treatments following local injection indicate that delivery of morpholinos to the dermis in the flap model and to skeletal muscle in the hind limb model is relatively efficient.

We recently applied the same CD47 morpholino treatment to skin grafts. In a murine model of full thickness skin graft healing, direct injection of a CD47-targeting morpholino into both the graft and underlying wound bed resulted in a dramatic increase

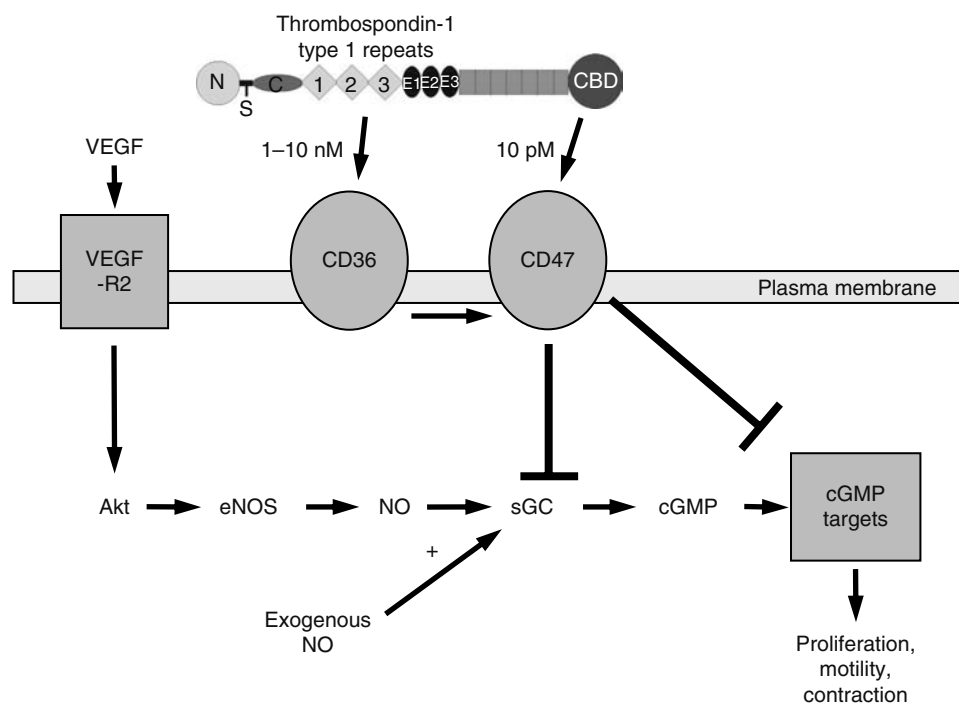

FIGURE 22.3 Thrombospondin-1 antagonism of nitric oxide signaling to regulate tissue perfusion and angiogenesis. Thrombospondin-1 inhibits nitric oxide signaling at the level of soluble guanylate cyclase (sGC) and downstream of cGMP by binding to its cell surface receptors CD36 and CD47. Of these, CD47 is the essential thrombospondin-1 receptor, and its genetic deletion, blocking with antibodies, or temporary suppression using a morpholino relieves the NO/cGMP signaling cascade from inhibition by thrombospondin-1. In endothelial cells, this pathway regulates proangiogenic signaling downstream of vascular endothelial growth factor (VEGF), which induces NO synthesis by increasing phosphorylation of endothelial nitric oxide synthase (eNOS) by the kinase Akt. In VSMC, exogenous NO produced by adjacent endothelial cells activates sGC leading to cGMP-mediated dephosphorylation of myosin light chain, which causes relaxation of the smooth muscle cells and increased tissue perfusion.

in skin graft survival [80]. Saline and control sequence treated skin grafts demonstrated approximately 100% tissue necrosis. In contrast, grafts treated with the CD47 morpholino showed near complete survival (Figure 22.5).

Interestingly, such a therapeutic response in the mouse does not require use of the proprietary delivery peptide that enhances cellular uptake via phagocytosis. We compared responses for mice injected with the CD47 morpholino in saline versus the morpholino-delivery peptide mixture in saline. We saw equivalent responses in terms of tissue survival of full thickness skin grafts and random myocutaneous flaps (Figure 22.6 and [80]). This implies that morpholinos can efficiently gain entry into the relevant target cells in a surgical wound independent of any cell delivery agent. We propose that surgical wounds may mimic the conditions of physical stress that are known to stimulate morpholino uptake in cell cultures, either due to the local physical stress on the tissue or in response to inflammatory cytokines that are released during the physiological wound response and may stimulate phagocytic uptake of morpholinos by the target cells. Thus, cells in a surgical field may be intrinsically more efficient for uptake of morpholinos. However, further research is needed to quantify the relative efficiencies of morpholino uptake into tissues in response to surgical stresses and other stressors

such as inflammation and to define the signaling pathways that regulate this uptake.

Murine models of tissue injury are economical and readily reproducible based on the genetic background homogeneity of laboratory mouse strains. However, mice differ substantially in their soft tissue vascular anatomy compared to other higher mammals including humans. The pig offers a model of soft tissue vascular anatomy that more closely parallels that found in people. Using the Yucatan white hairless pig, we are currently evaluating the ability of CD47 targeting morpholinos to enhance ischemic tissue survival in a random tissue flap model. As in murine studies of comparable ischemic tissue injury, local administration of the CD47 morpholino results in enhanced tissue survival [81].

In both the murine and porcine models of fixed ischemic tissue injury, the CD47 morpholino has been delivered via local subcutaneous and intradermal injection. Under these conditions, we have found that tissue survival was increased by the target morpholino but not by a control morpholino. These data support the possibility that the same approach can be effective to treat ischemic injuries in humans [82]. The ease of delivery via local injection at the site of soft tissue injury and vascular compromise will allow for ready therapeutic applications during surgical procedures.

FIGURE 22.4 (See color insert following blank page 206.) Improved survival of fixed ischemic injury following CD47 morpholino treatment of dorsal skin flaps and ischemic hind limbs in C57BL/6 mice. Wild-type C57BL/6 age- and sex-matched mice underwent 1×2 cm random myocutaneous flaps. Flaps were treated at the time of surgery with saline, a mismatched morpholino control or a target CD47 morpholino, and tissue survival determined (A). Wild-type C57BL/6 age- and sex-matched mice underwent ligation of the femoral artery at the inguinal ligament. Limbs were treated at the time of surgery by direct intramuscular injection of vehicle (saline), a mismatched control morpholino sequence, or a CD47 morpholino.

FIGURE 22.5 (See color insert following blank page 206.) Improved survival of full thickness skin grafts following CD47 morpholino treatment in C57BL/6 mice. Wild-type C57BL/6 age- and sex-matched mice underwent 1×1 cm full thickness skin grafts. At the time of surgery, grafts and wound beds were treated by direct injection with saline (vehicle), a missense control morpholino, or a CD47 morpholino ($10 \mu\text{M}$), recognizing the murine sequence of the protein. Tissue survival was assessed on postoperative day 7.

FIGURE 22.6 (See color insert following blank page 206.) CPP does not enhance the efficacy of a CD47 morpholino for ischemic injury. Wild-type C57BL/6 age- and sex-matched mice underwent 1×2 cm random myocutaneous flaps. Flaps were treated at the time of surgery with a targeted CD47 morpholino plus the manufacturer's recommended cell uptake agent (Endoporterr®) in saline or a CD47 morpholino in saline alone and tissue survival determined.

22.4 CLINICALLY ORIENTED APPLICATIONS

Several studies in humans involving morpholino therapy are currently in phase I or II clinical trials [54,83,84]. An oligonucleotide morpholino targeting *c-myc* (AVI-4126), which was effective in decreasing tumor burden in a murine xenograft model of bladder cancer, has been administered to human volunteers in a phase I trial as a single intravenous bolus with no reported adverse events [83]. Plasma concentrations were reported to approach baseline within several hours of administration. This same agent is now in phase II trials [84]. Other agents are in development targeting coronary vascular stenosis, polycystic kidney disease, and drug metabolism via cytochrome P450 enzymes.

22.5 SUMMARY

Morpholino oligonucleotides represent an evolving and promising means of manipulating gene expression that could overcome several persistent limitations of alternative oligonucleotide-based technologies. Extensive use as a research tool in developmental biology has proven their efficacy for temporarily suppressing gene expression with minimal off-target effects. Their stability and lack of charge are clearly advantages to therapeutic applications. Morpholinos have demonstrated therapeutic activities in a number of animal species and disease models. However, many areas deserve continued research. In particular, efforts should be made to more fully describe the molecular mechanism by which the administered drug reaches the target mRNA in order to optimize drug delivery. Further development is also needed to optimize delivery protocols in both injured and uninjured tissues and to develop

effective targeting strategies to permit selective suppression of gene expression in tumors and other diseased tissues that are not accessible to direct injection. Further studies are also needed to clarify the pharmacokinetics and pharmacodynamics of morpholinos, both for systemic delivery and in target tissues following local delivery to optimize their activities.

23.1 INTRODUCTION

Antisense oligonucleotides are short synthetic oligonucleotides, usually between 15 and 25 bases in length designed to hybridize to RNA through Watson–Crick base pairing (Figure 23.1). Upon binding to the target RNA, the oligonucleotide prevents expression of the encoded protein product in a sequence-specific manner. As the rules for Watson–Crick base pairing are well characterized [1], antisense oligonucleotides represent, in principle, one of the few examples of rational drug design. In practice, exploitation of antisense oligonucleotides for therapies has presented a unique set of

challenges, some anticipated and others unanticipated. Nevertheless, antisense oligonucleotides are showing promise as therapeutic agents broadly applicable for the treatment of human diseases. Currently there is one approved antisense product on the market and approximately 30 agents in clinical trials, several of which are in advanced stages of development (Table 23.1). In this review, we will summarize the properties of antisense oligonucleotides in terms of their application as therapeutic agents. Because of the wealth of information available on first-generation antisense oligonucleotides, i.e., phosphorothioate oligodeoxynucleotides, they will serve as a benchmark for comparison with some of the newer modified

FIGURE 23.1 Phosphorothioate antisense oligodeoxynucleotide targeting an RNA receptor. Watson–Crick base pairing rules are indicated: nucleobase adenosine hydrogen bonds to nucleobase uracil and nucleobase cytosine hydrogen bonds to nucleobase guanine.

oligonucleotides. However, as discussed in this chapter, second-generation antisense chemistries exhibit a number of improved properties compared to first-generation oligonucleotides and should be viewed as the current standard.

23.2 ANTISENSE MECHANISM OF ACTION

Antisense oligonucleotides are small synthetic oligonucleotides designed to bind to mRNA through Watson–Crick

hybridization. Although most antisense oligonucleotides currently target protein coding mRNAs or pre-mRNAs, they can also be used to inhibit the function of noncoding RNAs [2–6]. Upon binding to the RNA, the oligonucleotide may inhibit function of the RNA through either inducing cleavage of the RNA by endogenous RNases or by occupancy of critical regulatory sites on the RNA, disrupting its function (Figure 23.2). Although intuitively one would anticipate that an antisense oligonucleotide that worked through a catalytic mechanism

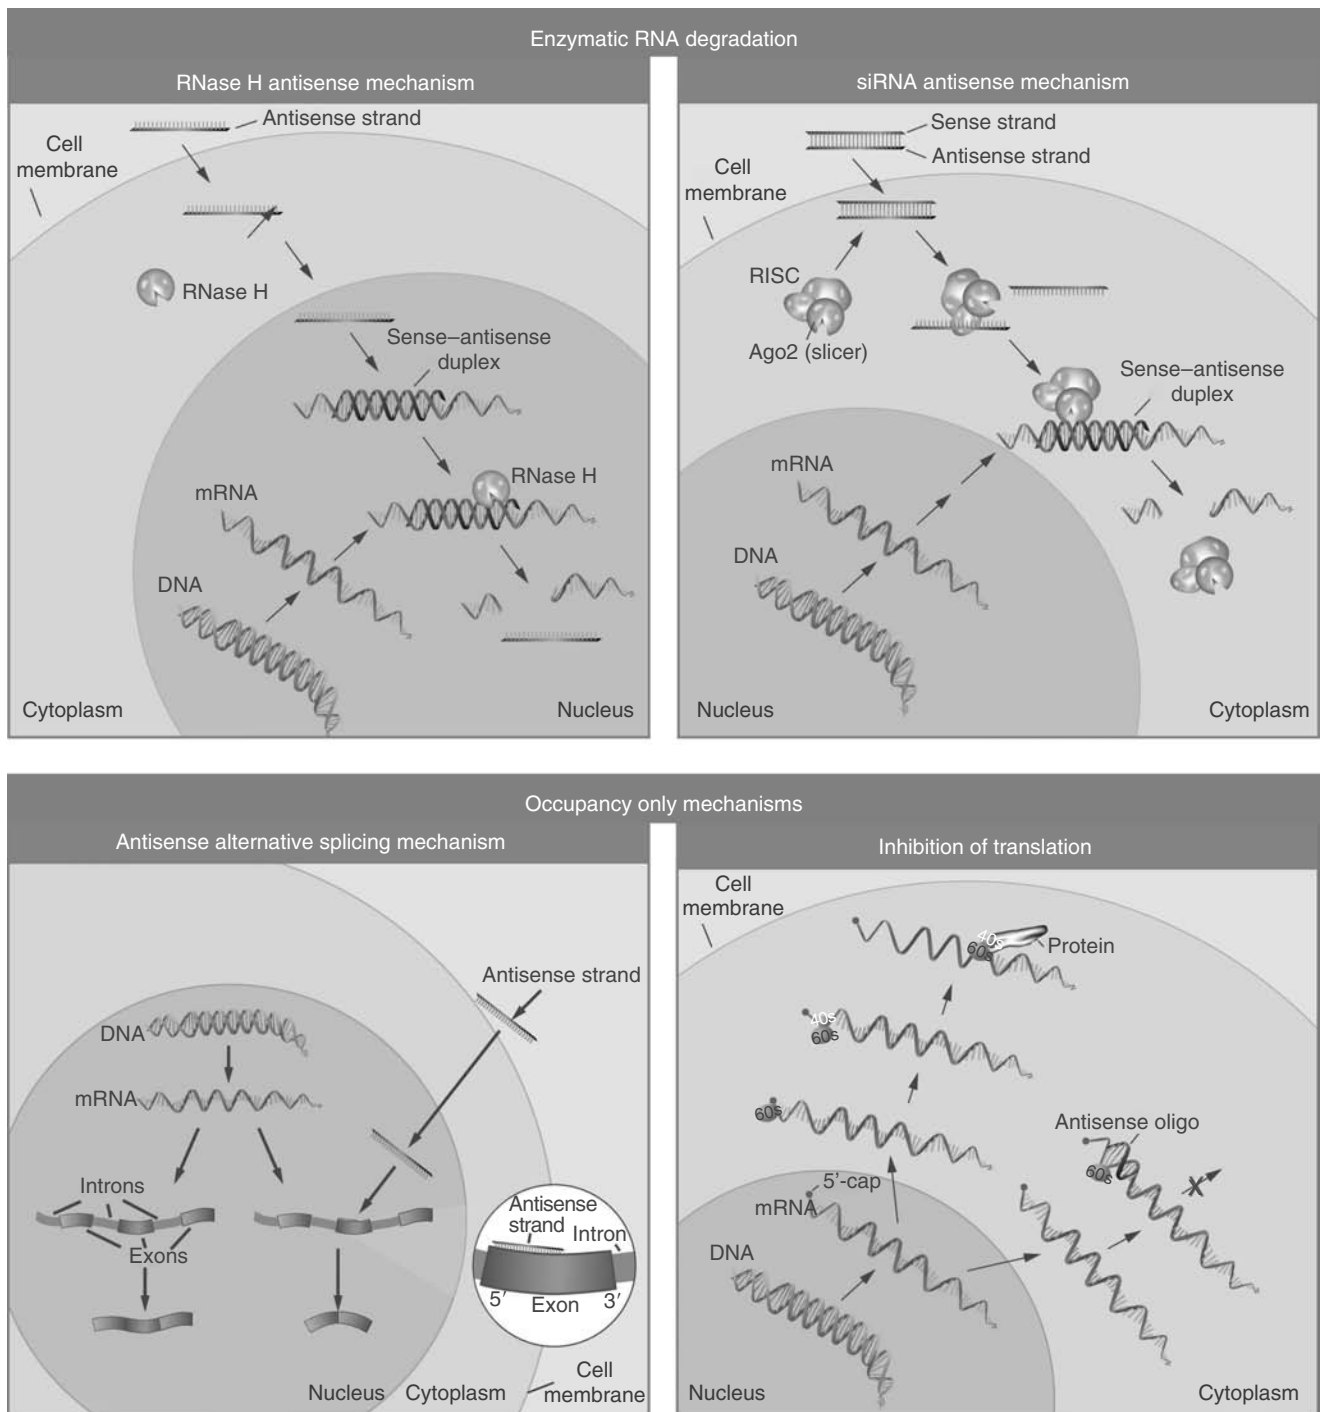

FIGURE 23.2 (See color insert following blank page 206.) Antisense mechanisms of action. Cartoon depicting three different mechanisms by which an antisense oligonucleotide can inhibit expression of a targeted gene product by hybridization to the mRNA or pre-mRNA, which codes for the gene product.

such as RNase H or RNA interference (RNAi) would result in more potent oligonucleotides, this has not necessarily been the case (Figure 23.3).

23.2.1 RNA DEGRADATION

Several studies have documented that phosphorothioate oligodeoxynucleotides promote cleavage of the targeted RNA by a

mechanism consistent with RNase H cleavage [7–12]. RNase H is a ubiquitously expressed enzyme, which cleaves the RNA strand of an RNA–DNA heteroduplex [11,13–15]. If the antisense oligonucleotide contains at least five consecutive DNA nucleotides, it is capable of directing RNase H to specifically cleave the target RNA upon binding.

Another RNase-dependent antisense mechanism that has recently received much attention is RNAi [16–21]. Introduction

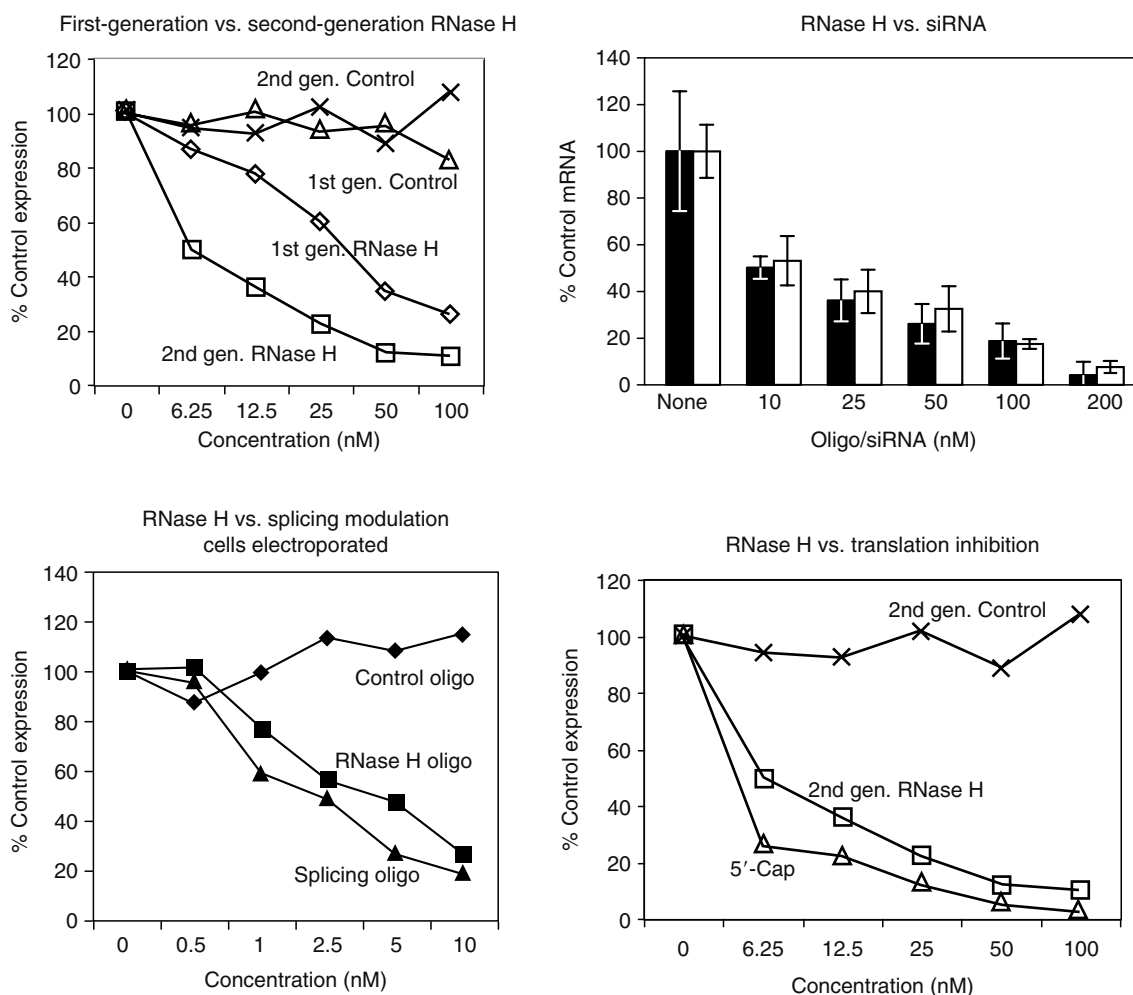

FIGURE 23.3 Comparison of the potency of oligonucleotides that work through different antisense mechanisms.

of long double-stranded RNA (dsRNA) into eukaryotic cells leads to the sequence-specific degradation of homologous gene transcripts. The long dsRNA molecules are metabolized to small 21–23 nucleotide-interfering RNAs (siRNAs) by the action of an endogenous ribonuclease [22–24]. The siRNA molecules bind to a protein complex, termed RNA-induced silencing complex (RISC), which contains a helicase activity that unwinds the two strands of RNA molecules, allowing the antisense strand to bind to the targeted RNA molecule [20,25]. The RISC contains an endonuclease, Ago 2, which hydrolyzes the target RNA by an RNase H-like mechanism at the site where the antisense strand is bound [26,27]. Therefore, RNAi is an antisense mechanism, as ultimately a single-strand RNA molecule binds to the target RNA molecule by Watson–Crick base pairing rules and recruits a ribonuclease that degrades the target RNA. More in depth discussion on RNAi is provided elsewhere in this book.

There are other RNases present in cells that may be exploited in manner similar to RNase H or the Ago 2 associated with RNAi. As an example, another RNase enzyme that has been

exploited for antisense applications is RNase L [28]. RNase L is ribonuclease activated by 2'–5'-linked oligoadenylates generated in response to interferon activation. Selective linkage of 2'–5'-oligoadenylate to an antisense oligonucleotide has been reported to promote selective cleavage of the targeted mRNA [28–30].

It should be noted that not all oligonucleotides designed to hybridize to a target RNA effectively inhibit target gene expression [7,31–33]. This is thought to be due to inaccessibility of some regions of the RNA to the oligonucleotide due to secondary or tertiary structure or to protein interactions with the RNA. At this time, there are no good predictive algorithms for predicting antisense oligonucleotide binding sites on a target RNA. Thus some serendipity is still involved in the process of identifying and optimizing potent and effective antisense inhibitors.

23.2.2 OCCUPANCY ONLY

Early on, it was thought that occupancy of the RNA (the receptor for the antisense oligonucleotide) by the oligonucleotide would be sufficient to block translation of the RNA, i.e., translation

arrest [34]. Subsequent studies have documented that oligonucleotides are not efficient at blocking translation of mRNA if they bind 3' to the AUG translation initiation codon. Furthermore, we have found that only certain sites in the 5'-untranslated region of an mRNA are effective target sites for an antisense oligonucleotide. In particular, the 5'-terminus of a transcript appears to be a good target site for oligonucleotides for some molecular targets in that occupancy of this region prevents assembly of the ribosome on the RNA [35]. It should be noted that occupancy of the receptor (RNA) and steric blocking factor of binding by high-affinity oligonucleotides can be an efficient mechanism for blocking gene expression. For the example cited above, the steric blocking oligonucleotide was approximately 10-fold more potent than an oligonucleotide that supports RNase H activity. These results suggest that catalytic turnover of the target RNA is not the rate-limiting step for antisense oligonucleotides.

Another process through which noncatalytic oligonucleotides can alter gene expression is by regulating RNA processing. Most mammalian RNAs undergo multiple post- or cotranscriptional processing steps including addition of a 5'-cap structure, splicing, and polyadenylation. Because single-stranded antisense oligonucleotides localize to the cell nucleus [36–39], they have the potential of regulating these processes. Several studies have been published documenting that antisense oligonucleotides can be used to regulate RNA splicing in both cell-based assays and in rodent tissues [40–50]. Oligonucleotides can be used to modulate alternative splicing by promoting use of cryptic splice sites as was exemplified for β -thalassemia and SMN-2 [40,41,48,51], by enhancing use of an alternative splice site [45]. Oligonucleotide binding to the pre-mRNA can also be exploited to mask polyadenylation signals on the pre-mRNA, forcing the cell to utilize alternative poly A sites [52]. Finally, oligonucleotides can regulate RNA function by sterically preventing factors from binding or changing the structure of the RNA such that it is no longer recognized by the factor. Thus there are multiple mechanisms by which oligonucleotides can be utilized to inhibit or modulate expression of a target gene product. No single mechanism is vastly superior to other mechanisms, thus one should select the antisense mechanism that best addresses the specific biological need.

23.3 ANTISENSE OLIGONUCLEOTIDE CHEMISTRY

The most advanced oligonucleotide chemistry used for antisense drugs is phosphorothioate oligodeoxynucleotides. These differ from natural DNA in that one of the nonbridging oxygen atoms in phosphodiester linkage is substituted with sulfur (Figure 23.1). Phosphorothioate oligodeoxynucleotides are commercially available, easily synthesized, support RNase H activity, exhibit acceptable pharmacokinetics for systemic and local delivery, and have not exhibited major toxicities, which would prevent their use in humans. There have been significant resources employed to identify chemical modifications that further improve upon the properties of phosphorothioate oligodeoxynucleotides. The primary objectives of the effort

FIGURE 23.4 Positions, which have been chemically modified, for antisense oligonucleotides.

are similar to medicinal chemistry efforts for other types of pharmacological agents, i.e., to increase potency, improve pharmacokinetics, and to decrease toxicity.

A dimer of an oligonucleotide depicting subunits that may be modified to enhance oligonucleotide drug properties is depicted in Figure 23.4. In naturally occurring nucleic acids, these subunits are composed of heterocycles, carbohydrate sugars, and phosphodiester-based linkages between the sugars. The combination of the carbohydrate sugar (ribose in RNA, 2'-deoxyribose in DNA) and the linkage provides the backbone of the oligonucleotide polymer. Many modifications have been made on the individual base, sugar, and linkage subunits, and the sugar-phosphate backbone has been completely replaced with an appropriate substitute. Additionally, many diverse moieties have been conjugated to various positions in the subunits, mainly in an attempt to alter the biophysical properties of the polymer. Finally, prodrug modifications may be employed to enhance drug properties. Most of the positions available in a nucleoside dimer (approximately 25 positions for each dimer that do not directly interfere with Watson-Crick base pair hydrogen bonding) have been modified and studied for their effects on the properties of the resulting oligonucleotides.

The nucleobases or heterocycles of nucleic acids provide the recognition points for the Watson-Crick base pairing rules and any oligonucleotide modification must maintain these specific hydrogen bonding interactions. Thus, the scope of heterocyclic modifications is somewhat limited. The relevant heterocyclic modifications can be grouped into two structural classes: those that enhance base stacking and those that provide additional hydrogen bonding. The primary objective of heterocyclic modifications is to enhance hybridization, resulting in increased affinity (Figure 23.4). Modifications that enhance base stacking by expanding the π -electron cloud are represented by conjugated, lipophilic modifications in the 5-position of pyrimidines, such as propynes, hexynes, azoles, and simply a methyl group [53–56] and the 7-position of 7-deaza-purines position including iodo, propynyl, and cyano groups [57–59]. Investigators have continued to build out of the 5-position of cytosine by going from the propynes to five-membered heterocycles to tricyclic fused systems emanating from the 4,5-positions of cytosine clamps (Figure 23.5) [60–63]. A second type of heterocycle modification is represented by

FIGURE 23.5 Examples of different heterocycle modifications, which support antisense activity.

the 2-amino-adenine (Figure 23.4), where the additional amino group provides another hydrogen bond in the A-T base pair, analogous to the three hydrogen bonds in a G-C base pair. Heterocycle modifications providing a combination of effects are represented by 2-amino-7-deaza-7-modified A [59] and the tricyclic cytosine analog having hydrogen bonding capabilities in the major groove of heteroduplexes [62] (Figure 23.4). Furthermore, N^2 -modified 2-amino adenine-modified oligonucleotides have exhibited interesting binding properties [64,65]. All of these modifications are positioned to lie in the major or minor groove of the heteroduplex, do not affect sugar conformation of the heteroduplex, provide little nuclease resistance, but will generally support an RNase H cleavage mechanism.

Modifications in the ribofuranosyl moiety have provided the most value in the quest to enhance oligonucleotide drug properties (Figure 23.5). In particular, certain 2'-*O*-modifications

have greatly increased binding affinity, nuclease resistance, altered pharmacokinetics, and are potentially less toxic [66]. Preorganization of the sugar into a 3'-*endo* pucker conformation is responsible for the increased binding affinity [67–69]. The 2'-*O*-methoxyethoxy (MOE) and 2'-*O*-methyl modifications (Figure 23.5) are the most advanced of the 2'-modified series having entered clinical trials and showing promising results in the clinic [70,71]. The cationic 2'-*O*-aminopropyl [72] and 2'-*O*-(dimethylaminoethoxyethyl) [73,74] have shown favorable binding affinity, with dramatically improved nuclease resistance. In an attempt to extend on the increased nuclease resistance of these cationic modifications to the high affinity seen with MOE, a dimethylaminoethoxyethyl version (DMAEOE) was prepared. This modification displays hybridization properties equal to or superior to that those of 2'-*O*-methoxyethyl, and nuclease resistance equal to that of the 2'-*O*-aminopropyl modification.

The sugar modification showing the largest known improvement in binding affinity is a bicyclic system having the 4'-carbon tethered to the 2'-hydroxyl group. As this modification “locks” the conformation of the ribose sugar into an RNA-like (3'-endo) conformation, it is referred to as locked nucleic acid (LNA) [75,76]. LNA shows dramatically improved hybridization affinity with regard to a reference DNA:RNA duplex and has increased nuclease resistance compared to RNA or DNA. LNA oligonucleotides have shown utility in several antisense oligonucleotide designs and have increased potency compared to first-generation oligonucleotides in several mouse models [76–79]. However, several oligonucleotides tested in mice exhibited profound hepatotoxicity, resulting in a decrease in the therapeutic index [79]. Two different oligonucleotide-containing LNA nucleosides are in phase I clinical trials for the treatment of cancer (Table 23.1). While extremely promising from early biophysical and *in vitro* data, it remains to be seen whether these properties will translate into oligonucleotides with acceptable therapeutic index for broad therapeutic applications.

It is now well known that uniformly 2'-O-modified oligonucleotides do not support an RNase H mechanism [80].

The heteroduplex formed has been shown to present a structural conformation that is recognized by the enzyme but cleavage is not supported [15,81,82]. Thus, uniformly modified, “RNA-like” oligonucleotides (3'-endo sugar conformation) will be unable to effect cleavage of the target mRNA and must therefore exert their effects via other means. This has led to the development of a chimeric strategy [8,80,83–85], which focuses on the design of high-affinity, nuclease-resistant antisense oligonucleotides that contain a “gap” of contiguous phosphorothioate-modified oligodeoxynucleotides (Figure 23.6). On hybridization to target RNA, a heteroduplex is presented, which supports an RNase H-mediated cleavage of the RNA strand via interaction with the 2'-deoxy gap region. The stretch of the modified oligonucleotide–RNA heteroduplex, which is recognized by RNase H may be placed anywhere within the modified oligonucleotide. The modifications in the flanking regions of the gap should not only provide nuclease resistance to exo- and endonucleases, but also not compromise binding affinity and base pair specificity. There are several types of structures that have been successfully developed (Figure 23.6), with the most advance being “gapmers,” having a 7 to 10 base oligodeoxynucleotide gap flanked by 2 regions of

FIGURE 23.6 Examples of different sugar and backbone modifications that support antisense activity.

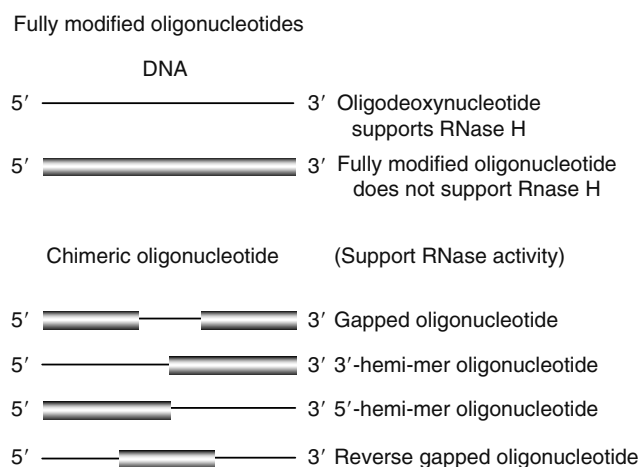

FIGURE 23.7 Examples of different oligonucleotide structures.

2'-modified nucleosides (Figure 23.7). These oligomers, in particular 2'-MOE modified, show reduced toxicity, increased potency, and superior pharmacokinetics relative to the parent-unmodified 20-mer phosphorothioate oligodeoxynucleotide [85–89].

Several possible mechanisms exist for uniformly modified, non-RNase H activating oligonucleotides to show efficacy, such as prevention of assembly of the ribosome through binding in the 5'-UTR, “translation arrest” or ribosome stalling by blocking the reading of the mRNA ribosome, and modulation of splicing events by binding to splice junctions. While all of these strategies have been pursued, no uniformly modified oligonucleotides have advanced beyond RNase H oligonucleotides. However, much recent progress has been made with non-RNase H active oligonucleotides and there remains much potential for these modifications. LNA and MOE have been used in a uniform context in addition to the gapmer strategy (Figure 23.7), and early studies show promise. Another interesting uniform modification is the phosphoramidate modification, which substitutes an amino group for the 3' oxygen atom of the deoxyribose sugar of DNA. This results in a preference for the RNA-like (3' endo) sugar conformation, and results in increased affinity as is seen with the 2'-O-alkyl modifications [90,91].

One of the most intriguing backbone oligonucleotide modifications is peptide nucleic acid (PNA). PNA is unique in that the sugar-phosphate backbone is completely replaced with a peptide-based backbone (Figure 23.5) [92]. This results in a polymer with a neutral backbone that has high affinity for complementary nucleic acids. PNA has been extensively investigated as an antisense agent, but these efforts have generally been frustrated by the poor cellular penetration and *in vivo* pharmacokinetic properties of PNA [93]. A four-lysine peptide conjugated to a PNA was found to provide robust *in vivo* activity when targeted to a splice junction [47]. Extension of this work has led to additional PNA motifs, which display activity in cell culture in the absence of a transfection agent and promising pharmacokinetics in animals [94,95]. Although these

TABLE 23.2

Attributes of Various Modified Oligonucleotides

Attribute	Examples
Increased affinity for RNA	2'-O-methyl, 2'-fluoro, MOE, DMAEOE, LNA, 5-MeC, 5-propynyl, phenoxazine
Increased nuclease resistance	G-clamp, PNA, phosphoramidate, others
Alter tissue distribution	MOE, DMAEOE, LNA, PNA, phosphoramidate, morpholino, others
Decrease toxicity	MOE, PNA, cholesterol conjugate, phosphoramidate, morpholino, others
	2'-O-methyl, MOE, 5-MeC, morpholino, others

data are encouraging, initial pharmacological evaluation in animals has not yielded reproducible or robust effects. Thus more investment is required before the promise of PNA as an antisense therapeutic agent can be realized.

The most advanced uniform modification is the “morpholino” modification (Figure 23.6), which is currently in phase II clinical trials (Table 23.1). The morpholino modification simultaneously replaces the ribofuranosyl sugar with a morpholine ring and the negatively charged phosphate ester with a neutral phosphorodiamidate linkage [96,97]. Morpholinos are generally used around the translation initiation start codon and are believed to function via translation arrest. A morpholino oligonucleotide has shown *in vivo* activity [98], as well as oral bioavailability in rats [99], which would be a major advance if studies proved general and translated to larger mammalian species.

In addition to heterocycle, backbone, and sugar modifications discussed above, various pendant groups have been attached to oligonucleotides such as cholesterol, folic acid, fatty acids, etc. to alter pharmacokinetic properties [100,101]. The reader is referred to several reviews, which discuss the chemistry of oligonucleotides in more detail [102–106]. It should be noted that there is no single modification that covers all the desired properties for a modified oligonucleotide. Modifications have been identified, which increase hybridization affinity of the oligonucleotide for its target RNA, increase nuclease resistance, decrease toxicity, and alter the pharmacokinetics (Table 23.2). Furthermore, the ideal oligonucleotide will differ for different applications. Therefore, it is important to be able to mix and match the various modifications so as to obtain the optimal oligonucleotide for the task at hand.

23.4 PHARMACOKINETICS OF OLIGONUCLEOTIDES

23.4.1 CELLULAR PHARMACOKINETICS

Cellular uptake of phosphorothioate oligonucleotides has been documented to occur in most mammalian cells [107–114]. Cellular uptake of oligonucleotide is time- and temperature-dependent. It is also influenced by cell type, cell culture

conditions and media, and the length/sequence of the oligonucleotide itself [107]. No obvious correlation between the lineage of cell, whether the cells are transformed or virally infected, and uptake has been identified. Cellular uptake appears to be an active process, i.e., oligonucleotide will accumulate in greater concentration intracellular than in the medium and is energy-dependent. Despite the fact that mammalian cells in culture will readily accumulate oligonucleotides, it has been necessary to further facilitate cytosolic delivery for many, but not all cells with transfection agents such as cationic lipids, dendrimers, fusogenic peptides, electroporation, etc. [38,115–119,46]. In the absence of these facilitators, it has been difficult to demonstrate true antisense effects in cultured cells although there are some exceptions. However, *in vivo* this is not the case. It has become apparent that *in vitro* cell uptake studies do not predict *in vivo* cell uptake and pharmacokinetics of oligonucleotides [107,158,120–124]. Our understanding of cellular and subcellular uptake has evolved as superior analytical tools have been developed. These advances include development of immunohistochemical techniques utilizing oligonucleotide-specific antibodies [125] or *in situ* hybridization with labeled oligonucleotide probes.

Our understanding of cellular and subcellular distribution and pharmacokinetics of oligonucleotides in whole animals is emerging. In our laboratories, we have utilized more specific tools for qualification and even quantification of intact oligonucleotide [121,125–127]. Phosphorothioate oligonucleotides rapidly distribute to whole tissue with distribution half-lives ranging from 30 to 60 min *in vivo*. Approximately half of the oligonucleotide associated with the liver (as an example) is intracellular in both parenchymal and nonparenchymal cells by 4 h after intravenous administration [121,128]. The other half of the organ-associated oligonucleotide appears to be associated with extracellular matrix, interstitium, or loosely bound to the cell membrane. Consistent with this observation, others have shown that phosphorothioates have been localized to connective tissue and can bind to various proteins within these matrices such as laminin and fibronectin [125,129,130]. Some of this matrix-associated oligonucleotide will diffuse to cells over time or be lost to efflux from the organ [125]. It is likely that both of these processes are functioning up to 24 h after administration of oligonucleotide. By 24 h after injection of phosphorothioate oligonucleotide, very little is seen to be associated with extracellular matrix [125]. Thus, whole-organ pharmacokinetic evaluation after the initial 24 h distribution phase parallels cellular clearance kinetics.

Although the *in vitro* studies fail to predict well which cell types will take up oligonucleotide *in vivo*, the general trend of variability from cell type to cell type continues to be observed *in vivo* [125]. Based upon these results, one would not expect to uniformly inhibit expression of a targeted gene product within a tissue or whole organism, resulting in differential sensitivity of different tissues and cells within tissue to the antisense effect. Subcellular distribution has been shown to be broad and the extent of cytosolic and nuclear distribution differs between cells [121]. In general, the total number of oligonucleotide molecules is greatest in the cytosol. However,

because of the much smaller volume of the nucleus, the nucleus may often contain a higher concentration of oligonucleotide than cytosol.

Nuclease metabolism has been shown to account for the clearance of phosphorothioate oligonucleotide from organs of distribution. Within the cells, the pattern of metabolites appears to be quite similar between cell types and the subcellular compartments (membrane associated, cytosolic, and nuclear). Increasing doses from 5 to 50 mg/kg only moderately decreased metabolism inside cells consistent with whole-organ data [121].

Several studies have suggested that active uptake processes including receptor-mediated endocytosis and pinocytosis are involved in uptake of oligonucleotides *in vivo*. At very low doses (less than 1 mg/kg), competition of binding for scavenger receptors *in vivo* altered the whole-organ distribution of oligonucleotides in liver but not kidney [131–133]. However, distribution studies conducted in scavenger receptor knockout mice did not show significantly altered intracellular and whole-organ distribution of phosphorothioate oligonucleotides [134].

Distribution in the kidney has been more thoroughly studied, and drug has been shown to be present in Bowman's capsule, the proximal convoluted tubule, the brush border membrane, and within renal tubular epithelial cells [125,135]. These data suggested that the oligonucleotides are filtered by the glomerulus and then reabsorbed by the proximal convoluted tubule epithelial cells. Moreover, the authors identified a specific protein in the brush border that may mediate uptake. In subsequent studies, the authors have purified the 45 kDa protein, reconstituted it in phospholipid vesicles, and demonstrated that it served as a channel allowing nucleic acid to pass through phospholipid bilayers [136]. In separate studies, other investigators have shown that although some oligonucleotide is taken up from the tubular lumen brush border, the distribution to the tubule epithelial cells is predominantly from the capillary serosal side [137]. The uptake from capillary circulation may not be receptor-mediated. In summary, it is likely that there are multiple processes involved in the uptake of oligonucleotides into cells *in vivo*. Additional research will be required to further elucidate these mechanisms.

23.4.2 WHOLE-ANIMAL OLIGONUCLEOTIDE PHARMACOKINETICS

23.4.2.1 Phosphorothioate Oligodeoxynucleotides

The plasma pharmacokinetics of phosphorothioate oligodeoxynucleotides are characterized by rapid and dose-dependent clearance (30–60 min half-life) driven primarily by distribution to tissue and secondarily by metabolism. Only a minor fraction of a parenteral dose of phosphorothioate oligonucleotide is excreted in urine or feces by 24 h after administration [138–141]. Dose-dependent distribution kinetics from plasma is predominantly a function of saturable tissue distribution [140,142]. Metabolism has been shown to be unchanged in plasma over a large dose range (1–50 mg/kg) and after repeated

administration up to 1 month, suggesting that metabolism is neither inhibited or induced by repeat administration [143].

The plasma pharmacokinetics are quite similar between animals and humans, and they scale from one species to the next on the basis of body weight, not surface area [138, 143–146]. For example, it is possible to show that, when dosed on the basis of body weight, the concentrations of oligonucleotides in plasma administered by a 2h constant intravenous infusion are similar between humans and monkeys. Thus it has been possible to predict plasma concentrations in humans from nonclinical pharmacokinetic data.

Phosphorothioate oligonucleotides bind to circulating plasma proteins such as albumin and α -2-macroglobulin [147,148]. The apparent affinity for human serum albumin is low (10–30 μ M). Therefore, plasma protein-binding provides a repository for these drugs preventing rapid renal excretion. Because serum protein binding is saturable at high concentrations, intact oligonucleotide may be found in urine in increasing amounts as dose rate and/or amount is increased [143, 149,150].

Phosphorothioate oligonucleotides are rapidly and extensively absorbed after intradermal, subcutaneous, intramuscular, or intraperitoneal administration [120,142,151,152]. Nonparenteral absorption has been characterized for pulmonary and oral routes of administration. Estimates of bioavailability range from 3% to 20% following intratracheal dosing, and <1% by the oral route [153,154]. Although permeability in the intestine is low, stability of these compounds in the intestine (prior to absorption) may be a rate-limiting factor to oral absorption [155,156]. As discussed below, some chemical modifications to the oligonucleotide enhance oral absorption. The metabolic half-life of a 20-mer phosphorothioate oligonucleotide in the rat intestine (*in vivo*) is less than 1h (data shown in formulation section of this chapter).

Phosphorothioates are broadly distributed to all peripheral tissues. Highest concentrations of oligonucleotides are found in the liver, kidney, spleen, lymph nodes, and bone marrow with no measurable distribution to the brain [120,142,143,149,155]. Many other tissues take up smaller amounts of oligonucleotide, resulting in lower tissue concentrations. Phosphorothioate oligonucleotides are primarily cleared from tissues by nuclease metabolism. Rate of clearance differs between tissues with the spleen, lymph nodes, and liver generally clearing more rapidly than kidney, for example. In general, the clearance rates result in half-lives of elimination ranging from 2 to 5 days in rodents and primates [140,146].

In summary, pharmacokinetic studies of phosphorothioate oligonucleotides demonstrate that they are well absorbed from parenteral sites, distribute broadly to all peripheral tissues, do not cross the blood–brain barrier, and are eliminated primarily by slow metabolism. In short, once-a-day or every-other-day systemic dosing should be feasible. In general, the pharmacokinetic properties of this class of compounds appear to be largely driven by chemistry rather than sequence. Additional studies are required to determine whether there are subtle sequence-specific effects on the pharmacokinetic profile of this class of drugs.

23.4.2.2 Second-Generation Oligonucleotides

The plasma pharmacokinetics of 2'-*O*-methyl-, 2'-*O*-propyl-, or 2'-*O*-methoxyethyl-modified oligonucleotides do not differ significantly from their phosphorothioate oligodeoxynucleotide congeners [87,88,147,157]. Since metabolism plays only a minor role in the plasma distribution kinetics, 2'-ribose modifications do very little to alter the distribution and excretion kinetics. Early studies in our laboratory indicate that the binding affinity to serum albumin may be somewhat lessened by 2'-ribose sugar modifications, but the overall capacity of the plasma proteins to bind these oligonucleotides is not significantly changed (Table 23.3). Therefore, urinary excretion remains a minor route of elimination and these compounds are broadly distributed to peripheral tissues.

Several of the 2'-ribose sugar modification produces enough of an increase in nuclease resistance that it is possible to produce relatively stable oligonucleotides with phosphodiester linkages (Table 23.2). Thus this modification allows for elimination or reduction in the number of sulfurs contained in the internucleotide bridge, but these compounds are less stable than their 2'-modified phosphorothioate congeners [158]. In addition, as sulfur is removed, plasma protein binding is greatly decreased and rapid removal from plasma by filtration in the kidney increases significantly. This pharmacokinetic characteristic may limit the use of phosphodiester second-generation modified oligonucleotides intended for treatment of systemic disease [87]. Alternatively, this pharmacokinetic profile may be ideal for locally administered oligonucleotides since it limits the accumulation of systemically absorbed drug.

Absorption for parenterally administered modified oligonucleotides is consistently rapid and nearly complete. Some of the second-generation modified oligonucleotides have exhibited improved intestinal permeability [155] as well as significantly improved stability in the intestine [156]. This combination of improved biochemical characteristics has led

TABLE 23.3
Serum Albumin Affinity, Whole Plasma Fraction Bound to Proteins (F_b), and Fraction of Dose Excreted in Urine (f_{excreted} , 0–24 h) Following Intravenous Administration At 3 mg/kg: Comparison of First- and Second-Generation Chemistries

Compound No.	Chemistry	K_d (μ M)	F_b (%)	f_{excreted}
ISIS 2302	PS ODN	17.7	99.2	0.003
ISIS 11159	PS 2'-MOE	29.3	95.5	0.032
ISIS 16952	PO 2'-MOE	>500	79.6	0.45

Note: PS ODN, phosphorothioate oligodeoxynucleotide; PS 2'-MOE, 2'-*O*-methoxyethyl ribose modified phosphorothioate (all nucleotides were modified); PO 2'-MOE, 2'-*O*-methoxyethyl ribose modified phosphodiester (all nucleotides were modified).

TABLE 23.4
Summary of Observed Organ Clearance Half-Lives
(in Days) Comparing First- and Second-Generation
Chemistries

Organ	2'-Modified Phosphorothioate Oligonucleotide ^a	Phosphorothioate Oligodeoxynucleotide
Kidney cortex	20–30	5.0
Kidney medulla	10–20	3.1
Liver	14–30	2.8
Spleen	8–15	3.3
Lymph nodes	16–24	0.9
Bone marrow	12–16	1.3

^a Observed half-life range for more than five different chimeric 2'-MOE/2'-deoxy modified phosphorothioate oligonucleotide; differences apparently due to sequence. (From Krutzfeldt, J., Rajewsky, N., Braich, R., Rajeev, K. G., Tuschl, T., Manoharan, M., and Stoffel, M. *Nature*, 685, 438, 2005.)

to the observation of improved oral bioavailability [155] for this class of oligonucleotide compounds.

The distribution pattern of the 2'-ribose-modified phosphorothioate oligonucleotides is similar to first-generation phosphorothioates and similarly not altered by changes in sequence. Kidney, liver, spleen, bone marrow, and lymph nodes are the major sites of distribution. The most exciting difference in pharmacokinetics is not surprisingly manifested in prolonged terminal elimination half-lives from tissues of distribution. The elimination half-lives appear to be increased nearly 5–10-fold suggesting that once-weekly systemic dosing may be feasible (Table 23.4). Subsequent nonclinical and clinical testing have confirmed the effectiveness of once weekly dosing frequency for 2'-MOE-modified antisense oligonucleotides [70,127,141,159–164].

In summary, pharmacokinetic studies of 2'-modified ribose phosphorothioate oligonucleotides demonstrate that they are well absorbed from parenteral sites, may have improved oral absorption attributes, and distribute broadly to all peripheral tissues. Although stability has been greatly enhanced, nuclease metabolism remains the primary mechanism for ultimate elimination of these modified oligonucleotides [139,163]. In short, once-a-week systemic dosing should be feasible and oral administration may be possible in the near future. Additional studies are required to determine whether there are substantial sequence-specific effects on the pharmacokinetic profile of this class of drugs.

23.5 TOXICOLOGY OF OLIGONUCLEOTIDES

Phosphorothioate oligodeoxynucleotides have been examined extensively in a full range of acute, chronic, and reproductive studies in rodents, lagomorphs, and primates. At high doses, there is a distinctive pattern of toxicity that is common to all phosphorothioate oligodeoxynucleotides [165–168]. The remarkable similarity in toxicity with different phosphorothioate

oligodeoxynucleotides suggests that, for this class of antisense compounds, toxicity is independent of sequence and is the result of nonantisense-mediated mechanisms. The most probable mechanism of the observed toxicities is the binding of phosphorothioate oligodeoxynucleotides to proteins. These nonantisense-mediated pathways are thought to be responsible for most, if not all, of the toxicities associated with the administration of these compounds to laboratory animals. This conclusion is strengthened by studies in which little or no differences in toxicity is observed between pharmacologically active and inactive sequences. Different patterns of toxicity exist between rodents and primates. Understanding the mechanisms behind these differences is crucial to understanding which species best predicts the potential human effects. A comparison of the toxicological profiles of phosphorothioate oligodeoxynucleotides with that of the second-generation phosphorothioate oligonucleotides suggests that some of the chemical class-related toxicities of phosphorothioate oligodeoxynucleotides can be ameliorated by chemical modification.

A number of phosphorothioate oligodeoxynucleotides have been examined in one or more of the following battery of genotoxicity assays: Ames test, *in vitro* chromosomal aberrations, *in vitro* mammalian mutation (hypoxanthine-guanine phosphoribosyl transferase [HGPRT] locus and mouse lymphoma), *in vitro* DNA synthesis tests, and *in vivo* mouse micronucleus. In all of these assays, the results were negative and there was no evidence of mutagenicity or clastogenicity of these compounds [169].

23.5.1 ACUTE TOXICITIES

23.5.1.1 Phosphorothioate Oligodeoxynucleotides

In rodents, the acute toxicity of phosphorothioate oligodeoxynucleotides has been characterized as part of an effort to determine the maximum tolerated dose for *in vivo* genotoxicity assays. The doses of three phosphorothioate oligodeoxynucleotides required to produce 50% lethality (LD₅₀) were estimated to be approximately 750 mg/kg [169].

In primates, the acute dose-limiting toxicities are a transient inhibition of the clotting cascade and the activation of the complement cascade [165,170,171]. Both of these toxicities are thought to be related to the polyanionic nature of the molecules and the binding of these compounds to specific protein factors in plasma.

Prolongation of clotting times following administration of different phosphorothioate oligodeoxynucleotides is characterized by a concentration-dependent prolongation of activated partial thromboplastin times (aPTT) [168,172–174]. The prolongation of aPTT is highly transient and directly proportional to plasma concentrations of phosphorothioate oligodeoxynucleotide and therefore parallels the plasma drug concentration curves with various dose regimens. As drug is cleared from plasma, the inhibition diminishes such that there is complete reversal within hours of dosing. With repeated administration, there is no evidence of residual inhibition. Prolongation of aPTT has been observed in all species examine

to date, including human, monkey, and rat. The mechanism of prolongation of aPTT by phosphorothioate oligodeoxynucleotides is thought to be a result of the interaction of the oligonucleotides with proteins. It is well known that polyanions are inhibitors of clotting, and phosphorothioate oligodeoxynucleotides may act through similar mechanisms. If these oligonucleotides inhibit the clotting cascade as a result of their polyanionic properties, then binding and inhibition of thrombin would be a likely mechanism of action. However, the greater sensitivity of the intrinsic pathway to inhibition by phosphorothioate oligodeoxynucleotides suggests that there are other clotting factors specific to this pathway that may be inhibited as well. Recent data suggest that there is a specific allosteric inhibition of the tenase complex as well as binding to thrombin [171,175].

Activation of the complement cascade by phosphorothioate oligodeoxynucleotides has the potential to produce the most profound acute toxicological effects. In primates, treatment with high doses over short infusion times (i.e., generating high C_{\max} values) resulted in marked hematological effects and marked hemodynamic changes that are thought to be secondary to complement activation. Hematological changes are characterized by transient reduction in neutrophil counts, presumably due to margination, followed by neutrophilia with abundant immature, nonsegmented neutrophils [166,170]. In a small fraction of monkeys, complement activation was accompanied by marked reductions in heart rate, blood pressure, and subsequently cardiac output. In some animals, these hemodynamic changes were lethal [165,170,176].

There is an association between cardiovascular collapse and complement activation. That is, all monkeys demonstrating some degree of cardiovascular collapse or hemodynamic changes had markedly elevated levels of complement split products. However, the converse is not true, in that only a fraction of the animals with activated complement had cardiovascular functional changes [169]. Thus, this observation suggests that there may be sensitive subpopulations or predisposing factors within individual animals that make them susceptible to the physiologic sequelae of complement activation. Because of these observed hemodynamic changes, primate studies to monitor for these effects have become part of the normal evaluation of these compounds [177,178]. Although complement activation at high doses is consistent and predictable between animals, there is currently little appreciation for the variability in the severity of the associated hemodynamic changes. While the split product Bb can be used to monitor complement activation, it is C5a (complement split product) that is the most biologically active split product. Preliminary data obtained relating response to complement split product levels indicate that C5a levels are elevated more significantly in some of the more affected animals [169].

The goal of toxicity studies is to characterize the toxicity of compounds and to establish a framework upon which clinical safety studies can be designed. In this regard, it is useful to examine the relationship between plasma concentrations of oligonucleotides and the activation of complement. When Bb concentrations were plotted against the concurrent plasma concentrations of oligodeoxynucleotides in primates, it was

apparent that complement was only activated at concentrations of phosphorothioate oligodeoxynucleotides that exceed a threshold value of 40–50 $\mu\text{g}/\text{mL}$ [170]. Bb levels remained unchanged from control values at plasma concentrations below the threshold. Remarkably, this threshold concentration is similar for three 20-mer phosphorothioate oligodeoxynucleotides and for an 8-mer phosphorothioate oligodeoxynucleotide that forms a tetrad complex [179,180]. Recent data demonstrate that human serum may be less sensitive to activation than monkey serum, suggesting a species difference in sensitivity. Regardless of small differences, it is clear that clinical dose regimens should be designed to avoid plasma oligodeoxynucleotide concentrations that exceed 40–50 $\mu\text{g}/\text{mL}$. To this end, the similarities in plasma pharmacokinetics between monkeys and humans have allowed the design of dose regimens that achieve desired plasma concentration profiles.

The most direct approach for staying below the plasma thresholds for complement activation is to reduce the dose rate by substituting prolonged infusions for bolus injections. In clinical trials with phosphorothioate oligodeoxynucleotides, the drugs are administered either as 2 h infusions or as constant 24 h infusions. At a rate of infusion of 2 mg/kg over 2 h, the C_{\max} was 8–15 $\mu\text{g}/\text{mL}$, still well below the threshold for complement activation [144]. Phosphorothioate oligodeoxynucleotides have been administered by intravenous infusion to more than 3000 patients and volunteers without any significant indication of activation of the alternative complement cascade.

23.5.1.2 Modified Oligonucleotides

Replacement of phosphorothioate linkages with natural occurring phosphodiester linkages in oligodeoxynucleotides may reduce the potential to activate complement. However, as noted above, reduction of phosphorothioate linkages dramatically reduces distribution of oligonucleotide to tissues, diminishing the pharmacological effects. As a result, for antisense drugs that work inside of cells, replacement of phosphorothioate linkages with phosphodiester linkages may not be a viable approach for systemically administered drugs. Second-generation oligonucleotides containing 2'-*O*-methoxyethyl modifications appear to have a lower potency for complement activation in primates and anticoagulant effects [168,169,181]. The plasma concentration thresholds for complement activation are markedly increased for 2'-*O*-methoxyethyl-modified oligonucleotides, which may be due to the decrease in protein interactions this modification confers onto an oligonucleotide. Although the safety profile of phosphorothioate oligodeoxynucleotides has proven satisfactory, the acute safety profile of the next generation of oligonucleotides appears to be improved by the 2'-*O*-methoxyethyl modification.

23.5.2 TOXICOLOGICAL EFFECTS ASSOCIATED WITH CHRONIC EXPOSURE

23.5.2.1 Phosphorothioate Oligodeoxynucleotides

One of the characteristic toxicities observed with repeated exposure of rodents to phosphorothioate oligodeoxynucleotides is

a profile of effects that can be described as immune stimulation. The profile is characterized by splenomegaly, lymphoid hyperplasia, and diffuse multiorgan mixed mononuclear cell infiltrates [168]. The severity of these changes is dose-dependent and most notable at doses equal to or exceeding 10 mg/kg. The mixed mononuclear cell infiltrates consisted of monocytes, lymphocytes, and fibroblasts and were particularly notable in liver, kidney, heart, lung, thymus, pancreas, and periadrenal tissues [167,182–184].

Although immune stimulation in rodents is thought to be a class effect of phosphorothioate oligodeoxynucleotides and not dependent on hybridization, sequence is an important factor in determining immunostimulatory potential [185–188]. Immunostimulatory motifs have been described in the literature and involve palindromic sequences and CpG (cytosine–guanosine) motifs [188].

Among the most remarkable features of oligodeoxynucleotide-induced immune stimulation are the species differences. Rodents are highly susceptible to this generalized immune stimulation, whereas primates appear to be relatively insensitive to the effect at equivalent doses. Even 6 months of treatment of cynomolgus monkeys with 10 mg/kg of a 20-mer oligodeoxynucleotide, ISIS 2302, given every other day produced only a relatively mild increase in B cell numbers in spleen and lymph nodes of the primates with no change in organ weights. The mixed mononuclear cellular infiltrates in liver and other organs that are so characteristic of the response in rodents are absent even after long-term exposure in monkeys [168]. It is evident that there are both species and sequence differences involved in immune stimulation and specific sequences should, if possible, be excluded from oligodeoxynucleotides.

Morphologic changes in the bone marrow of mice were observed after 2 weeks of treatment (3 doses/week) with 100–150 mg/kg phosphorothioate oligodeoxynucleotide. There was a reduction in number of megakaryocytes that were accompanied by a reduction of approximately 50% in circulating platelet counts [183]. Reductions in platelets have been observed in rats treated with 21.7 mg/kg ISIS 2105 given every other day [167], but were not observed in primates administered 10 mg/kg. Similarly, a reduction in platelets was observed in mice, but not in monkeys treated for 4 weeks with ISIS 2302 at doses of 100 and 50 mg/kg every other day, respectively. Similar observations were made for ISIS 5132 with reductions in platelets at 20 and 100 mg/kg in mice and no observed effect in monkeys up to 10 mg/kg [182]. These data suggest that the mouse may be more sensitive to these subchronic effects on platelets than nonhuman primates. However, in acute studies in primates, transient reductions in platelets are occasionally observed. These transient reductions in platelets occur acutely during 2 h infusions at doses of 10 mg/kg, reverse after completion of the infusion, and have not been associated with any measurable change in platelet number 24 to 48 h after subchronic or chronic treatment regimens [169]. Thrombocytopenia has been reported in AIDS patients treated with GEM 91, a 27-mer phosphorothioate oligodeoxynucleotide [189].

Tissue distribution studies have shown that the liver and kidney are major sites of deposition of phosphorothioate

oligodeoxynucleotide. In toxicity studies with phosphorothioate oligodeoxynucleotides, a variety of hepatic changes have been observed. The immune-mediated cellular infiltrates in rodent livers were discussed above. With high-dose administration of oligodeoxynucleotides in all species examined, there was a hypertrophic change in Kupffer cells accompanied by inclusions of basophilic material that was observed with hematoxylin and eosin staining. These basophilic granules have been identified as inclusions of oligodeoxynucleotide [125]. Furthermore, it was demonstrated that the presence of these inclusions was related to dose.

Hepatocellular changes were not a prominent feature of toxicity in primates. In cynomolgus monkeys, 50 mg ISIS 2302 per kg administered every other day for 4 weeks by intravenous injection produced no morphologic indication of liver toxicity, although there was a slight (1.5-fold) increase in aspartate aminotransferase (AST) in this group [190]. Following subcutaneous doses of ISIS 3521 and ISIS 5132 of up to 80 mg/kg every other day for four doses, there was Kupffer cell hypertrophy and periportal cell vacuolation, but no indication of necrosis and only a very slight increase in alanine aminotransferase (ALT) [169]. After 4 weeks of alternate-day dosing with 10 mg/kg via 2 h intravenous infusion of either ISIS 3521 or ISIS 5132, there were no alterations in AST or ALT, suggesting that at clinically relevant doses of these compounds, there was no evidence for hepatic pathology or transaminemia. In clinical trials with ISIS 2302, ISIS 3521, and ISIS 5132 at doses of 2 mg/kg administered by 2 h infusion on alternate days for 3–4 weeks, there was no indication of hepatic dysfunction nor was there any evidence of transaminemia.

Like Kupffer cells in the liver, renal proximal tubule epithelial cells take up oligodeoxynucleotide, as demonstrated by autoradiographic studies and immunohistochemistry as discussed previously [125,129,191,192] and by the use of special histologic stains [166]. The appearance of basophilic inclusions is dose-dependent in proximal tubule cells. Significant renal toxicity can be induced by extremely high doses. Doses of 80 mg/kg in rats and monkeys have induced both histologic and serum chemistry changes in the kidney [193]. At clinically relevant doses, however, there was no indication of renal dysfunction. In 4-week or 6-month toxicity studies with phosphorothioate oligodeoxynucleotides, we observed a much more subtle type of morphologic change in the kidney. At a dose of 10 mg/kg on alternate days, there was a decrease in the height of the brush border and enlarged nuclei in some proximal tubule cells. These changes have been characterized as minimal to mild tubular atrophic and regenerative changes. At a dose of 3 mg/kg and below, these changes were only infrequently observed if at all.

An important aspect of dose-dependent effects is characterization of exposure concentrations and their relationship to morphological changes. To assess exposure, concentrations of oligodeoxynucleotides have been measured in the renal cortex obtained in subchronic and chronic toxicity studies. Renal concentrations increase with increasing doses. The concentration of total oligodeoxynucleotide in the renal cortex associated with minimal to mild (although not clinically relevant) renal tubular atrophy or regenerative

changes is approximately 1000 $\mu\text{g/g}$ of tissue. The cortex concentrations of total oligodeoxynucleotides that are associated with moderate degenerative changes after subcutaneous doses of 40–80 mg/kg are greater than 2000 $\mu\text{g/g}$. At a clinically relevant dose of 3 mg/kg every other day, the steady-state concentration of total oligodeoxynucleotide in the kidney is in the range of 400–500 $\mu\text{g/g}$, thus demonstrating a significant margin of safety between the clinical doses and the doses associated with even the most minimal morphologic renal changes. Application of clearance and steady-state pharmacokinetic models suggests that continued administration of oligodeoxynucleotide at this dose should never achieve the renal concentrations associated with dysfunction [143]. These models have been confirmed in 6-month chronic toxicology studies where tissue concentrations measured at the end of 6 months of every other day dosing were no different than levels observed after 4 weeks of dosing at a similar or equivalent dose.

23.5.2.2 Chemical Modification of Oligodeoxynucleotides

Chemical modifications of oligodeoxynucleotides have been shown to reduce the potency of immune stimulation. The simplest modification with remarkable activity for reducing the immunostimulatory effects of oligodeoxynucleotides is the replacement of cytosine with 5-methyl cytosine. Methylation of a cytosine not in a CpG motif did not reduce the immunostimulatory potential [194]. In our experience with mice, when sequences with 5-methyl cytosine are compared with the same sequence without methylation, the methylated sequence has a lower potency for inducing immune stimulation, as determined by spleen weights and immune cell activation [195,196]. The addition of 2'-*O*-methyl and 2'-*O*-methoxyethyl substituents also reduced immunostimulatory potential [86,197]. In particular, we have found that 2'-*O*-methoxyethyl modification dramatically reduces signaling through Toll-like 9 receptors.

23.6 OLIGONUCLEOTIDE FORMULATIONS

23.6.1 PHYSICAL-CHEMICAL PROPERTIES

Due to the presence of a mixture of diastereoisomers, phosphorothioate oligodeoxynucleotides are amorphous solids possessing the expected physical properties of hygroscopicity, low-bulk density, electrostatic charge pick up, and poorly defined melting point prior to decomposition. Their good chemical stability allows storage in the form of a lyophilized powder, spray-dried powder, or a concentrated, sterile solution; more than 3 years of storage is possible at refrigerated temperatures.

Due to their polyanionic nature, phosphorothioate oligodeoxynucleotides are readily soluble in neutral and basic conditions. Drug-product concentrations are limited (in select applications) only by an increase in solution viscosity. The counterion composition, ionic strength, and pH also influence

the apparent solubility. Phosphorothioate oligodeoxynucleotides have an apparent pK_a in the vicinity of 2 and will come out of solution in acidic environments, i.e., the stomach. This precipitation is readily reversible with increasing pH or by acid-mediated hydrolysis.

Instability of phosphorothioate oligodeoxynucleotides has been primarily attributed to two degradation mechanisms: oxidation and acid-catalyzed hydrolysis. Oxidation of the (P=S) bond in the backbone has been observed at elevated temperatures and under intense UV light, leading to partial phosphodiester (still pharmacologically active) and are readily monitored by anion-exchange high-performance liquid chromatography. Under acidic conditions, hydrolysis reactions followed by chain-shortening depurination reactions have been documented by length-sensitive electrophoretic techniques.

23.6.2 PARENTERAL INJECTIONS

Given the excellent solution stability and solubility possessed by phosphorothioate oligodeoxynucleotides, it has been relatively straightforward to formulate the first-generation drug products in support of early clinical trials. Simple, buffered solutions have been successfully used in clinical studies by i.v., intradermal, and subcutaneous injections. And recently, the intravitreal route was approved for the first antisense drug application.

23.6.3 ORAL DELIVERY

Of the numerous barriers proposed by Nicklin et al. [152] to the oral delivery of oligonucleotides, our experience has confirmed that two factors stand out as critical: instability in the gastrointestinal (GI) tract and low permeability across the intestinal mucosa. Given the formidable nature of these two barriers, it is not surprising that oral delivery of oligonucleotides has been considered impossible, or at best difficult, as is the case with proteins, which has necessitated the latter's nonenteral administration in order to achieve systemic concentrations considered therapeutic. Nevertheless, progress has been made to address and understand each of these barriers with respect to oligonucleotides. (P=S)-oligonucleotides have a distinct advantage over proteins in that the former does not rely on secondary structure for activity. This provides freedom from concern over secondary structure destabilization and allows for (P=S)-oligonucleotide structural modifications to address both presystemic and systemic metabolism.

Natural DNA and RNA are rapidly digested by the ubiquitous nucleases found within the gut. As a consequence, oligonucleotides need to be stabilized in order to achieve a reasonable GI residence time to allow for absorption to occur. Surprisingly, phosphorothioate oligodeoxynucleotides were found to be rapidly degraded by nucleases found in the GI tract, therefore additional protection from nuclease degradation is required to achieve significant oral bioavailability. Oligonucleotides that are uniformly modified or modified on

the 3'-end (gapmers or 3'-hemimers; Figure 23.6) with nuclease-resistant modification have the potential to exhibit increased oral bioavailability. This was demonstrated for both backbone modifications (methylphosphonates) and sugar modified (2'-*O*-methyl) oligonucleotides [155,198]. We have found that 2'-*O*-methoxyethyl-modified oligonucleotides also exhibit increased oral absorption compared to phosphorothioate oligodeoxynucleotides [156,199,200].

The physicochemical properties of phosphorothioate oligodeoxynucleotides present a significant barrier to their GI absorption into the systemic circulation or the lymphatics. These factors include their large size and molecular weight (i.e., up to 6.5 kDa for 20-mers), hydrophilic nature ($\log D_{o/w}$ approximating -3.5), and multiple ionization pK_a values (e.g., unpublished titration data), using a Sirius GIpKa instrument on a 20-mer sequence, noted over 17 pK_a values for phosphorothioate oligodeoxynucleotide and over 32 pK_a values for the 2'-*O*-methoxyethyl hemi-mer form (Figure 23.7). The use of formulations can improve upon GI permeability. Oligonucleotide drug formulations designed to improve oral bioavailability need to consider the mechanism of oligonucleotide absorption—either paracellular via the epithelial tight junctions or, transcellular, by direct passage through the lipid membrane bilayer. By using paracellular and transcellular models appropriate for water-soluble, hydrophilic macromolecules, it was determined that oligonucleotides predominantly traverse GI epithelium via the paracellular route. In this regard, formulation design considerations involve the selection of those penetration enhancers (PEs), which facilitate paracellular transport and meet other formulation criteria including suitable biopharmaceutics, safety considerations, manufacturability, physical and chemical stability, and practicality of the product configuration (i.e., regarding production costs, dosing regimen, and patient compliance, etc.). Work is in progress optimizing oligonucleotide chemistry with various permeation enhancers [156,199–202]. Preliminary data are encouraging and support continued investment of resources on this endeavor.

23.6.4 LIPOSOME FORMULATIONS

Early in the development of antisense oligonucleotides, it was speculated that cellular delivery of large polyanionic molecules across a plasma membrane was going to be challenging and therefore considerable effort was invested in delivery technologies such as liposomes [203–206]. Fortunately, single-stranded phosphorothioate oligonucleotides do, in fact, distribute to a variety of tissues and cell types within the tissues when administered systemically or locally [120,125,146,149,154,164,207]. More importantly, it was demonstrated that the oligonucleotides produced a sequence-specific reduction in targeted RNA supporting that some of the oligonucleotides in the cells within the tissue was pharmacologically active [122,207–214]. Thus, the need for liposome formulations to enable antisense technology did not transpire. In contrast to single-stranded antisense oligonucleotides, double-stranded oligonucleotides that work through the RNAi pathway do

appear to require formulations to exhibit activity following systemic administration, at least as currently designed. There are marked physical–chemical differences between single-stranded DNA-like oligonucleotides and dsRNA-like oligonucleotides, which may account for these findings. More in depth coverage of formulations for delivery of siRNAs are covered elsewhere in this volume.

Although liposomes or other types of formulations are not obligatory to enable single-stranded antisense oligonucleotides, they may offer value to further improve the profile of antisense drugs. As an example, preliminary data suggest that not all of the oligonucleotide within tissues is available for binding to the target RNA. Therefore, using formulations as a means to deliver more antisense oligonucleotide to cellular compartments that contain the mRNA could increase the potency of the antisense drug. Secondly, attaching targeting ligands to liposome or other nanoparticulate carriers could change the tissue distribution and cellular distribution within tissues, resulting in more antisense drug accumulating in target tissue and less in nontarget tissues, increasing therapeutic index. In the design of such delivery systems, it is important to consider the value added by the formulation more than offsets the extra expense and complexity of formulating and characterization of the drug as well as demonstrate that the toxicological profile inherent in the formulation is an improvement over the oligonucleotide alone. Finally, increased cost for preparing the liposome formulation and different routes of administration have to be considered.

23.7 CLINICAL EXPERIENCE WITH ANTISENSE OLIGONUCLEOTIDES

Approximately 30 different antisense oligonucleotides are currently in clinical trials or approved for use in humans (Table 23.1). Similar to any other class of drugs, it can be expected that there will be failures in the clinic due to a variety of reasons such as selection of the wrong molecular target resulting in lack of efficacy, incorrect dosing, marketing consideration, toxicity, etc. It is hoped that because of the generic pharmacokinetics and chemical class-specific toxicity that the failure rates for antisense oligonucleotides will be lower than other classes of agents. However, this remains to be seen. Following is a brief summary of clinical status of several antisense oligonucleotides. An exhaustive review of clinical data on antisense oligonucleotides currently in development is beyond the scope of this review.

23.7.1 USE OF ANTISENSE OLIGONUCLEOTIDES IN ANTIVIRAL THERAPY

The most advanced antisense product is Vitravene (fomivirsen, ISIS 2922), which is marketed in the United States and the rest of the world for the treatment of patients with cytomegalovirus (CMV) retinitis. Fomivirsen was identified from a screen of a series of phosphorothioate oligodeoxynucleotides targeting human CMV (HCMV) DNA polymerase gene

or to RNA transcripts of the major immediate-early regions 1 and 2 (IE1 and IE2) [215]. Fomivirsen is a 21-mer phosphorothioate oligodeoxynucleotide targeting the coding region of the IE2 gene. Fomivirsen inhibits viral protein expression, as measured by an enzyme-linked immunosorbent assay (ELISA) detecting an HCMV late protein product in fibroblasts with an EC_{50} value of $0.1\ \mu\text{M}$. Published studies in aggregate suggest that fomivirsen is a potent inhibitor of CMV replication, which is capable of inhibiting viral gene expression by an antisense mechanism of action, but also may inhibit viral replication by a nonantisense mechanism of action at higher concentrations [215–218]. Whether both mechanism of action are operational in the clinic remains to be elucidated.

Fomivirsen is approved for the local treatment of CMV retinitis in patients with acquired immunodeficiency syndrome, who are intolerant of or have a contraindication to other treatments of CMV retinitis [219,220]. The recommended dose is $330\ \mu\text{g}$ every other week for two doses and then a maintenance dose administered every 4 weeks given as an intravitreal injection. The most frequently observed adverse event reported for fomivirsen is ocular inflammation (uveitis) including iritis and vitritis [221]. Ocular inflammation has been reported to occur in approximately 25% of the patients. Topical corticosteroids have been useful in treating the ocular inflammation. Open label, controlled clinical studies have been performed evaluating the safety and efficacy of fomivirsen in newly diagnosed CMV retinitis patients. Based upon assessment of fundus photographs, the median time to progression was approximately 80 days for patients treated with fomivirsen compared to 2 weeks for patients not receiving treatment [220]. Although the market for CMV retinitis is relatively small, this drug represents an important validation for the technology.

The other antiviral antisense oligonucleotide currently in clinical trials is ALN-RSV-01 for the treatment of respiratory syncytial virus (RSV). RSV is a highly contagious virus that infects both upper and lower respiratory tract, predominantly in children. This antisense drug is a dsRNA that works through the RNAi mechanism [222]. Phase I trials in healthy volunteers demonstrated that ALN-RSV-01 was safe and well tolerated in over 100 volunteers [223]. ALN-RSV-01 is currently in phase II trials in which the safety, tolerability, and antiviral activity are determined in healthy volunteers experimentally challenged with RSV infection [223].

23.7.2 USE OF ANTISENSE OLIGONUCLEOTIDES FOR CANCER THERAPY

Overexpression of *bcl-2* is common in several cancers, in particular non-Hodgkin lymphoma, and may contribute to decreased sensitivity to chemotherapeutic agents [224,225]. An 18-mer phosphorothioate antisense oligodeoxynucleotide (oblimersen, also known as Genasense® or G3139) targeting the translation initiation codon of the *bcl-2* gene was shown to inhibit the growth of lymphoma cells in severe combined immunodeficient (SCID) mice [226]. Follow-up studies demonstrated that oblimersen inhibited growth of lymphoma cells in severely immunocompromised SCID and NOD/SCID

mice, suggesting that the activity of the oligonucleotide was not secondary to an immunostimulatory effect [227]. Oblimersen has also demonstrated antitumor activity in pre-clinical models of various other cancers such as melanoma, prostate cancer, and gastric cancer [228–232]. Webb et al. conducted a phase I clinical trial of oblimersen at the Royal Marsden Hospital in London [233]. Genta 3139 was administered as a daily subcutaneous infusion for 14 days to patients with BCL-2-positive non-Hodgkin lymphoma. The dose of the drug given ranged from 4.6 to $73.6\ \text{mg}/\text{m}^2$. Other than local inflammation at the site of infusion, no treatment-related side effects were noted. In two patients, tomography scans revealed reductions in tumor size with one complete response. In two additional patients, the number of circulating lymphoma cells decreased during treatment. Reduced levels of *bcl-2* protein expression in circulating lymphoma cells were detected in two out of five patients. These findings again demonstrate that phosphorothioate oligodeoxynucleotides can be safely administered to patients and also provide preliminary efficacy data with a *bcl-2* antisense oligonucleotide. Several other phase I/II studies on oblimersen have been performed including studies in prostate cancer, breast cancer, colorectal cancer, AML, CML, multiple myeloma, and malignant melanoma [232,234]. Side effects associated with the use of oblimersen included thrombocytopenia, hypotension, fever, and hypoglycemia [232]. The sponsor completed positive phase III programs for oblimersen in advanced melanoma [235] and chronic lymphocytic leukemia [236]. Data from both trials were separately submitted to the U.S. Food and Drug Administration for marketing authorization and the melanoma data were submitted to the European Medicines Agency for approval. In all three cases, the regulatory agencies denied marketing approval for the drug. The company is continuing to conduct clinical studies with oblimersen to address deficiencies raised by the regulatory agencies.

Several additional first- and second-generation antisense oligonucleotides are currently in clinical trials for the treatment of a variety of malignancies (Table 23.1). One of the more advanced oligonucleotides in this group is OGX-011, a second-generation 2'-MOE modified gapped oligonucleotide targeting clusterin mRNA, a cytoprotective gene product [71,237]. In a phase I trial, prostate cancer patients scheduled to undergo prostatectomy were pretreated with OGX-011 by 2h intravenous infusions on days 1, 3, 5 and then weekly from days 8 to 29 at doses ranging from 40 to 640mg combined with androgen ablative therapy [71]. Following prostatectomy, tumor tissue was analyzed for drug, clusterin expression, and markers for apoptosis. The drug was well tolerated and demonstrated dose-dependent accumulation in tumor, dose-dependent decreases in clusterin expression, and increases in tumor cell apoptosis. Maximal effects were observed at doses between 480 and 640mg per infusion. Although these data do not address clinical efficacy of OGX-011, they do demonstrate that second-generation antisense oligonucleotides can modulate gene expression in tumor tissue at a dose that is well tolerated. OGX-011 is currently in several phase II trials for prostate cancer, breast cancer, and small cell lung carcinoma. As noted in

Table 23.1, there are several additional antisense drugs being evaluated in clinical trials for treatment of malignancies. However, with limited published clinical studies on these drugs, it is difficult to determine how they are performing. It is anticipated that over the next couple of years, the trials will mature and additional information will become available.

23.7.3 USE OF ANTISENSE OLIGONUCLEOTIDES FOR THE TREATMENT OF INFLAMMATORY DISEASES

Intercellular adhesion molecule 1 (ICAM-1) is a member of the immunoglobulin gene family expressed at low levels on resting endothelial cells and can be markedly up regulated in response to inflammatory mediators such as tumor necrosis factor alpha (TNF- α), interleukin-1, and interferon- γ on a variety of cell types. ICAM-1 plays a role in the extravasation of leukocytes from the vasculature to inflamed tissue and activation of leukocytes in the inflamed tissue [238–241]. Alicaforsen (Isis 2302) was identified out of a screen of multiple first-generation phosphorothioate oligodeoxynucleotides targeting various regions of the human ICAM-1 [7,242]. Alicaforsen inhibits ICAM-1 expression in a variety of cell types by an RNase H-dependent mechanism of action [242–244]. Alicaforsen blocks both leukocyte adhesion to activated endothelial cells and costimulatory signals to T lymphocytes, both activities predicted based on previous studies with monoclonal antibodies to ICAM-1.

Numerous studies have been published demonstrating anti-inflammatory activity of the ICAM-1 antisense oligonucleotides in a variety of rodent models [184,245–254]. These data demonstrate that ICAM-1 antisense oligonucleotides administered systemically can attenuate an inflammatory response in animals and suggest that inhibition of ICAM-1 expression in humans could provide therapeutic benefit in patients suffering from a variety of inflammatory diseases.

Safety and pharmacokinetics of systemically administered alicaforsen was established in a phase I study performed at Guy's hospital in normal volunteers [144]. Alicaforsen was evaluated in a series of small phase IIa studies (20 to 40 patients in each trial) in patients with rheumatoid arthritis, psoriasis, Crohn's disease, ulcerative colitis, and renal transplant. With the exception of the psoriasis study, the trials were placebo-controlled, double-blinded in which the drug is administered as a 2h intravenous infusion. In all trials, the drug was well tolerated. In the rheumatoid arthritis trial, alicaforsen failed to produce significant efficacy but showed positive trends [255]. The small sample size of the trial, 43 patients, did not allow definitive conclusions to be drawn. In the phase IIa Crohn's disease study, the drug was well tolerated and showed encouraging signs of efficacy [256]. Unfortunately, the initial results were not confirmed in several larger studies, therefore is no longer being studied in Crohn's disease [257–259].

Alicaforsen is currently being developed as an enema formulation for the treatment of ulcerative colitis. Several phase II studies have demonstrated efficacy of alicaforsen delivered as an enema [260–263]. Delivered as an enema, alicaforsen

exhibits less than 1% bioavailability, suggesting that the beneficial effects of the drug are due to local effects on GI tissue [264]. Additional trials to support registration of alicaforsen are in progress.

ATL 1102 is a second-generation antisense oligonucleotide targeting the mRNA of another cell adhesion molecule, CD49d (the alpha subunit of VLA4). An antibody targeting VLA4, natilizumab, has demonstrated clinical benefit for the treatment of multiple sclerosis and Crohn's disease [265,266] and has been approved for the treatment of multiple sclerosis. VLA4 is an integrin expressed on lymphocytes, monocytes, and a subset of granulocytes and binds to vascular cell adhesion molecule 1 (VCAM-1) and fibronectin expressed on endothelium and other cell types. Similarly to ICAM-1, blocking VLA4 function or expression decreases extravasation of leukocytes into sites of inflammation and attenuates activation of leukocytes in inflamed tissue. A mouse-specific CD49d antisense oligonucleotide was shown to prevent and reverse clinical symptoms in a mouse model of multiple sclerosis [267]. ATL 1102 has completed phase I trials in normal volunteers and is currently in phase II trials for the treatment of multiple sclerosis (Table 23.1).

Two antisense drugs, both delivered by aerosol, are currently in clinical trials for the treatment of asthma. TPI ASM 8 is actually two different first-generation antisense oligonucleotides in a single formulation. One antisense oligonucleotide targets the common beta subunit of the IL-3, IL-5, and granulocyte-monocyte colony stimulatory factor (GM-CSF) receptor with the second antisense oligonucleotide targeting the CCR3 receptor. Early clinical trials with TPI ASM8 have generated encouraging data. This drug is currently in phase II trials. Another inhaled antisense oligonucleotide in clinical trials is ISIS 369645 (Table 23.1). ISIS 369645 is a second-generation antisense oligonucleotide targeting the IL-4 receptor alpha chain. Inhibiting the expression of the alpha chain blocks both IL-4 and IL-13 cytokine signaling, both of which have been implicated in contributing to the pathophysiology in asthma. Preclinical studies with a mouse specific IL-4 receptor alpha chain antisense oligonucleotide produced clinical benefit in both acute and chronic models of asthma when delivered by an aerosol [211]. ISIS 369645 is currently in phase I trials and if tolerated will be tested in asthmatic subjects.

23.8 CONCLUSION

As is to be expected with first-generation technology, undesirable properties have been identified for phosphorothioate oligodeoxynucleotides [168,169,268,269]. Despite these limitations, it is possible to use phosphorothioate oligodeoxynucleotides to selectively inhibit the expression of a targeted RNA in cell culture and *in vivo*. The pharmacokinetics of phosphorothioate oligodeoxynucleotides are similar across species and do not appear to exhibit major sequence-specific differences. When dosed at high levels, it is possible to identify toxicities in rodents and primates. However, at doses currently under evaluation in the clinic, phosphorothioate oligodeoxynucleotides have been well tolerated. In addition,

there is evidence that phosphorothioate oligodeoxynucleotides provide clinical benefit to patients with viral infections, cancer, and inflammatory diseases. There are still several phosphorothioate oligodeoxynucleotides in late stage clinical trials, which will hopefully deliver more effective therapies for patients suffering from life-threatening and debilitating diseases.

Extensive medicinal chemistry efforts have been successfully focused on identifying improved antisense oligonucleotides, which address some of these issues. There are at least four areas in which chemistry can add value to first-generation drugs: increase potency, decrease toxicity, alter pharmacokinetics, and lower costs. As an example, numerous modified oligonucleotides have been identified, which have a higher affinity for target RNA than phosphorothioate oligodeoxynucleotides [92,97,101–103,270–272]. Oligonucleotide modifications, which exhibit increased resistance to serum and cellular nucleases, have been identified, enabling use of oligonucleotides that do not have phosphorothioate linkages. The tissue distribution of oligonucleotides may be altered with either chemical modifications or formulations [87,147,154,155, 157,198,272,273–275]. Preliminary data also suggest that oral delivery of antisense oligonucleotides may be feasible [155,199–201]. Finally a number of modified oligonucleotides have been described, which potentially exhibited less toxicities than first-generation phosphorothioate oligodeoxynucleotides [86,168,197]. The most advanced second-generation antisense chemistry is 2'-O-methoxyethyl, with over 700 subjects treated with oligonucleotides containing this modification [276]. To date, 2'-O-methoxyethyl-modified oligonucleotides have been well tolerated and have exhibited a marked increase in therapeutic index compared to first-generation phosphorothioate oligodeoxynucleotides.

In conclusion, first-generation phosphorothioate oligodeoxynucleotides have proven to be valuable pharmacological tools for the researcher and have produced new therapies for the patient. Identification of improved second- and third-generation oligonucleotides with novel formulation should be better therapies for patients. Although tremendous progress has been made for antisense technology during the past 14 years, there are far more questions that remain for the technology.

24.1 INTRODUCTION

Within less than a decade since its discovery, RNA interference (RNAi) as a novel mechanism to selectively silence messenger RNA (mRNA) expression has revolutionized the biological sciences in the postgenomic era. With RNAi, the target mRNA is enzymatically cleaved, leading to decreased levels of the corresponding protein. The specificity of this mRNA silencing is controlled very precisely at the nucleotide level. Given the identification and sequencing of the entire human genome, RNAi is a fundamental cellular mechanism that can also be harnessed to rapidly develop novel drugs against any disease target. The reduction in expression of pathological proteins through RNAi is applicable to all classes of molecular targets, including those that have been traditionally difficult to target with either small molecules or proteins including monoclonal antibodies. Numerous proof-of-concept

studies in animal models of human disease have demonstrated the broad potential applicability of RNAi-based therapeutics. Further, RNAi therapeutics are now under clinical investigation for age-related macular degeneration (AMD) and respiratory syncytial virus (RSV) infection, with numerous other drug candidates poised to advance into clinic development in the years to come.

In this chapter, I will outline and discuss the various considerations that go into developing RNAi-based therapeutics starting from *in vitro* lead design and identification to *in vivo* preclinical drug delivery and testing, and lastly, to a review of clinical experiences to date with RNAi therapeutics.

24.2 RNAi OVERVIEW

The discovery of long double-stranded RNA (dsRNA)-mediated RNAi in the worm by Fire and Mello [1] and the subsequent

publication by Tuschl and colleagues demonstrating that RNAi, mediated by small interfering RNA (siRNA), operates in mammalian cells [2] sparked an explosion of research to uncover new mechanisms of gene silencing, revolutionizing understanding of endogenous mechanisms of gene regulation and providing powerful new tools for biological research and drug discovery. While much is known about RNAi, this remains an area of intense research rich in new discoveries, with multiple classes of small noncoding RNA being discovered that play important roles in cell biology. At present, the majority of research into RNAi has focused on siRNAs and microRNAs (miRNAs), with the latter deriving from imperfectly paired noncoding hairpin RNA structures naturally transcribed by the genome [3,4]. Gene silencing can be induced by siRNA through

sequence-specific cleavage of perfectly complementary mRNA, while miRNAs mediate translational repression and transcript degradation for imperfectly complementary targets (Figure 24.1). In the endogenous pathway, RNAs containing stem-loops or short hairpin structures, encoded in intragenic regions or within introns, are processed in the nucleus and exported into the cytoplasm as precursor molecules, called pre-miRNA [4,5]. In the cytoplasm, the pre-miRNA is further shortened and processed by an RNase III enzyme, called Dicer, to produce an imperfectly matched, double-stranded miRNA, while Dicer similarly processes long, perfectly matched dsRNA into siRNA (Figure 24.1). A multienzyme complex including Argonaute 2 (Ago2) and the RNA-induced silencing complex (RISC) binds either the miRNA duplex or the siRNA duplex and discards one

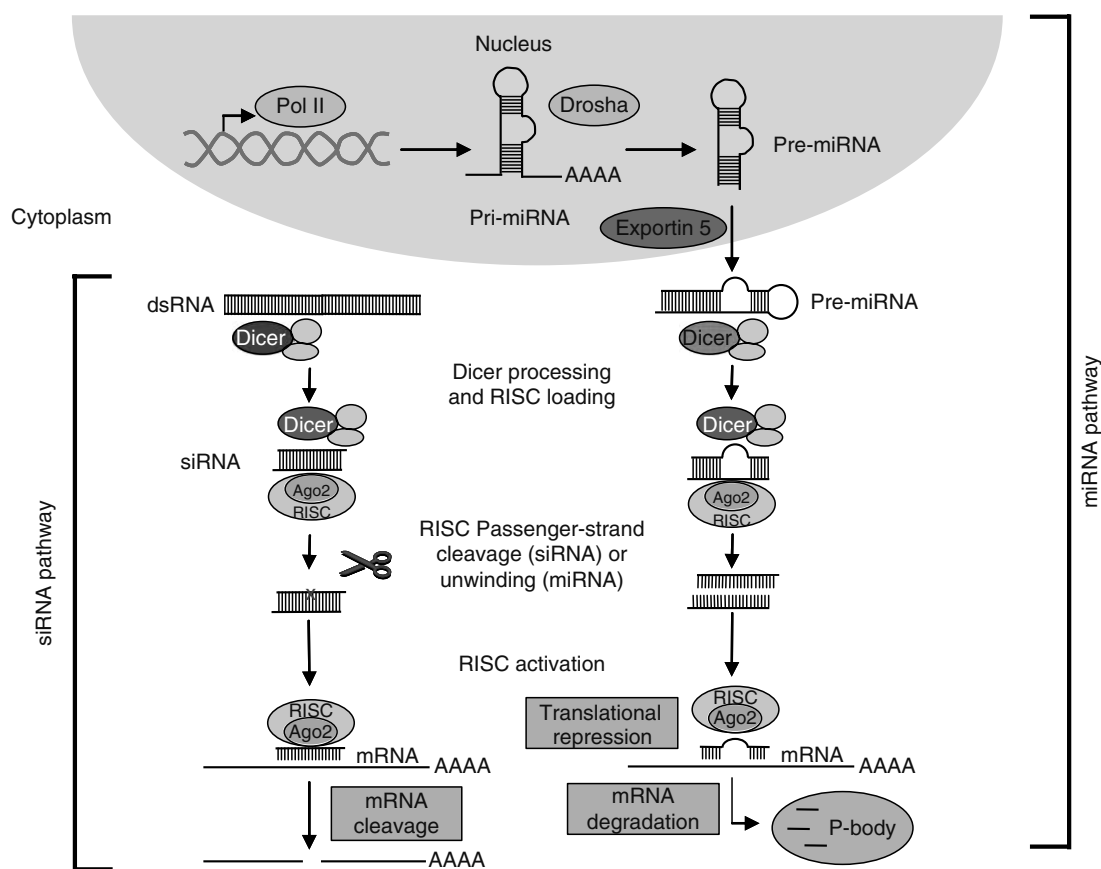

FIGURE 24.1 RNAi in mammalian cells. RNAi pathways are guided by small RNAs that include siRNA and miRNAs. The siRNA pathway begins with cleavage of long dsRNA by the Dicer enzyme complex into siRNA. These siRNA are incorporated into Ago2 and the RISC. When the RNA duplex loaded into RISC has perfect sequence complementarity, Ago2 cleaves the passenger (sense) strand so that active RISC is produced that contains the guide (antisense) strand. The siRNA guide strand recognizes target sites to direct mRNA cleavage, which is carried out by the catalytic domain of Ago2. RNAi therapeutics developed to harness the siRNA pathway typically involves delivery of synthetic siRNA into the cell cytoplasm. The miRNA pathway begins with endogenously encoded primary miRNA transcripts (pri-miRNAs) that are transcribed by RNA polymerase II (Pol II) and are processed by the Droscha enzyme complex to yield precursor miRNAs (pre-miRNAs). These precursors are then exported to the cytoplasm by exportin 5, and subsequently bind to the Dicer enzyme complex, which processes the pre-miRNA for loading into the Ago2/RISC complex. When the RNA duplex loaded into RISC has imperfect sequence complementarity, the passenger (sense) strand is unwound, leaving a mature miRNA bound to active RISC. The mature miRNA recognizes target sites (typically in the 3' UTR) in the mRNA, leading to direct translational inhibition. Binding of miRNA to target mRNA may also lead to mRNA target degradation in P-bodies. (Adapted from de Fougères, A.R. et al., *Nat. Rev. Drug Discovery*, 6, 443, 2007.)

strand (it is thought the passenger or sense strand is cleaved in the case of siRNA and is released in the case of miRNA) to form an activated complex containing the guide or antisense strand [6]. The activated Ago2/RISC complex then seeks and binds an mRNA strand bearing a complementary sequence and inactivates its expression, either by blocking translation (if complementarity is less than perfect such as with miRNA) or by cleaving it between the nucleotides complementary to nucleotides 10 and 11 of the guide strand (relative to the 5' end) (when complementarity is perfect or nearly perfect such as with siRNA) (Figure 24.1). In addition to translational repression, miRNAs may also mediate mRNA degradation which occurs in cytoplasmic compartments known as processing bodies (P-bodies) [7]. Gene silencing by mRNA cleavage is thought to be particularly potent, in part because mRNA cleavage leads to rapid nucleolytic degradation of the RNA fragments and frees the activated RISC complex to seek and destroy another target mRNA in a catalytic fashion [8]. While the mechanism by which an activated Ago2/RISC cleaves a target RNA is well understood, the molecular basis for how this complex finds its target RNA is less well understood. Recent studies have shown that the accessibility of the target site correlates directly with efficiency of cleavage, and that in the course of target recognition, the activated Ago2/RISC complex transiently contacts single-stranded RNA nonspecifically and promotes siRNA–target RNA annealing [9]. Furthermore, the 5' part of the siRNA within RISC seems to create a thermodynamic threshold that then determines the stable association of RISC and the target RNA.

The goal of RNAi-based therapy is to activate selective mRNA cleavage for efficient gene silencing. It is possible to harness the endogenous pathway in one of two ways—either by using a viral vector to express short hairpin RNA (shRNA) that look like miRNA precursors or by introducing siRNAs that mimic the Dicer cleavage product into the cytoplasm. These siRNAs can bypass the earlier steps in the RNAi silencing pathway and can be taken up directly into the Ago2/RISC complex. While delivery of synthetic siRNA and viral delivery of shRNA are being developed as potential RNAi-based therapeutic approaches, this chapter focuses solely on the development of synthetic siRNA as drugs. Synthetic siRNAs are readily defined drugs that harness the naturally occurring RNAi pathway in a manner that is consistent and predictable, thus making them particularly attractive as therapeutics. Moreover, since they enter the RNAi pathway later, siRNA is less likely to interfere with gene regulation by endogenous miRNAs [10,11]. As a consequence, siRNAs are the class of RNAi therapeutics that are most advanced in preclinical and clinical studies.

24.3 IN VITRO SELECTION OF LEAD CANDIDATES

This section highlights the various steps required to identify potent lead siRNA candidates starting from bioinformatics design through to *in vitro* characterization. The overall scheme is summarized in Figure 24.2. The three most important attributes to take into account when designing and selecting

FIGURE 24.2 (See color insert following blank page 206.) Developing RNAi therapeutics. Steps involved in developing an RNAi therapeutic. This three-step process begins with *in silico* design and *in vitro* screening of target siRNA, is followed by incorporating stabilizing chemical modifications on lead siRNA as required, and ends with selection and *in vivo* evaluation of delivery technologies appropriate for the target cell type/organ and the disease setting. A schematic illustration of some of the important features of siRNA structure (two base pair overhangs, seed region, and mRNA cleavage site) is shown. An example of an optimized siRNA molecule, which incorporates chemical modifications to increase nuclease stability and to minimize off-targeting, is shown below. The phosphorothioate and 2' base modifications shown are illustrative of exo-nuclease and endo-nuclease stabilizing chemistries, respectively; other chemistries also exist that confer similar properties on an siRNA duplex. (From Bumcrot, D. et al. *Nat. Chem. Biol.*, 2006, 2, 711; de Fougères, A.R. et al., *Nat. Rev. Drug Discovery*, 6, 443, 2007.)

siRNA are potency, specificity, and nuclease stability. With regard to specificity of siRNA, the two issues of “off-targeting” due to silencing of genes sharing partial homology to the siRNA and “immune stimulation” due to recognition of certain siRNAs by the innate immune system have been of special concern. With an increased understanding of the molecular and structural mechanism of RNAi, all issues around lead siRNA selection are better understood and also are now generally resolvable through the use of bioinformatics, chemical modifications, and empirical testing. Thus, it is now possible, in the span of several months, to very rapidly identify potent, specific and stable *in vitro* active lead siRNA candidates to any target of interest.

24.3.1 POTENCY

Work by Tuschl and colleagues [2] represented the first published study to demonstrate that RNAi could be mediated in mammalian cells through introduction of small fragments of dsRNA, termed siRNA, and that siRNAs had a specific architecture comprised of 21 nucleotides in a staggered 19 nucleotide duplex with a two-nucleotide 3' overhang on each strand (Figures 24.1 and 24.2). siRNAs can be identified to silence any gene, often with *in vitro* activity at nanomolar or lower concentrations. Algorithms to predict effective siRNAs, developed based on common features of siRNAs identified by empiric testing, are available on the Web [12,13]. While algorithms can increase the chances of identifying active siRNA, they are imperfect and may sometimes miss the most potent siRNAs, which can only be identified by experimental testing. An alternative to using algorithms as a starting point to identify candidate siRNAs is to test all the tiled 21 nt sequences from the mRNA coding region experimentally and select a group of candidates that induce effective silencing at the lowest concentrations. One study suggests that somewhat longer siRNAs that need to be processed by Dicer before they can be incorporated into RISC can be used as “Dicer substrates” and maintain silencing activity, although these longer siRNAs are more complicated to synthesize and could have an increased propensity to activate untoward immune responses [14,15]. Loading of RISC with respect to the sense and antisense siRNA strands is not symmetrical [16–18]. The strand that is least tightly bound at its 5'-end is favored to bind into a deep pocket in the RISC to become the active strand. Strand selection could in fact be biased by making a single nucleotide substitution at the end of the duplex to alter the relative binding of the ends [16]. Thus, by designing an siRNA with a mismatch at the 5'-end of the intended active strand that favors its incorporation into RISC, it may be possible to increase the likelihood of identifying a potent duplex.

24.3.2 SPECIFICITY

RNAi-mediated silencing of gene expression has been shown to be exquisitely specific as evidenced by silencing fusion mRNA without affecting an unfused allele [19,20] and by

studies showing ability to silence point-mutated genes over wild-type sequence [21,22]. Nevertheless, along with on-target mRNA silencing, siRNA might have the potential to recognize nontarget mRNA, otherwise known as “off-target” silencing. Based on *in vitro* transcriptional profiling studies, siRNA duplexes have been reported to silence multiple genes in addition to the intended target gene under certain conditions. Not surprisingly, many of these observed off-target genes contain regions that are complementary to one of the two strands in the siRNA duplex [23–25]. More detailed bioinformatic analysis revealed that complementarity between the 5' end of the guide strand and the mRNA was the key to off-targeting silencing, with the critical nucleotides being in positions 2 to 8 (from 5' end of guide strand), which corresponds to the so-called “seed region” for miRNA recognition of endogenous target mRNAs [26,27] (Figure 24.2). Accordingly, one approach for minimizing off-target effects is careful design of siRNA to minimize exact seed pairings, although seed regions of 7 nucleotides are very short in length. Alternatively, chemical modifications of riboses in the guide strand can suppress most off-target effects, while maintaining target mRNA silencing [28,29]. In fact, incorporation of a single 2'-O-Me modification at nucleotide 2 was sufficient to suppress most off-target silencing of partially complementary mRNA transcripts by all siRNAs tested. Thus, in summary, bioinformatics design or position-specific, sequence-independent chemical modifications can be incorporated into siRNA that reduces off-target effects while maintaining target silencing.

A second mechanism whereby siRNA can also induce potential unwanted effects is by activating the innate immune response to dsRNAs, setting off defense systems usually used to combat viruses. One pathway involves recognition of dsRNAs by the PKR kinase (reviewed in Ref. [30]). This pathway is efficiently triggered only by dsRNAs > 30 nucleotides long. At higher concentrations, however, smaller siRNAs may be able to activate this pathway, resulting in global translational blockade and cell death. Perhaps of more concern is the potential to activate Toll-like receptors (TLRs), especially the dsRNA receptor TLR-7, in plasmacytoid dendritic cells to trigger the production of Type I interferons and proinflammatory cytokines and NF- κ B activation [31]. In much the same way that certain CpG motifs in antisense oligonucleotides mediate TLR-9 immunostimulation, interferon induction by some siRNAs occurs principally via TLR-7, which is largely found within endosomes in immune antigen-presenting cells. Fortunately, TLR-7 binding is sequence-specific, favoring GU-rich sequences, and can be avoided by choosing sequences that are not recognized by the receptor. Additional work remains to identify immunostimulatory motifs and determine whether other receptors might also be involved. Several approaches exist to circumvent the immunostimulatory properties of certain siRNA duplexes. Candidate duplexes can be transfected into plasmacytoid dendritic cells to test whether they induce interferon expression [31,32], and those that do can be discarded. Moreover, the presence of 3' overhang nucleotides and 2'-O-methyl

modifications can be used to abrogate TLR-7 binding and thereby abolish immunostimulatory activity [31,33]. Since modifications of this sort also greatly reduce sequence-dependent off-target silencing, this type of modification may be particularly beneficial in enhancing siRNA target specificity. Potentially, TLR-7 signaling could also be evaded by using siRNA delivery strategies that avoid the cell types responsible for immune stimulation or that transport the siRNA directly to the cytoplasm, thereby avoiding TLR activation in the endosome.

24.3.3 STABILITY

Naked siRNAs are degraded in human plasma with a half-life on the order of minutes [34–36]. To convert siRNAs into optimized drugs, much effort has been expended to investigate chemical modifications that prolong half-life without jeopardizing biological activity. The starting point for these efforts has been chemistries already in use with antisense oligonucleotide and aptamer therapeutics. For instance, introduction of a phosphorothioate (P=S) backbone linkage at the 3'-end is used to protect against exonuclease degradation and 2'-sugar modification (2'-O-Me, 2'-F, others) is used for endonuclease resistance [34–38]. With respect to maintenance of RNAi silencing activity, exonuclease-stabilizing modifications are all very well tolerated. Introduction of internal sugar modifications to protect against endonucleases is also generally tolerated but can be more dependent on location of the modification within the duplex, with the sense strand being more amenable to modification than the antisense strand. Nevertheless, using simple, well-described modifications such as P=S, 2'-O-Me, and 2'-F it is possible in most instances to fully nuclease-stabilize an siRNA duplex and maintain mRNA silencing activity. Importantly, the degree of modifications required to fully stabilize the siRNA duplex can generally be limited in extent, thereby avoiding the toxicities associated with certain oligonucleotide chemistries.

Improved nuclease stability is especially important *in vivo* for siRNA duplexes, which are exposed to nuclease-rich environments (such as serum) and are formulated using excipients that do not themselves confer additional nuclease protection on the duplex. As might be expected in these situations, nuclease-stabilized siRNA shows improved pharmacokinetic properties *in vivo* [36,39]. In other situations, when delivering siRNA directly to more nuclease-amenable sites such as the lung or when delivering in conjunction with delivery agents such as liposomes, the degree of nuclease stabilization that is required can be reduced significantly. While the ability of an siRNA duplex to reach its target cell type intact is vitally important, whether nuclease protection confers a measurable benefit once an siRNA is inside the cell is now being more fully understood. *In vitro* comparisons of naked siRNA versus fully stabilized siRNA do not reveal significant differences in longevity of mRNA silencing whether rapidly dividing cells [34,36] or slowly dividing cells are used [36]. In fact, the most important factor affecting the *in vitro* longevity of siRNA-mediated silencing is dilution due to cell division and not

intracellular siRNA half-life [36,40]. Studies using rapidly dividing HeLa cells found target suppression lasting for around 1 week, while the same target is suppressed for up to 1 month in slowly dividing CCD-1074Sk cells [36]. Investigation into the role of chemical stabilization on *in vivo* silencing suggests that the stabilization advantages of nuclease-stabilized siRNA originate primarily from effects prior to and during internalization before the siRNA can interact with the intracellular machinery [36]. With the recent advent of fluorescence resonance energy transfer studies using siRNA [41], it should be possible in the near future to more completely understand the intracellular benefit of nuclease stabilization on longevity of RNAi-mediated silencing.

24.3.4 THERAPEUTIC CONSIDERATIONS

In designing siRNAs for therapeutic purposes, other considerations beyond an active target sequence exist. Where possible, it is desirable to identify target sequences that have identity across all the relevant species used in safety and efficacy studies, thus enabling development of a single drug candidate from research stage all the way through clinical trials. Other considerations in selecting a target sequence involve presence of single nucleotide polymorphisms and general ease of chemical synthesis.

Predicting the nucleotide sequence and chemical modifications required to yield an ideal RNAi therapeutic still remains a work in progress. While much progress has been made in understanding what attributes are required to identify an *in vitro* active and stable siRNA, much less is known about how well those attributes translate into identifying *in vivo* active siRNAs. For example, many of the issues around specificity are based on *in vitro* data and their *in vivo* relevance remains to be determined. For example, the range of off-target genes identified in tissue culture can differ dramatically depending upon the transfection method used to introduce siRNAs into cells [42]. Likewise, induction of innate immune responses by certain siRNAs has been shown to be cell-type-specific [15]. At present, in order to identify robust *in vitro* active lead candidate siRNAs suitable for subsequent *in vivo* study, the practical and prudent approach is to synthesize and screen a library of siRNA duplexes for potency, specificity, nuclease stability, and immunostimulatory activity.

24.4 IN VIVO DELIVERY

Effective delivery is the most challenging remaining consideration in the development of RNAi as a broad therapeutic platform. To date, animal studies using siRNA either have employed no additional formulation (i.e., “naked siRNA”) or have delivered siRNA formulated as conjugates, as liposome/lipoplexes, or as complexes with peptides, polymers, or antibodies (Figure 24.3). The route of administration of siRNA has also ranged from local, direct delivery to systemic administration. Local delivery or “direct RNAi” has particular advantages for a developing technology in that, as with any

FIGURE 24.3 Delivery of siRNAs. Different strategies have been employed to deliver and achieve RNAi-mediated silencing *in vivo*. Direct injection of naked siRNA (unmodified or chemically modified) has proven efficacious in multiple contexts of ocular, respiratory, and CNS disease [46–66]. Direct conjugation of siRNA to a natural ligand such as cholesterol has demonstrated *in vivo* silencing in hepatocytes [68,69] and neuronal cells [70]. Liposome-mediated delivery of siRNA has been used to silence multiple targets following systemic administration [80–82,84]. Aptamer–siRNA conjugates have demonstrated specific delivery and silencing following local injection in a tumor xenograft model [75]. Lastly, antibody–protamine fusion proteins have been used to noncovalently bind siRNAs through charge interactions and deliver siRNA specifically to cells that express the surface receptor recognized by the antibody [115,116].

pharmacologic approach, doses of siRNA required for efficacy are substantially lower when siRNAs are injected into or administered at or near the target tissue. Direct delivery also allows for more focused delivery of siRNA, which might circumvent any theoretical undesired side effects resulting from systemic delivery. Systemic delivery of siRNA, especially with cholesterol conjugates and liposome formulations have also been widely explored with considerable success. This section will provide a review of the different delivery approaches utilized with siRNA. Many recent review publications offer comprehensive listings of successful *in vivo* efficacy studies [43–45].

24.4.1 NAKED siRNA

Many reports describing success with RNAi *in vivo* involve direct delivery of “naked” siRNA to tissues such as eye, lung, and central nervous system. It remains incompletely understood why certain cells, but not others, can directly take up siRNA into the cytoplasm where the RNAi machinery operates. As used here, the term “naked” siRNA refers to delivery of siRNA (unmodified or modified) in saline or other simple excipients such as 5% dextrose (D5W). The ease of formulation and administration using direct delivery of naked siRNA to tissues make this an attractive therapeutic approach.

Not surprisingly, the initial development of RNAi therapeutics has focused on disease targets and clinical indications (AMD and RSV infection) that allow for direct administration of siRNA to the diseased organ.

24.4.1.1 Ocular

Multiple examples of efficacious local delivery of siRNA in the eye exist, where proof-of-concept has been attained in animal models of ocular neovascularization and scarring using both saline- and lipid-based formulations [46–51]. Much evidence suggests that direct administration of naked siRNA is able to target cell types in the back of the eye and have profound disease-modifying effects. Using an optimized vascular endothelial growth factor (VEGF) targeting siRNA, we demonstrated robust specific inhibition of pathologic retinal neovascularization in a rat oxygen-induced model of retinopathy [51]. Following a single intravitreal injection of saline-formulated VEGF siRNA, over 75% inhibition of pathological neovascularization was achieved with no effect on the normal retinal vasculature. The inhibition seen was both dose-dependent and specific as a mismatched siRNA showed no inhibition. Separate earlier studies using lipid-formulated VEGF siRNA had shown a reduction of laser-induced choroidal neovascularization (CNV) in a mouse model of AMD [46]; this initial study was followed by nonhuman primate laser-induced CNV study where it was reported that intravitreal injection of a saline-formulated VEGF siRNA was well tolerated and efficacious [47]. Lastly, intravitreal injection of saline-formulated siRNA targeting VEGF receptor-1 was effective in reducing the area of ocular neovascularization by one-third to two-third in two mouse models [48]. These encouraging proof-of-concept studies in animal models have led to clinical trials of siRNA targeting the VEGF pathway in AMD.

24.4.1.2 Respiratory

A number of studies have demonstrated that intranasal or orotracheal local administration of siRNA can result in a significant target gene silencing and distinct phenotypes in the lung. Typically, siRNAs were administered in concentrations of ~100 µg per mouse and were directed against viral or endogenous disease-related targets. Most of the examples of successful direct delivery of siRNA to lung have involved delivery of naked siRNA either in saline or with excipients such as D5W or lung surfactants. In instances when delivery formulations such as Transit-TKO have been used, they are sometimes shown to be dispensable. However, the required dose or delivery to certain cell types in the lung for some indications will likely be improved by incorporating siRNA into a carrier. In one groundbreaking study, intranasal instillation of siRNAs (either unformulated or complexed with Transit-TKO) directed against viral targets reduced the viral load of RSV and parainfluenza virus (PIV), two relevant pathogens in pediatric and immune-compromised patients, in the lung by more than three orders of magnitude in a mouse model of viral infection at a dose as low as 70 µg/animal with

no observed adverse events [52]. In addition, other pathological features of RSV infection such as elevated leukotriene levels, pulmonary inflammation, as well as increased respiratory rate were reduced to baseline levels after siRNA administration. The RSV-specific siRNA-mediated reduction of viral load could be achieved in both prophylaxis and treatment paradigms. In a similar approach, siRNA formulated in D5W was administered intranasally in a nonhuman primate model of SARS corona virus (SCV) infection [53]. Macaques treated with siRNA prior to, simultaneously with, or with repeated doses after viral infection, showed a milder response to viral infection as judged by a reduced elevation of body temperature, a key indicator for the severity for SARS-like symptoms. In addition, siRNA treatment resulted in a significant reduction of interstitial infiltrates and pathological changes to the lung as well as in an inhibition of viral replication in the respiratory tract. Both studies demonstrate the potential of RNAi therapeutics to treat viral infection in the respiratory system.

A number of studies showed that siRNAs can achieve delivery in pulmonary tissue in certain disease settings. Lee and colleagues demonstrated that siRNA-mediated silencing of heme-oxygenase-1 (HO-1) after intranasal siRNA administration resulted in enhanced apoptosis in an ischemia-reperfusion (I-R) mouse model [54]. While I-R induced HO-1 in a number of organs, siRNA mediated HO-1 silencing following intranasal administration was restricted to the lung and resulted in a local elevation of FAS expression and caspase3 activity. In addition, biotinylated siRNA was detected histologically in lung parenchyma up to 16 h after instillation. To further understand the pathogenesis of acute lung injury (ALI), siRNA targeting the two chemokines, keratinocyte-derived chemokine (KC) and macrophage-inflammatory protein 2 (MIP-2), was administered by intratracheal instillation in a hemorrhage-induced and septic challenge model of ALI [55]. KC and MIP-2 lung mRNA levels were decreased by about 50%, resulting in a significant reduction of local IL-6 concentrations, and in the case of MIP-2 siRNA, treatment also resulted in reduced neutrophil influx, interstitial edema, and disruption of lung architecture. Silencing with Fas-siRNAs in the same animal model resulted in reduction of Fas to a level similar to control animals and ameliorated pulmonary apoptosis and inflammation [56]. Recently, in a hyperoxia-based mouse model of ALI, intranasal administration of an angiotensin 2 (Ang2) siRNA in saline specifically and dramatically ameliorated hyperoxia-induced oxidant injury, cell death, inflammation, vascular permeability, and mortality [57]. Expression of Ang2 in this model is dramatically induced in lung epithelial cells and this was specifically inhibited by Ang2 siRNA but not control siRNA. Lastly, it was demonstrated that intranasal instillation of siRNA targeting discoidin domain receptor 1 (DDR-1) mRNA resulted in 60%–70% reduction of DDR1 protein in the lung of animals treated with bleomycin to induce pulmonary fibrosis [58]. DDR1 silencing was accompanied by an attenuation of infiltration of inflammatory cells and a reduction of cytokines. As a consequence, bleomycin-induced transforming growth factor (TGF)-beta up-regulation was

suppressed and collagen deposition was significantly reduced. In sum, these studies exhibit the potential for direct instillation of naked siRNA to effectively silence endogenous lung genes and have disease-modifying effects.

24.4.1.3 Nervous System

The nervous system is a third area where direct instillation of siRNA in saline has proven successful in validating disease targets *in vivo*. Direct administration of saline-formulated siRNA by intracerebroventricular, intrathecal, or intraparenchymal infusion resulted in silencing of specific neuronal mRNA targets in multiple regions of the peripheral and central nervous system [59–62]. While the naked unformulated siRNA dose typically required for target silencing in these rodent studies is on the order of ~0.5 mg/day, use of polymer or lipid-based delivery systems seems to facilitate cellular uptake as effective *in vivo* doses are ~50 µg with these delivery systems [63–65].

24.4.1.4 Other

Other local administration paradigms are potentially amenable to injection with naked siRNA. Examples may include intramuscular, intradermal, and transtympanic injection of siRNA. In fact, a recent report demonstrated that intradermal injection of siRNA into a mouse footpad was able to specifically inhibit expression of a vector-based target mRNA [22,66].

24.4.2 CONJUGATION

Direct conjugation with molecular entities designed to help target or deliver drug into the appropriate target cell type is naturally appealing. Through conjugation, the therapeutic can be fixed as a one-component system thereby significantly reducing the complexity from a chemistry, manufacturing, and controls perspective. For siRNA, conjugation is especially attractive given the fact that only one of two strands in the duplex is active. Thus, conjugates can be attached to the sense strand without disrupting activity of the antisense strand. Typically, conjugates have been placed on either the 5' or 3' end of the sense strand, though they can in some instances also be tolerated on the antisense strand. To date, siRNA conjugates have been made using lipophilic molecules, proteins, peptides, aptamers, and even small-molecule antagonists.

24.4.2.1 Cholesterol

While the use of cholesterol conjugates to aid *in vivo* delivery to liver had been established using antisense oligonucleotides [67], the report in 2004 by Soutschek et al. [68] using a cholesterol–siRNA conjugate provided the first mechanistic *in vivo* proof-of-concept for RNAi. Effective silencing of the apolipoprotein B (ApoB) in mice was demonstrated following intravenous administration of cholesterol-conjugated siRNA duplexes. In these experiments, injections of cholesterol-conjugated ApoB siRNA at a relatively high dose of 50 mg/kg resulted in silencing of the ApoB mRNA by ~55%

in the liver and ~70% in the jejunum, the two principal sites for ApoB expression; control cholesterol-conjugated siRNA demonstrated no silencing activity. Critically, the authors went on to demonstrate that the reduction in ApoB mRNA was a result of RNAi, through 5'RACE detection of specific mRNA cleavage product. Paralleling the mRNA decrease in ApoB mRNA, ApoB protein levels in the plasma dropped by ~70%, and in addition, consistent with the biological function of ApoB, a 35%–40% decrease in serum cholesterol levels was also seen. Cholesterol conjugation imparted critical pharmacokinetic and cellular uptake properties to the duplex as evidenced by the fact that the unconjugated ApoB siRNA was rapidly cleared and unable to effect mRNA silencing. The mechanism by which cholesterol conjugates promote improved distribution and cellular uptake is an area of active research recently shown to involve incorporation of the cholesterol–siRNA conjugate into circulating lipoprotein particles and then delivery through receptor-mediated processes into hepatocytes [69].

Whether other tissues or cell types can be efficiently targeted by cholesterol conjugates is also an area of intense interest. One recent publication has demonstrated that a single intrastriatal injection of cholesterol-conjugated siRNA targeting huntingtin in mice expressing a mutant huntingtin gene silences the target mRNA, attenuates neuronal pathology, and delays the abnormal behavioral phenotype observed in a rapid-onset, viral transgenic mouse model of Huntington's disease [70].

24.4.2.2 Other Natural Ligands

Beyond cholesterol, other natural ligands have been successfully directly conjugated to siRNA duplexes. Among some siRNA conjugates described are membrane-permeant peptides such as penetratin and transportan [71]. While these conjugates were successfully synthesized with RNAi silencing activity preserved, robust *in vitro* or *in vivo* evidence indicative of an impact on cellular delivery is still lacking. Nevertheless, work done using natural ligands as targeting agents for siRNA formulated in conjunction with delivery vehicles has been positive. Molecules such as transferrin [72], folate [73], and Arg-Gly-Asp (RGD) peptide [74] have been introduced into particle-based delivery vehicles to help provide specific targeting of siRNA to cells bearing the natural receptor.

24.4.2.3 Aptamers

The use of RNA aptamers as a conjugate for delivery and targeting of siRNA is a promising and elegant approach. In contrast to most of the other described delivery methods, this approach allows for specific targeting of particular cell types and yet, unlike a similar antibody-based approach, has an additional advantage that the therapeutic can be composed entirely of RNA (i.e., RNA aptamer linked to an siRNA). Recently, *in vitro* and *in vivo* proof of concept has been generated using aptamers to prostate-specific membrane antigen (PSMA), a cell-surface receptor overexpressed in prostate cancer cells and tumor vascular endothelium [75,76]. PSMA

aptamers, when either directly linked to siRNA [75] or conjugated through a modular streptavidin bridge [76], were capable of promoting specific cellular uptake and RNAi-mediated silencing of target mRNA *in vitro*. Using siRNA directed against survival genes (plk1 and bcl-2) directly linked to PSMA aptamer, it was found these RNA chimeras were internalized by cells and resulted in RNAi-mediated target mRNA silencing and cell death [75].

One concern about aptamer–siRNA chimeras is the potential difficulties in synthesis of long RNA molecules. Short aptamers (25–35 bases) that bind to a wide variety of targets with high affinity have been described [77]. Thus, in theory, it is possible to design siRNA–aptamer chimeras that would have a long strand of 45–55 bases, a synthesis length that is within the range of technical and commercial feasibility.

24.4.2.4 Small Molecules

Beyond natural ligands and aptamers as targeting vehicles for siRNA, there also exists the possibility of using small-molecule drugs in this fashion. Conceptually, targeting siRNA to specific cell types through conjugation to small molecules (or as discussed below through complexation to antibodies) is appealing. Developing small-molecule conjugates capable of promoting entry of siRNA into cells requires selection of an appropriate small molecule that is capable of efficient cellular internalization and endosomal escape.

24.4.3 LIPOSOMES AND LIPOPLEXES

Drugs have traditionally been formulated in liposomes in order to provide increased pharmacokinetic properties or decreased toxicity profiles. With the advent of RNAi, research

in the use of liposomes to deliver drugs into cells has surged. Liposomes are vesicles that consist of an aqueous compartment enclosed in a phospholipid bilayer with drug typically entrapped in the central aqueous layer. When lipids simply complex with nucleic acids to form particles, they are known as lipoplexes and are typical of most commercial transfection agents, such as Lipofectamine 2000 and TKO. Liposomes are multicomponent lipid-based nanoparticle delivery systems typically comprising a lipid component (often containing a cationic or a fusogenic lipid), cholesterol, and a polyethylene glycol (PEG)–lipid. Each of these components have a critical function to play in the fusogenicity and pharmacokinetic properties of the liposome (Figure 24.4; for review see Refs. [78,79]).

Both liposomes and lipoplexes have been extensively utilized to deliver siRNA *in vitro* and *in vivo*. *In vitro* transfection of siRNA using lipid-based delivery agents is now a routine laboratory procedure. More recently, significant success has been demonstrated with both local and systemic administration of siRNA. One of the most important advances in the development of RNAi as a therapeutic came with the demonstration by Zimmermann et al. that systemically delivered siRNA in stable nucleic acid lipid particles (SNALPs [32]) was able to dramatically silence ApoB in mice and nonhuman primates [80]. Most importantly, a single intravenous dose of 2.5 mg/kg of SNALP-formulated siRNA in cynomolgus monkeys was able to reduce ApoB mRNA levels in the liver by >90%. As expected, accompanying ApoB mRNA silencing, levels of serum cholesterol and low-density lipoproteins were reduced by greater than 65 and 85%, respectively. Remarkably, the durability of silencing following a single intravenous dose of 2.5 mg/kg SNALP-formulated siRNA was shown to last for at least 11 days. Treatment with liposomally formulated siRNA was well tolerated in these

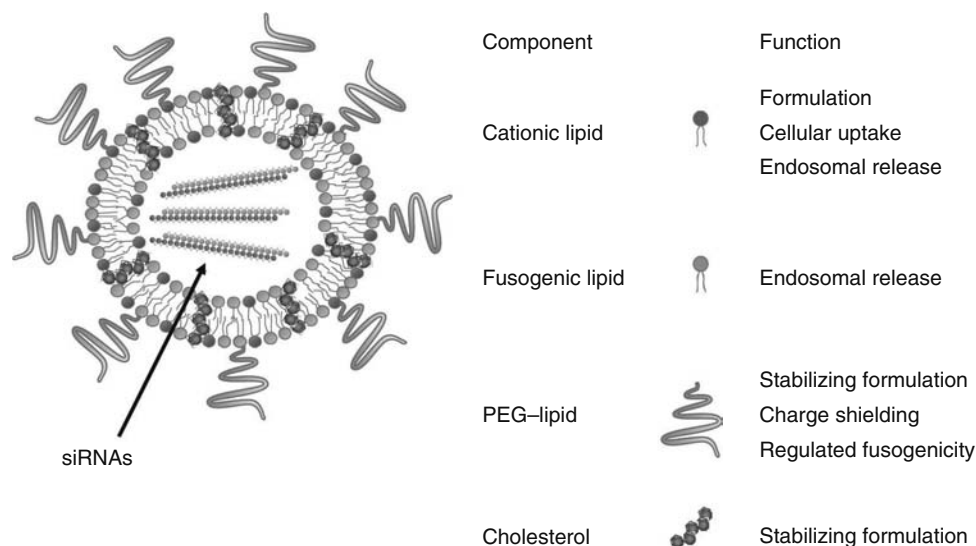

FIGURE 24.4 (See color insert following blank page 206.) Structure and function of a cationic liposome. Composition of a SNALP is shown. Other cationic liposome formulations also exist, which may or may not contain a fusogenic or PEG–lipid. Ratios of different components also can vary between formulations.

experiments, with transient increases in liver enzymes as the only reported evidence of toxicity, and these effects may be related to the targeting of ApoB itself. The general applicability of SNALP formulations for hepatic delivery of siRNA was also demonstrated in animal models of Hepatitis B virus and Ebola virus infection [81,82]. Other “non-SNALP” liposomes have also been demonstrated to be effective in delivering siRNA to different organs. Systemic delivery of a cationic liposome containing TNF α siRNA specifically inhibited TNF α production in knee joints and alleviated disease in a mouse model of rheumatoid arthritis [83], while a liposomally formulated caveolin-1 siRNA reduced target expression by 90% in mouse lung endothelia with concomitant expected physiological effects [84]. In summary, use of lipid-based formulations for systemic delivery of siRNA, especially to liver, represents one of the most promising near-term opportunities for development of RNAi therapeutics.

Local administration of liposomes and lipoplexes has also been successful in delivering siRNA to target cell types in the eye, nervous system, and tumors. Within the ocular context, subretinal injection of VEGF siRNA formulated in Transit-TKO was found to reduce CNV in a laser-induced mouse model [46], and subconjunctival injection of TGB- β receptor II siRNA in Transit-TKO to suppressed inflammation and fibrosis in a mouse subconjunctival scarring model [49]. With regards to the nervous system, intracranial delivery of lipid-complexed siRNA targeting the viral envelope genes protected mice against Japanese encephalitis virus- and West Nile Virus-induced encephalitis [65]. Similarly, intrathecal administration of cationic lipid formulated delta opioid receptor (DOR) siRNA facilitated delivery and specific target gene silencing in the spinal cord and dorsal root, resulting in blocked antinociception by a DOR-selective agonist [63]. Numerous publications have reported successful antitumoral effects following either direct or systemic tumoral injection of lipid-formulated siRNA (for reviews, see Refs. [38,43–45]). One recent example demonstrated that either intratumor injection or intraperitoneal injection of TransMessenger-formulated siRNA directed against the human papillomavirus E6 oncogene inhibited tumor growth, suppressed E6 expression, and induced tumor apoptosis in a subcutaneous cervical cancer xenograft model [85]. It is important to note that the necessity for lipid-based delivery systems (and this holds true for other delivery systems as well) in many of these direct RNAi applications must be assessed in a target cell- and disease-specific manner. For eye, lung, and nervous system, there are numerous examples of siRNA being successfully delivered in the absence of such agents and other examples where the converse is true.

Lastly, an area of increasing interest is direct application of lipoplexed siRNA to mucosal surfaces such as the vagina and intestine. Intravaginal delivery of lipid-complexed siRNA directed against herpes simplex 2 virus was found to protect mice when delivered before or after lethal herpes virus challenge [86]. Corroborating these results is evidence for specific lamin A/C and CCR5 silencing using the relevant targeting siRNA complexed with Lipofectamine 2000; similarly complexed

irrelevant siRNA had no effect on silencing [87]. Direct delivery of a TNF α siRNA in a Lipofectamine formulation has also recently been demonstrated to not only reduce TNF α levels but also attenuate colonic inflammation after enema administration [87]. Intravaginal and intracolonic administration of siRNA using these lipid-based delivery systems was well tolerated in mice with no reported evidence of toxicity or activation of an interferon response [86,87]. Given the relatively easy physical access, the large number of potential unmet medical disorders, the general tolerability of the siRNA-lipid formulations, and importantly, the demonstrated robust *in vivo* delivery success, mucosal administration of lipid-formulated siRNA will be a fertile area for the development of future RNAi therapeutics.

24.4.4 PEPTIDES AND POLYMERS

Complexation of siRNA with positively charged peptides or polymers has been a field of increasing interest [88]. In general, cationic peptides and polymers are used to form complexes with the negatively charged phosphate backbone of the siRNA duplex. This noncovalent association is very stable and results in nanometer-sized particles. One concern with complexation approaches is the ability to prevent aggregation and thus control particle formation in a reproducible manner. This is most often done by either maintaining a net positive charge on the surface or incorporating molecules such as PEG that help stabilize the particle and prevent aggregation. PEG groups are also used with polymers to improve the pharmacokinetic profile, while agents such as folate, transferrin, antibodies, or sugars such as galactose and mannose can be incorporated for tissue targeting [89]. Beyond improving particle targeting *in vivo*, another essential aspect is to design particles that are capable of promoting efficient endosomal escape. Several pH-triggered polymers that facilitate endosomal escape have been identified [79,90]; data with one of these peptides have already been shown to improve RNAi-mediated silencing *in vitro* [91].

One of the most widely studied polymers for delivery of nucleic acids is polyethylenimine (PEI). PEI polymers are synthetic linear or branched structures with protonable amino groups and high cationic charge densities. Following complexation with siRNA, the cationic polyplexes are thought to interact with the cell surface through electrostatic interaction and are taken up by cells through endocytosis, where intracellularly, they act to buffer the low endosomal pH. Endosomal escape is hypothesized to occur due to a “proton sponge” effect, whereby PEI enhances the influx of protons and water, leading to endosomal destabilization and osmotic release of the polyplexes into the cytoplasm [92]. Multiple reports of use of siRNA-PEI complexes *in vivo* now exist. PEI complexed with influenza siRNA were reported to result in profound antiviral effects in infected mice [93], while similar targeting of the Ebola L gene resulted in protection against lethal Ebola infection in guinea pigs [82]. Profound antitumor activity was seen upon administration of PEI-siRNA complexes targeting pleiotrophin [94], VEGF [74], and HER2

[95]. Lastly, local injection of PEI-siRNA polyplexes targeting the NMDA receptor subunit NR2B significantly attenuated formalin-induced nociception in the rat [64]. One of the main concerns with the use of PEI as a therapeutic delivery vehicle is the extreme toxicity seen at higher doses. In an attempt to expand the safety margin, several groups are optimizing the physical structure of PEI to enable improved *in vivo* delivery of siRNA [96–98]. In addition to PEI, other synthetic polycations consisting of histidine and polylysine residues have also been evaluated for delivery of siRNA and appear to have improved *in vitro* efficacy as compared to standard PEI [99].

Four other polymer approaches that have yielded *in vivo* siRNA data are dynamic polyconjugates, chitosan nanoparticles, cyclodextrin-based nanoparticles, and atelocollagen nanoparticles. The first of these delivery approaches uses dynamic polyconjugates and has been shown *in vivo* in mice to effectively deliver siRNA and silence endogenous target mRNA (ApoB and PPAR- α) in hepatocytes [100]. This is a multicomponent polymer system whose key features include a membrane-active polymer to which siRNA is covalently coupled via a disulfide bond and where both PEG (for charge masking) and *N*-acetylgalactosamine (for hepatocyte targeting) groups are linked via pH-sensitive bonds [100]. Upon binding to the hepatocyte and entry into the endosome, the polymer complex disassembles in the low pH environment, with the polymer exposing its positive charge, leading to endosomal escape and cytoplasmic release of the siRNA from the polymer. While this is an elegant and exciting approach using both targeted delivery and endosomal escape mechanisms, further work remains to be done to understand whether it represents a viable drug delivery modality. Another interesting, though complex, polymer approach involves using transferrin-targeted cyclodextrin-containing polycation nanoparticles. These nanoparticles have demonstrated targeted silencing of the EWS-FLI1 gene product in transferrin receptor-expressing Ewing's sarcoma tumor cells [72] and siRNA formulated in these nanoparticles was well tolerated in nonhuman primates [101]. A third approach has used chitosan, which is a well-tolerated natural biodegradable polymer, to form cationic complexes with nucleic acids. Effective *in vivo* RNAi interference was achieved both in bronchiole epithelial cells of transgenic EGFP mice after intranasal administration of chitosan/siRNA formulations [102] and in subcutaneously implanted breast cancer cells of nude mice after intravenous administration of chitosan/RhoA siRNA complexes [103]. A fourth polymer approach, which has received substantial attention, uses a fragment of collagen known as atelocollagen. Systemic administration of atelocollagen-siRNA complexes had marked effects on subcutaneous tumor xenografts as well as on bone metastases [104,105]. Lastly, other related polymer approaches such as polyamidoamine (PAMAM) dendrimers and poly(DL-lactic-co-glycolic acid) (PLGA) nanoparticles are also being investigated as vehicles for siRNA delivery [106,107], though *in vivo* evidence for RNAi-mediated silencing remains to be demonstrated using these approaches.

Peptide-based approaches, including use of cell-penetrating peptides, to deliver oligonucleotides is an area of active research [90,108–110]. Several peptide-based gene delivery systems such as MPG [111], Penetratin [112], and cholesteryl oligo-D-arginine (Chol-R9) [113] have been shown to promote siRNA uptake *in vitro*. In the case of Chol-R9, local *in vivo* administration of complexed VEGF-targeting siRNA, but not complexed scrambled siRNA, led to tumor regression in a mouse model [113]. Another peptide-based system to demonstrate *in vivo* silencing was a synthetic chimeric peptide consisting of nonamer arginine residues (9R) added to the carboxy terminus of a 29-amino acid rabies virus glycoprotein (RVG) peptide, which specifically binds to the acetylcholine receptor expressed by neuronal cells [110]. Using this system, siRNA were complexed with the positively charged RVG-9R peptide and found to be capable of delivering siRNA to neuronal cells following intravenous administration, resulting in specific gene silencing [110]. Lastly, peptide-based approaches are often coupled with other delivery systems, such as liposomes to enable more targeted delivery of oligonucleotides [74,114].

24.4.5 ANTIBODIES

Antibody-based approaches for specific targeted delivery of siRNA hold much promise. Recently, elegant studies have demonstrated that a protamine-antibody fusion protein was able *in vitro* to selectively deliver siRNA to HIV-envelope expressing B16 melanoma cells or HIV-infected CD4 T cells [115]. Protamine is used for its nucleic acid-binding properties while the Fab fragment was used to mediate receptor-specific binding to only those cells expressing the gp160 HIV envelope protein. Importantly, using gp160-B16 cells as a tumor model, it was shown that siRNA-antibody-protamine complexes when delivered either intratumorally or intravenously are able to specifically deliver siRNA *in vivo* and retard tumor growth. Recently fusion proteins that target all human white blood cells or just activated leukocytes using conformation-sensitive, single-chain antibodies to the integrin LFA-1 have demonstrated the exquisite selectivity of this targeting strategy both *in vitro* and *in vivo* [116]. These studies demonstrate the potential for antibodies to direct siRNA selectively into cells *in vivo*.

24.5 CLINICAL TRIALS

RNAi has rapidly advanced from research discovery to clinical trials. Four different RNAi therapeutics are under clinical investigation, with several more poised to enter trials soon. Initial trials have focused on well-validated therapeutic targets, such as the VEGF pathway for the wet form of AMD and the RSV genome, for the treatment of RSV infection. The status of the clinical-stage programs is summarized below.

24.5.1 OCULAR

Ophthalmic indications have historically been attractive for oligonucleotide-based therapeutics. The only approved

oligonucleotide-based drugs are used in the eye—Vitravene® to treat CMV retinitis [117] and Macugen® for AMD [118]. Direct injection into the vitreal cavity efficiently targets oligonucleotide drugs to the retina. Another advantage of the ocular compartment is that it is relatively free of nucleases, compared to serum. While this permits unmodified siRNA to be used in the vitreal cavity, exonuclease-stabilizing chemistries can dramatically improve the persistence of intact siRNA following intravitreal injection [51]. The ease of intraocular drug delivery, combined with the clinical validation of VEGF as an attractive therapeutic target for proliferative vascular retinopathies, led to the rapid development of several RNAi therapeutics.

Intravitreal injection of Bevasiranib or Cand5, an unmodified siRNA targeting all VEGF-A spliced isoforms, has completed a phase II trial in patients with serious progressive wet AMD and has been reported to provide dose-related benefits against several endpoints including near vision and lesion size (Opko Pharmaceuticals press release). Cand5 is currently being tested in phase III clinical trials for wet AMD.

Sirna-027, a chemically modified siRNA targeting the VEGF receptor (VEGF-R1), completed phase I trials in patients with wet AMD and was reported to be well tolerated. It was also reported to stabilize or improve visual acuity in a subset of patients (Sirna Pharmaceuticals press release). Development of this molecule has transitioned to Merck Pharmaceuticals following their acquisition of Sirna Therapeutics.

RTP801i-14, a chemically modified siRNA targeting the hypoxia-inducible gene RTP801, is currently in phase I/II trials for the treatment of wet AMD. Intravitreal injection of RTP801i-14 resulted in inhibition of CNV and vessel leakage in mouse and primate models (Quark press release). In pre-clinical studies, RTP 801i-14 was shown to work in cooperation or synergy with VEGF-based drugs.

24.5.2 RESPIRATORY

There are many advantages to delivering siRNA therapeutics directly to the lungs for targeting lung epithelial cells. Lung epithelial cells are capable of naked siRNA uptake and RNAi-mediated silencing [52,54,57]. Moreover, the local lung environment is relatively nuclease-free compared to serum. Delivery to the lung by inhalation is noninvasive and directly targets the tissue epithelium, which improves drug concentrations at the target tissue without first-pass metabolism, reduces drug dosing, and decreases the likelihood of systemic side effects. While in many instances, naked siRNA in saline appears to be effective, other approaches to optimize lung delivery may need to be developed for different indications.

The first pulmonary studies are directed at treating RSV, a serious neonatal respiratory infection. Two phase I intranasal trials with ALN-RSV01, an siRNA targeting the viral nucleocapsid (N) gene, have been completed in over 100 healthy adult volunteers. ALN-RSV01 was found to be safe and well tolerated (Alnylam Pharmaceuticals press release).

Clinical development of ALN-RSV01 is progressing with experimental infection studies ongoing.

24.6 SUMMARY

RNAi has advanced from research discovery to clinical trials in a very short span of time, starting with the now Nobel Prize winning discovery in 1998 by Fire and Mello that long dsRNA could mediate RNAi in *Caenorhabditis elegans* [1], to evidence in 2001 by Tuschl and colleagues that short synthetic siRNA could induce RNAi in mammalian cells [2], to the present day when four different RNAi therapeutics are in human clinical trials and numerous others poised to enter. Since discovery of its utility in mammalian cells six years ago, RNAi has revolutionized biomedical research and has spawned a veritable explosion of scientific knowledge covering all aspects of *in vitro* and *in vivo* RNAi biology. The principal challenge that remains in achieving the broadest application of RNAi therapeutics is the hurdle of delivery. Tremendous progress has been made on this front through the use of different approaches, such as conjugation, complexation, and lipid-based approaches, though it is clear that delivery is yet to be solved for all cell types and tissues. Delivery solutions as they arrive will likely need to be tailored for target cell type and the disease indication. In identifying and optimizing delivery solutions, the use of reporter systems (either endogenous cell-type-specific genes or transgenes) can greatly expedite the process. Likewise in optimizing formulations, it is vital that the key parameters of efficacy and safety be assessed in parallel in order to rapidly arrive at the optimal formulations, which have the greatest therapeutic window. As the challenge of siRNA delivery is met, it will be possible to rapidly advance RNAi therapeutics against potentially any disease target into clinical studies. The ongoing clinical trials with siRNA for the treatment of AMD and RSV infection will be the first indicator of the potential for RNAi therapeutics to be a revolutionary new class of drug molecules.

25.1 INTRODUCTION

Despite a trend toward decreasing incidence and mortality during the past decade, cancer is responsible for one in four deaths and approximately 1.5 million new cases annually in the United States [1]. Advances in surgical technique, as well as new forms of neoadjuvant chemotherapy and radiotherapy, are increasing the number of patients who can be cured by surgery. On the other hand, cancer patients who present with advanced disease not amenable to curative resection are being treated with radiotherapy and chemotherapy with the goal of achieving local and systemic disease control. Responses to these forms of treatment are usually temporary and cause significant toxicity to healthy tissues. Efforts are being made to

direct the cytotoxic effects of chemotherapy and radiotherapy to malignant cells in order to avoid injury to nonneoplastic tissues. At the same time, improved understanding of tumor immunology and genetics is fueling the development of new treatment modalities that will achieve the same goals.

Although initially perceived as a potential treatment for inherited single-gene defects, gene therapy is attracting significant research interest as a cancer treatment that could achieve selective tumor cell toxicity. The therapeutic principle behind gene therapy is the correction of genetic abnormalities by the insertion and expression of normal genes in cells with inherited or acquired monogenic defects. In contrast to single-gene disorders such as cystic fibrosis, the genesis of an invasive neoplasm is characterized by multiple gene mutations.

By the time tumor volume is significant to cause clinical manifestations, it consists of multiple subclones of cells that have resulted from different combinations of mutations. Hence, attempts to treat tumors by restoring the function of mutated genes would be impractical.

As a result of these limitations, suicide gene therapy has evolved as a different approach to cancer gene therapy, which can be used alone or in combination with other treatment modalities. Since suicide gene therapy emerged in the 1980s, two forms of therapy have been suggested [2]. The first relies on inserting genes into tumor cells that encode cytotoxins, which directly lead to cell death once the gene is expressed. This form of treatment has not received significant attention and will not be further discussed. The other form of suicide gene therapy, also known as gene-directed enzyme prodrug therapy (GDEPT), virus-directed enzyme prodrug therapy (VDEPT), or gene-prodrug activation therapy (GPAT), consists of inserting a gene into malignant cells, which encodes an enzyme able to convert a nontoxic prodrug to a toxic compound, which will result in cell death [3]. In this chapter, the term "suicide gene therapy" will be used. Key steps for the success of suicide gene therapy are (1) efficient suicide gene delivery to as many tumor cells as possible and (2) expression of the suicide gene in all transfected cells and until enough toxic metabolite has been produced to cause cell death. At the same time, delivery and expression of the suicide gene to normal cells should be avoided or minimized to prevent toxicity to healthy host tissues. Based on these principles, a number of "suicide" gene-prodrug combinations have been developed.

This chapter will discuss the physiologic principles of suicide gene therapy, the suicide gene-prodrug combinations currently in use, the different vectors used to deliver suicide genes, the mechanisms responsible for the bystander effect, and the current status of clinical trials of suicide gene therapy.

25.2 PRODRUGS, ENZYMES, AND SAFETY PRINCIPLES

A number of features are responsible for the different efficacy and safety of prodrugs and enzymes used in suicide gene therapy. Ideal prodrugs are stable compounds with minimal or no toxicity to host tissues that diffuse through the interstitial space and cell membrane to reach tumor cells in high concentrations. In addition, their activation should include as few steps and enzymes as possible to reduce the chance of enzyme mutation leading to reduced prodrug activation and resistance to treatment [3]. Prodrugs can be divided into two groups depending on their activation kinetics. Directly linked prodrugs are those that require chemical transformation to directly release an active, toxic compound. The second prodrug class, self-immolating prodrugs, produces an unstable intermediate during the activation process, which is converted to the final cytotoxic metabolite in a number of subsequent steps. Such prodrugs are characterized by a site of activation that differs from the site where the cytotoxic metabolite is released [2].

In contrast to prodrugs, enzymes have a large number of parameters that determine their efficacy and safety. At present, enzymes used in suicide gene therapy can be divided into two categories. The first consists of enzymes foreign to mammalian cells, with or without mammalian counterparts, such as viral thymidine kinase and bacterial cytosine deaminase (CD) that are part of metabolic pathways occurring exclusively in bacteria, viruses, or fungi. Structural differences must exist between these enzymes and their mammalian counterparts to ensure different prodrug affinity and hence selective prodrug activation in malignant cells. This is analogous to the selective effects of antimicrobials on bacteria, viruses, and fungi due to their ability to interfere with metabolic pathways specific to these organisms. The fact that such enzymes are foreign proteins makes them immunogenic. The second class of enzymes are normally present in mammalian cells but are not expressed in neoplastic cells. These include deoxycytidine kinase (dCK), carboxypeptidase A (CPA), β -glucuronidase (β -Glu), and cytochrome P450 (CYP). Their main advantage is reduced immunogenicity. On the other hand, their presence in healthy host tissues increases their potential for prodrug activation in these cells, reducing their safety profile. To solve this problem, these enzymes require modification prior to use to ensure different substrate affinity in tumor cells [3].

Besides lack of immunogenicity, the efficacy of enzymes depends on several other characteristics. Advantageous enzymes produce significant metabolite concentrations even at low enzyme concentrations, i.e., when the suicide gene is inefficiently or transiently expressed. Furthermore, enzyme catalytic activity should not require cofactors [3]. In terms of classic enzyme kinetics, ideal enzymes should have a high maximal velocity of catalytic activity, V_{\max} , and a low substrate concentration at which the reaction can proceed efficiently, as expressed by the Michaelis-Menten constant, K_m . Current kinetic data available for enzyme-prodrug combinations are insufficient to accurately compare the different systems [3]. Also, it is unknown whether a sudden release of toxic metabolites is beneficial in terms of tumor cell killing compared to a slow, steady release. Finally, the relative sensitivity of resting and dividing tumor cells to toxic metabolites is also not known [3].

The enzymes used in suicide gene therapy are also characterized by different safety profiles, which are directly related to mechanism of enzyme action. Most suicide gene-prodrug combinations result in the production of metabolites that inhibit nucleic acid synthesis. Hence, their effects are more pronounced in cells that are in the S phase of the cell cycle, when nucleic acid synthesis occurs. As a result, malignant cells that divide more rapidly than normal host cells will be predominantly killed upon exposure to the cytotoxic products of suicide gene action. It follows that suicide gene-prodrug combinations that lack selectivity for dividing cells are associated with increased risks of host cell toxicity. Although this mechanism protects host cells from toxicity because of their lower rate of proliferation compared to tumor cells, it has the disadvantage of targeting only malignant cells that are proliferating. Since only a fraction of tumor cells are

proliferating at the time of prodrug administration, it follows that prolonged treatment would be required to kill all cells within a tumor or that combination therapy with other treatment modalities able to target quiescent tumor cells would be necessary.

25.3 SUICIDE GENE-PRODRUG COMBINATIONS

Although all suicide gene-prodrug combinations follow the principles of suicide gene therapy discussed above, they differ in mechanism of action, degree of tumor cell toxicity, safety, and presence of a bystander effect (Table 25.1). For comparison of the efficiency of different prodrug-enzyme systems, two parameters are in use: the potential of activation of a given system and its degree of activation. The activation potential indicates the maximal killing efficiency of a given system toward a tumor cell line. It is defined as the ratio of the prodrug concentration required to kill 50% of cells in culture (known as IC_{50}) to the IC_{50} of the active drug in a nontransfected tumor cell line. The degree of activation is the ratio of the prodrug IC_{50} in the nontransfected cell line to the prodrug IC_{50} in the transfected cell line that expresses the activating enzyme. Both these parameters depend on the cell line's sensitivity to the drug, but the degree of activation also indicates the efficiency of the prodrug toward a specific cell line [2].

It should be noted that, for a number of reasons, efficient tumor cell killing *in vitro* does not always translate into equivalent *in vivo* results. In addition, cancers differ in their susceptibility to suicide gene therapy as a whole and to specific suicide gene-prodrug combinations. For example, HSV-TK, the most widely used form of suicide gene therapy, is less effective in the treatment of hemopoietic malignancies despite good results against most solid tumors [4]. This is most likely due to more rapid downregulation of suicide gene expression

in hemopoietic malignancies, resulting in lower enzyme concentrations and inefficient prodrug conversion to its toxic metabolite [5].

25.3.1 HERPES SIMPLEX VIRUS-THYMIDINE KINASE

Herpes simplex virus-thymidine kinase (HSV-TK) has proven effective against a number of solid human tumors and is the most well-studied and widely applied suicide gene therapy strategy available. Since the first *in vivo* application of HSV-TK gene therapy in mice with gliomas, this form of suicide gene therapy has been tested in a number of human tumors including thoracic, head and neck, ovarian, and gastrointestinal tract malignancies [6–10]. HSV-TK-GCV is the “prototype” suicide gene therapy system and has been used to test new prodrugs, modified enzymes, multiple suicide gene therapy, combinations of suicide gene therapy with other cancer treatment modalities, and other techniques and ideas in the field of suicide gene therapy.

HSV-TK therapy relies on tumor cell transfection with the gene encoding the TK enzyme found in HSV. This enzyme monophosphorylates gancyclovir (GCV), an analog of acyclic guanosine that is in clinical use as an antiviral drug. GCV monophosphate is then further phosphorylated by mammalian cell kinases to GCV di- and triphosphate, which become incorporated into the replicating DNA chain in dividing tumor cells, inhibiting DNA polymerase, and terminating DNA production, resulting in apoptosis [11]. Although host cells express a mammalian thymidine kinase, which also monophosphorylates GCV, this occurs with 1000-fold lower efficiency than in tumor cells expressing the viral enzyme, leading to negligible host cell toxicity [12–16]. Importantly, phosphorylated GCV is a polar molecule that cannot cross the cell membrane and rapidly accumulates inside cells, enhancing its cytotoxicity to tumor cells in which it is produced [15,16]. However, it was

TABLE 25.1
Suicide Genes, Metabolites, Mechanisms of Action, and Bystander Effect

Gene	Final Metabolite(s)	Direct Cytotoxic Effect	Bystander Effect	Reference
HSV-TK	GCV TP	Disrupts DNA synthesis	Present	[12]
CD	5-FU-MP/TP	Disrupts DNA/RNA synthesis	Present	[25]
VZV-TK	Ara-ATP	Disrupts DNA synthesis	Low/absent	[29]
NTR	4-hydroxylamine metabolite of CB1954	Crosslinks DNA DNA breaks Disrupts DNA synthesis	Present	[32]
CYP2B1	Phosphoramidate mustard Acrolein	DNA alkylation (crosslinks DNA) Crosslinks cellular proteins	Present	[39]
CPG2	Benzoic acid mustard	DNA alkylation (crosslinks DNA)	Present	[42]
XGRPT	6-Thioguanine MP	Disrupts DNA synthesis	Presumed	[45]
PNP	6-Methylpurine	Direct toxin/cellular necrosis	Present	[49]
HRP	IAA	Free radical formation	Present	[50]
CYP1A2	NABQI	Protein arylation/oxidation	Present	[65]
Mutated tyrosinase	Quinone compounds	Unknown	Unknown	[56]
UPRT	FUMP	Disrupts DNA/RNA synthesis	Minimal	[57]

demonstrated that labeled GCV can pass between cells via gap junctions, a property that depends on its small molecular weight [17]. As explained later, this is one mechanism responsible for the “bystander effect.”

A relatively new strategy for targeting TK expression involves the use of tissue-specific promoters. These are gene elements that when activated by transcription factors stimulate gene expression. Inserting such a promoter upstream of a suicide gene to create a new “transgene” will stimulate gene expression in tissues expressing transcription factors that activate the promoter. TK has been the main suicide gene used to create transgenes with a number of tissue-specific promoters. An example of this technique is the rat insulin promoter (RIP)-TK transgene. This is a gene construct made by combining the RIP with the TK gene. The RIP is potently activated by pancreatic duodenal homeobox-1 (PDX-1), a transcription factor that activates the insulin gene and is expressed almost exclusively and in high levels by pancreatic β -cells. Hence, after systemic administration of this gene construct, TK gene expression will be potently stimulated in cells with abundant PDX-1. This strategy has been used against pancreatic adenocarcinoma *in vitro* and *in vivo* with encouraging results [18–20]. The same method has been used to treat metastatic prostate carcinoma using the osteocalcin (OC) gene promoter to create an OC-TK transgene. OC is expressed in human prostate cancer cells and surrounding stroma. However, due to its expression in normal osteoblasts, it is not entirely tumor-specific and cannot be given systemically. In a human clinical trial, OC-TK was injected into lymph node and bone prostate cancer metastases packaged in an adenoviral vector. This treatment was well tolerated and caused marked tumor cell apoptosis in seven of the eleven patients treated [21].

25.3.2 CYTOSINE DEAMINASE

CD is the second commonest suicide gene in clinical and pre-clinical application and shares a number of features with TK. It is also involved in nucleic acid metabolism and is absent from mammalian cells. CD is expressed in bacteria and fungi and normally catalyzes the deamination of cytosine to uracil. Its role in suicide gene therapy is due to its ability to convert the prodrug 5-fluorocytosine (5-FC) to 5-fluorouracil (5-FU) [22–24]. Due to the expression of CD in fungi and its absence from mammalian cells, 5-FC has been used as an antifungal. 5-FU is cytotoxic to mammalian cells without further phosphorylation, this being the basis of its use in cancer chemotherapy. However, in a step analogous to the phosphorylation of GCV monophosphate mentioned in the previous section, intracellular kinases present in both microbes and mammalian cells convert 5-FU to 5-fluorouridine 5'-triphosphate and 5-fluoro-2'-deoxyuridine 5'-monophosphate. These metabolic products are directly cytotoxic by disrupting RNA and DNA synthesis.

As with HSV-TK, CD-based suicide gene therapy results in a significant bystander effect. In this respect, CD is advantageous over HSV-TK due to the ability of 5-FU, the cytotoxic

product of this system, to cross cell membranes, enter neighboring nontransfected tumor cells and exert its lethal effects. In addition, 5-fluorouridine 5'-triphosphate and 5-fluoro-2'-deoxyuridine 5'-monophosphate have their own contribution to the bystander effect once they leak out of apoptotic tumor cells [25].

Like HSV-TK, CD has also been fused with tumor-specific promoters to create transgenes. Zhang and coworkers used the carcinoembryonic antigen (CEA) promoter to create a CEA-CD transgene, achieving specific *in vitro* expression of the CD gene by human colon cancer cell lines positive for CEA [26]. In a different study, the same group demonstrated tumor-specific expression of the CD suicide gene after adenoviral administration of CEA-CD to rats bearing hepatic tumors of human colon cancer cells [27]. CD has its own set of limitations that have to be addressed before it becomes more suitable for widespread clinical use. Although the effects of 5-FU are not S-phase-specific, it has increased toxicity on rapidly dividing cells, resulting in the implications on tumor cell toxicity described above. In addition, the intracellular concentrations of 5-FU required for cytotoxicity are relatively high, which translates into the need for efficient tumor cell transfection with CD, high levels of CD expression, and high doses of 5-FC. Due to CD expression by normal intestinal flora, high 5-FC doses result in bacterial 5-FU production that is released into the gut lumen and injures intestinal cells. Finally, the duration of 5-FU toxicity is approximately 10 min, requiring prolonged CD expression and 5-FC administration for 5-FU concentrations to reach toxic levels.

25.3.3 VARICELLA ZOSTER VIRUS-THYMIDINE KINASE

Varicella zoster (VZV) is another herpes virus that expresses its own TK, with a substrate specificity distinct from that of HSV-TK and mammalian enzymes. Once the gene is expressed after insertion into tumor cells, VZV-TK acts on the prodrug 9-(β -D-arabinofuranosyl)-6-methoxy-9H-purine, also known as araM [28]. AraM is initially phosphorylated by VZV-TK and then further metabolized by other enzymes that naturally occur in mammalian cells (AMP deaminase, AMP kinase, nucleoside diphosphate kinase, and adenylosuccinate synthetase lyase) into adenine arabinonucleoside triphosphate (araATP). AraATP is a highly toxic metabolite that kills tumor cells even when present in small concentrations. AraM cannot be metabolized by mammalian enzymes, ensuring exclusive araATP production in cells transfected with VZV-TK. This strategy is relatively new and shares the advantages and disadvantages of the HSV-TK-GCV. The safety and efficacy of VZV-TK-araM as well as the presence of a bystander effect are under investigation although in the *in vitro* bystander effect is minimal [29].

25.3.4 ESCHERICHIA COLI NITROREDUCTASE

E. coli nitroreductase (NTR) reduces dinitrophenylaziridine CB1954 to a 4-hydroxylamine metabolite that reacts with intracellular thioesters such as acetyl-CoA to produce an

alkylating agent that is 10,000-fold more toxic than the original prodrug [30]. This product exerts its toxicity on dividing and nondividing cells through crosslinking of DNA strands, resulting in disruption of DNA synthesis and breaks in the DNA molecule [31]. A bystander effect has been shown for this system *in vitro* and *in vivo* [32]. The NTR-CB1954 system has a more rapid onset of cytolytic action than HSV-TK-GCV, which has been attributed to its lack of selectivity for dividing cells [31,33]. As mentioned previously, this is a particularly advantageous feature regarding tumor cell killing, but could also increase toxicity to normal host tissues. Hence, specific tumor cell targeting is especially important with this strategy. This limitation has precluded more widespread use of NTR-CB1954 until increased transfection efficiency and tumor-specific targeting are possible. As part of this effort, the NTR gene has been used to create transgenes with promoters of human telomerase reverse transcriptase (hTERT) and human telomerase (hTR), the two genes encoding for subunits of human telomerase. The latter enzyme is expressed in more than 85% of human cancers but is absent from other adult human cells with the exception of stem cells [34]. Bilsland and coworkers achieved suppression of tumor growth in animals bearing ovarian and cervical cancer xenografts after administration of hTR-NTR and hTERT-NTR [35]. In their study, tumor specificity of suicide gene expression was not assessed because the transgene was delivered locally [35,36].

25.3.5 CYTOCHROME P450 2B1

The antineoplastic activity of the nontoxic prodrug cyclophosphamide (CPA) is initiated by hepatic cytochrome P450 2B1 (CYP2B1) [37], which converts CPA to 4-hydroxy-CPA. The latter compound then spontaneously decomposes into acrolein, which covalently crosslinks cellular proteins, and phosphoramidate mustard (PM), which alkylates DNA and causes DNA breaks during replication. Although both these compounds are theoretically toxic, the role of acrolein in killing tumor cells *in vivo* has not been demonstrated. It has been suggested that acrolein sensitizes tumor cells to PM [38]. On the other hand, PM is directly toxic to dividing and nondividing cells and shares the advantages and disadvantages of other suicide enzyme metabolites with this feature, as outlined above. In addition, 4-hydroxy-CPA is able to cross cell membranes and enter nontransduced tumor cells, resulting in a strong bystander effect [39].

The main concern with this form of suicide gene therapy is its safety profile. Despite low expression of CYP2B1 in tumor cells, hepatocytes express high levels of this enzyme, hence the potential for hepatotoxicity. In addition, lysis of hepatocytes releases intracellular toxic metabolites into the circulation, leading to systemic toxicity. Attempts to improve the safety of CYP2B1-CPA have focused on achieving high levels of CYP2B1 expression in tumor cells, which would decrease the CPA dose required for tumor cell killing and reduce hepatic and systemic injury. A recent phase I/II clinical trial evaluated the efficacy of CYP2B1 in the treatment of inoperable pancreatic tumors. Angiographic delivery of cells

expressing CYP2B1 to the tumors, followed by systemic administration of ifosfamide, a CPA analog, led to tumor regression, tumor suppression, symptomatic improvement, and significantly prolonged survival [40].

25.3.6 CARBOXYPEPTIDASE G2

The bacterial enzyme carboxypeptidase G2 (CPG2) acts by removing the glutamic acid moiety from 4-[(2-chloroethyl)(2-mesyloxyethylamino)benzoyl-L-glutamic acid (CMDA), releasing a toxic benzoic acid mustard derivative [41]. Unlike most other suicide enzyme metabolites, this product does not require further metabolic conversion for tumor cell toxicity. It owes its toxic effect to DNA alkylation and crosslinking, leading to apoptosis of both dividing and nondividing cells. The implications of this mechanism of action for tumor cytotoxicity and potential for systemic toxicity have already been discussed. A significant advantage of CPG2-CMDA is the one-step prodrug conversion process, which makes resistance to this form of therapy less likely than strategies that require multiple enzyme action. In the latter situation, a mutation in a single enzyme could prevent the formation of the final toxic product and lead to treatment resistance [42]. Finally, this system has one of the strongest bystander effects demonstrated *in vitro*, achieving significant tumor cell killing even with transfection of only 3.7% of tumor cells [43]. Clinically, this enzyme-prodrug combination is now almost exclusively used for antibody-directed enzyme prodrug therapy (ADEPT) with anti-CEA antibodies [44].

25.3.7 *E. coli* XGPRT

The *E. coli* gtp gene encodes the enzyme xanthine guanine phosphorybosyl transferase (XGPRT), which converts the xanthine analog, 6-thioxanthine (6-TX), into a weakly toxic purine analog that is subsequently phosphorylated into 6-thioxanthine monophosphate (6-XMP) by XGPRT. 6-XMP is then converted to 6-thioguanine monophosphate (6-GMP), a highly toxic compound. This form of suicide gene therapy has been studied in sarcomas and gliomas *in vitro* and *in vivo* [45,46]. Although only retroviral transfection has been attempted so far, adenoviruses could also prove suitable for this purpose.

25.3.8 *E. coli* PNP

The *E. coli* Deo gene encodes the enzyme purine nucleoside phosphorylase (PNP), which is normally absent from human cells and converts the prodrug 6-methyl purine deoxyriboside (MePdR) into the toxic compound 6-methylpurine (MeP). MeP can freely cross cell membranes and enter nontransduced tumor cells, resulting in a strong bystander effect. The efficacy of PNP-MePdR has been studied in human colon cancer, glioma, and melanoma cell lines *in vitro* and ovarian and glioma cell lines *in vivo* [47,48]. PNP-MePdR also had a potent effect against pancreatic tumors *in vitro* and *in vivo* [49].

25.3.9 HORSE RADISH PEROXIDASE–INDOLEACETIC ACID

This is an enzyme–prodrug system described in 2000 [50]. Horseradish peroxidase (HRP) is a heme enzyme isolated from the roots of the horseradish plant, while indoleacetic acid (IAA) is also a plant product and is involved in the regulation of plant growth, cell division, and differentiation. IAA also occurs in mammals as a product of amino acid tryptophan metabolism by monoamine oxidase [51]. At physiological pH, HRP activates IAA to produce a toxic radical. It is unlikely that nonspecific activation of IAA would take place in mammalian tissues, since IAA is a poor substrate for mammalian peroxidases [52]. IAA was given to patients and volunteers in the 1950s as a potential treatment for diabetes, with no major toxicities reported [53]. A strong bystander effect is induced by HRP–IAA in air and hypoxia, requiring only 5% of transfected cells to kill 70% of cells, probably because the toxic metabolite of IAA is freely diffusible through cell membranes [54]. Hence, the HRP–IAA system has the potential for hypoxia-regulated gene therapy and has been tested against an urothelial cancer cell line *in vitro* [50].

25.3.10 CYP1A2–ACETAMINOPHEN

The CYP1A2 enzyme converts acetaminophen to the toxic metabolite *N*-acetyl-benzoquinoneimine. This system has been reported to have a potent bystander effect and has *in vitro* efficacy against ovarian and colon carcinoma [55].

25.3.11 MUTANT TYROSINASE–*N*-ACETYL-4S-CYSTEAMINYL PHENOL

This system has been reported to have a dose-dependent anti-proliferative effect against breast adenocarcinoma, fibrosarcoma, and gliosarcoma [56].

25.3.12 *E. COLI*–URACIL

During DNA synthesis in mammalian cells, *E. coli* uracil phosphoribosyl transferase (UPRT) catalyzes the formation of uridine-5'-monophosphate from uracil. Its utility in suicide gene therapy comes from its ability to convert 5-FU to 5-fluorouridine-5'-monophosphate (FUMP). In mice-bearing tumors of human colon cancer cells transfected with the UPRT gene, 5-FU administration leads to significant tumor regression. A disadvantage of this system is its minimal bystander effect [57].

25.4 THE BYSTANDER EFFECT

At present, vectors used to introduce suicide genes in tumor cells *in vivo* can only transfect a minority of malignant cells comprising a tumor. Hence, to obtain significant antitumor effects, suicide gene therapy has to induce toxicity to cells not expressing the suicide gene. The bystander effect, defined as the toxicity of suicide gene therapy to tumor cells that have not been transfected with the suicide gene, is a property of

most forms of this therapy. The mechanisms responsible for the bystander effect of suicide gene therapy are outlined below.

25.4.1 METABOLIC COOPERATION AND GAP JUNCTIONS

The observation that tumor cell killing was greater than could be accounted for by the number of transfected cells was first made by Moolten in the HSV-TK-GCV system [13]. Bi et al. later hypothesized that the mechanism of metabolic cooperation was responsible for this phenomenon [58]. Metabolic cooperation, a concept introduced in 1966, describes the ability of low molecular weight compounds to pass between adjacent cells via the gap junctional network [59]. This is a physiologic mechanism that promotes homeostasis by exchange of nutrients between cells. In the same way, toxic metabolites produced in a tumor cell transfected by the suicide gene enter and kill neighboring tumor cells (Figure 25.1). Interestingly, there is evidence that toxic metabolites from transduced tumor cells can also kill surrounding vascular endothelial cells by the same mechanism. This phenomenon could induce an indirect antitumor effect by causing tumor cell ischemia [60,61].

Gap junctions consist of proteins called connexins, coded for by a family of 12 genes [62]. These are small hexameric structures approximately 2 nm in diameter that span the membranes of adjacent cells and allow exchange of cytoplasmic molecules. Mesnil et al. demonstrated that HeLa cells, which do not express connexins and lack gap junctional communication, are not susceptible to a bystander effect with HSV-TK-GCV treatment [63]. However, when expression of the gap junctional protein connexin 43 was induced in the same cells, they became susceptible to bystander killing. These experiments provided the definitive proof for the role of metabolic cooperation and gap junctions in the bystander effect.

FIGURE 25.1 The bystander effect: GCV-TP produced in transfected cells has cytotoxic effects on neighboring nontransduced cells.

In addition, Andrade-Rozental et al. showed that the magnitude of the bystander effect depends on the type of connexins that make up the gap junctions of adjacent cells [64]. Hence, it seems the bystander effect depends on the interaction between toxic metabolites, gap junctions, and other tumor cell-specific parameters [61,64].

Interestingly, gap junctions are also responsible for a reciprocal phenomenon, named the “good samaritan effect.” After production of toxic prodrug metabolite in transfected cells, gap junctions facilitate its diffusion into neighboring cells, hence lowering its concentration in the transfected cells and protecting them from toxicity. Despite this protection, persistence of these tumor cells can result in prolonged suicide gene transcription and toxic metabolite formation, which increases overall tumor cell toxicity [3,64,65].

25.4.2 TRANSFER OF TOXIC METABOLITES VIA APOPTOTIC VESICLES OR DIRECT TRANSMEMBRANE DIFFUSION

As described in the previous section, toxic metabolites produced in cells where the suicide gene is expressed are cytotoxic to nontransduced tumor cells once they reach their cytoplasm. There is evidence that gap junctions are not the only method by which this can be achieved. As initially observed by Freeman et al., apoptotic tumor cells release apoptotic vesicles [66]. It has been demonstrated by using fluorescent tracking dye and fluorescence microscopy that these vesicles are phagocytosed by surrounding viable tumor cells. Hence, apoptotic vesicles contain toxic metabolites such as phosphorylated GCV or even the suicide gene itself and can release these molecules into neighboring tumor cells, thereby contributing to the bystander effect. However, other studies showed that phagocytosis of apoptotic vesicles occurs after exchange of toxic metabolites and does not contribute to the bystander effect [67]. Finally, the molecular characteristics of certain toxic metabolites such as 5-FU and MeP allow them to cross cell membranes and enter other tumor cells without the need of gap junctions or apoptotic vesicles, also enhancing the bystander effect.

25.4.3 LOCAL ANTITUMOR IMMUNE RESPONSES

Although the effects of toxic metabolites on nontransduced tumor cells are considered the most important mechanism responsible for the bystander effect, the immune system is also thought to contribute to this phenomenon. Initial evidence for this came from observations that, following *in vivo* suicide gene therapy, tumors became infiltrated by inflammatory cells [68,69]. Other studies showed reduced efficacy of HSV-TK-GCV therapy in T-cell-deficient mice compared to wild-type animals, revealing that T-cells could contribute to tumor cell killing [70,71]. Furthermore, treatment of intraperitoneal tumors with cells transfected with HSV-TK results in a cascade of cytokine release into the peritoneal fluid, providing more evidence for local activation of the immune system as a result of suicide gene therapy. CD/5-FU suicide gene therapy also causes *in vivo* cytokine release and increases

tumor-infiltrating CD4-, CD8-, and NK cells, leading to tumor regression in a rat model of liver metastases from colorectal carcinoma [72]. Research into this aspect of the bystander effect has attracted significant attention in recent years.

25.4.4 SYSTEMIC ANTITUMOR IMMUNE RESPONSE

In addition to local antitumor activity, the immune system appears to be systemically activated following suicide gene therapy, which also contributes to the bystander effect. From a physiological standpoint, suicide gene therapy can elicit an antitumor immune response. First, suicide genes encode microbial proteins that render transduced cells immunogenic [73]. Second, tumor cell lysis after suicide gene therapy could expose tumor-specific antigens to antigen-presenting cells (Figure 25.2). Initial evidence for the role of the immune system in the etiology of the bystander effect came from *in vivo* studies showing that, following HSV-TK-GCV therapy, tumor-bearing experimental animals were protected from developing new tumors when given additional doses of malignant cells [70,74]. Although this protective effect of HSV-TK GCV therapy was not permanent, T-cell-deficient mice were susceptible to engraftment of tumor cells when rechallenged, showing that T-cells had a role in this phenomenon.

An immune aspect of the bystander effect has also been demonstrated with CD suicide gene therapy. After *in vitro* expression of CD in adenocarcinoma and fibrosarcoma cell lines, administration of these cells to mice resulted in tumors susceptible to 5-FU therapy. In addition, mice became resistant to developing tumors when given wild-type cells of the same cell lines [73]. However, similar to observations made for HSV-TK therapy, this resistance was absent when the experimental animals were challenged with tumor cells of an antigenically different cell line, indicating an antigen-specific immune response had been induced.

There have been attempts to elucidate the role of different classes of immune cells in the bystander effect using antibodies to deplete specific populations of immune cells.

FIGURE 25.2 Local antitumor immune response following suicide gene therapy.

This showed that depletion of both granulocytes and CD8-positive lymphocytes, but not CD4-positive lymphocytes, decreased the level of tumor regression after CD suicide gene therapy. However, depletion of CD4-positive lymphocytes and CD8-positive lymphocytes did each independently reduce the protective effect of CD suicide gene therapy against developing tumors by readministration of tumor cells [69]. Despite these interesting observations, the exact mechanisms of immune-mediated bystander effect and how they differ between different systems remain unknown. Answering these questions might provide clues regarding the levels of antitumor immunity and its only temporary efficacy following suicide gene therapy.

Another benefit of the immune-mediated bystander effect is its potential utility in attacking metastases after treatment of the primary tumor. Initial studies in experimental animals did not show regression of synchronous tumors growing at a distant site from tumors of the same cell line treated with CD or HSV-TK [73]. However, Consalvo et al. showed significant regression of lung metastases from an orthotopic mammary tumor after CD suicide gene therapy [69]. In another animal model, hepatic metastases of colonic adenocarcinomas regressed after HSV-TK therapy [75]. Hence, it seems that in some cases, antitumor immunity induced by suicide gene therapy has the potency to treat metastatic lesions. Why then is this immunity ineffective against synchronous lesions? A hypothesis put forward to explain these findings is that synchronous subcutaneous lesions are immunologically protected due to decreased numbers of immune cells at that site compared to liver and lung, where cells of the reticuloendothelial system are more abundant. Alternatively, antigen presentation at these sites might be more efficient than that of subcutaneous tissue. The second possible etiology for failure of antitumor efficacy of the immune system against synchronous metastases is the difference in tumor burden between large synchronous lesions and the usually smaller metastases. Evidence for the role of tumor volume comes from the observation that antitumor immunity induced by suicide gene therapy is strong enough to inhibit formation of new tumors when animals are given additional doses of tumor cells, but too weak to cause regression of established synchronous tumors, which consist of a much larger volume of tumor cells. In recent years, systemic antitumor immune responses following suicide gene therapy have been shown for a number of different tumors and suicide gene strategies.

25.5 COMBINATION SUICIDE GENE THERAPY

As described earlier, there have been efforts to improve the results of “classic” one-system suicide gene therapy. Multiple approaches to this have been described, including engineering of enzymes and prodrugs, combining multiple prodrug-enzyme systems, using tissue-specific promoters to direct suicide gene expression and combining suicide gene therapy with other forms of cancer therapy.

Prodrugs can be modified in a number of ways to improve the efficacy of suicide gene therapy [3]. A primary aim is to

design new prodrugs or alter existing compounds to improve kinetics of their respective enzyme-prodrug systems or confer other desirable features to the active drug, such as decreased toxicity to host tissues and enhanced ability to cross the blood-brain barrier for the treatment of central nervous system (CNS) tumors [3,76]. For example, despite its 10-fold greater potency compared to acyclovir, GCV has a reduced ability to cross the blood-brain barrier. Investigation into prodrugs with improved blood brain barrier permeability showed that administration of (*E*)-5-(2-bromovinyl)-2'-deoxyuridine (BVDU) in addition to GCV improved the efficacy of HSV-TK-GCV therapy [77,78].

Suicide genes and the enzymes they encode can also be modified. Suicide genes can be engineered for intra- or extracellular enzyme expression [43], extracellular enzymes becoming tethered to the outer surface of the cell membrane or secreted outside the cell. An advantage of extracellular suicide enzyme production is that prodrug does not need to enter malignant cells, leading to increased direct cytotoxicity and a potent bystander effect. On the other hand, a consequence of extracellular prodrug activation is the potential for systemic toxicity due to active metabolites entering the systemic circulation [43,79]. Further genetic engineering attempts to improve enzyme efficacy include the production of enzymes with improved affinity for their substrate [3]. In cases of gene-prodrug systems requiring multiple enzymatic reactions to produce the toxic metabolite, there have been efforts to transfect tumor cells with genes encoding more than one enzyme involved in the cascade. For example, in the HSV-TK-GCV system, tumor cell transfection with genes encoding kinases acting downstream of TK increased the yield of GCV triphosphate [80]. Interestingly, tumor cell transfection with two copies of the same gene has also been found to increase the production of active metabolite [81]. Finally, transfection of tumor cells with two different suicide genes followed by administration of their respective prodrugs improves *in vivo* and *in vitro* tumor cell killing compared to one enzyme-prodrug system [82,83].

It is established that tumor specific antigens present in the majority of cancers stimulate an antitumor immune response that usually lacks the potency to cause significant tumor regression. In addition, cytokines have a central role in effective antitumor immune responses induced by suicide gene therapy, as evidenced by alterations in cytokine levels following this treatment. Cytokines have been used to enhance this response in animal models and humans [84]. However, systemic administration of efficacious cytokine doses is associated with severe toxicity [85–87]. Cytokine gene therapy involves transfecting tumor cells with genes encoding for cytokines. The aim of this strategy is to achieve high and sustained cytokine concentrations within tumors to enhance tumor immunogenicity and at the same time avoid systemic cytokine toxicity. Importantly, this strategy has potential for synergism if combined with suicide gene therapy. Chen et al. treated colorectal cancer liver metastases with a combination of HSV-TK and interleukin (IL)-2 gene therapy, showing that intratumoral delivery of these genes lead to improved tumor

regression compared to administration of either gene alone. Despite failing to prolong survival, this treatment did generate a temporary protective effect against a second challenge of wild-type tumor cells given at a distant site [88]. On the other hand, combined HSV-TK and IL-2 gene therapy had a synergistic effect on regression of head and neck squamous cell carcinomas in mice and also prolonged survival [89]. Also in this model, combined HSV-TK and IL-2 gene therapy protected animals from developing tumors when rechallenged with tumor cells [84]. Interestingly, tumors from mice transfected with IL-2 had more intratumoral lymphocytes than those from animals not receiving the gene, suggesting this might contribute to better results seen with combined therapy [89]. Other studies have investigated a combination of HSV-TK, IL-2, and granulocyte-monocyte colony stimulating factor (GM-CSF) gene therapy, which also enhanced tumor regression and improved survival and also induced protection against engraftment of wild-type tumor cells [90]. Investigators have suggested that the addition of GM-CSF acts by stimulating antigen-presenting cells and induces prolonged antitumor immunity mediated by CD4-positive tumor cells [91]. Unfortunately, not all tumors have proven susceptible to this triple scheme, most likely due to inherent differences in tumor type and site that affect response to GM-CSF [92].

Another approach has been to combine suicide gene therapy with the administration of cytotoxic drugs to obtain synergistic tumor cell toxicity. For example, ponocidin, a compound that activates HSV-TK has been found to increase tumor cell toxicity 3- to 87-fold when administered in addition to acyclovir or GCV [93]. A number of other drugs (butyrate, camptothecin, taxol, 7-hydroxystaurosporine) enhance the apoptotic effects of HSV-TK-GCV therapy without affecting enzyme function [94]. Also, hydroxyurea improves the toxicity of GCV-triphosphate by reducing the intracellular concentration of deoxyguanosine triphosphate, which competes with GCV triphosphate for incorporation into the DNA molecule [95]. Other compounds improve the tumor cell toxicity of suicide gene therapy by enhancing the bystander effect. Retinoids, apigenin, lovastatin, and cyclic AMP upregulate gap junctions, augmenting the bystander effect of HSV-TK-GCV therapy *in vitro* and *in vivo* [96–99].

The HSV-TK system has also proven useful in sensitizing tumor cells to the effects of radiotherapy. Tumor cells transfected with this enzyme and exposed to bromodeoxycytidine were 1.4- to 2.3-fold more sensitive to radiotherapy compared to tumor cells transfected with a control gene [100]. In this model, HSV-TK converts bromodeoxycytidine to bromodeoxyuridine, which is then incorporated into the DNA molecule.

25.6 METHODS OF SUICIDE GENE DELIVERY

For suicide gene therapy to become an effective form of cancer treatment in humans, limitations pertaining to the delivery of suicide genes to malignant cells remain significant. Efficient tumor cell targeting is more important with systemic gene delivery, where the aim is to transfect both cells of the primary

tumor and metastatic cells in distant tissues. Targeting of tumor cells is less significant in trials that utilize intratumoral gene delivery [101]. The characteristics of the ideal gene delivery system include transfection of all malignant cells without the need for repeated treatments and lack of side effects. Gene delivery can be achieved with or without the use of viral vectors although combinations of viral and nonviral transfection methods have produced systems such as hemagglutinating virus of Japan liposomes and polycation-enhanced adenoviruses [102].

Nonviral gene delivery involves administration of the suicide gene itself and its control elements, such as promoters and enhancers, in the form of a circular double-stranded plasmid. Nonviral vectors include naked DNA, liposomes, peptides, and polymers [101]. Alternatively, suicide genes can be packaged into viral particles that utilize the natural process of inserting viral genes into the genome of mammalian cells. Viral methods achieve higher transfection efficiency and are being used in most human clinical trials of suicide gene therapy. However, they are far from being considered an ideal transfection method. The list of problems with viral vectors is long: poor transfection efficiency, random gene integration into the host cell genome, rapid clearance of systemically delivered vectors, reduced susceptibility of target cells to viral infection, generation of replication-competent particles, limited gene size that can be packaged in viral vectors, and inability to perform repeat treatments [103]. Importantly, safety concerns that were highlighted with the death of a patient following gene therapy with an adenoviral vector have increased interest in nonviral transfection methods [104,105]. In addition to the above issues, further problems need to be resolved before safe and efficient transfection vectors can be developed and used extensively in humans. First, development of new transfection methods using current animal models is unsatisfactory due to significant biological differences with human tissues. These include differences in susceptibility to infection by viral vectors and variations in vector doses that can be safely tolerated [106–108]. Finally, the optimal timing of vector administration with respect to prodrug administration is not well studied and depends on speed of transfection and suicide gene expression [101].

25.6.1 NONVIRAL TRANSFECTION

Nonviral transfection methods involve inserting a suicide gene and its regulatory elements in a double-stranded DNA molecule (plasmid) into target malignant cells. Gene regulatory elements, such as promoters and enhancers, also consist of double-stranded DNA and are inserted into the same plasmid. Other plasmid components can include engineered DNA sequences that control the processing and persistence of the suicide gene within the target cell. Plasmids dissolved in saline have been successfully expressed in muscle and thyroid after direct injection into these tissues and plasmid uptake by endocytosis [109,110]. However, this method is inefficient *in vivo*.

Currently, the optimal method of nonviral transfection is the use of liposomes or cationic lipids. These formulations

have been designed to enhance plasmid uptake and can be modified for optimal DNA delivery according to the type of target tumor [111]. Additional advantages include lack of toxicity and immunogenicity, the ability to deliver genes of unlimited size, slow clearance of systemically delivered vector, the ability to perform repeat treatments, its ease of production, and low cost [103,104]. The poor transfection efficiency of first-generation liposomal vectors has been improved and liposomes can be administered intravenously, intramuscularly, subcutaneously, intradermally, transdermally, and via additional routes [103,112]. Clinically, liposomes have been used to deliver HSV-TK to patients with cerebral glioblastoma, confirming lack of toxicity and achieving significant reduction in tumor volume [113]. In addition, liposomal TK has been used to treat human pancreatic cancer xenografts in mice, also with lack of toxicity and antitumor efficacy [114,115]. Interestingly, liposomes have been used to conjugate suicide genes within adenoviral vectors. This method decreases the immunogenicity and toxicity of adenoviral vectors used alone and has been applied to the treatment of brain gliomas in mice [116].

There are several problems with DNA-mediated gene delivery at present. First, the maximal transfection it can achieve *in vivo* is 1%–3%, even when liposomes and cationic lipids are used. Although only a minority of tumor cells needs to express the suicide gene for clinically significant tumor regression, higher transfection efficiency rates do correlate with better antitumor effects. In general, transfection rates of less than 10% of cells within a tumor are not associated with tumor regression or delay in progression. The second major problem of nonviral transfection methods is that suicide gene expression is transient, regardless of the formulation used. This occurs because plasmids become quickly degraded or extruded from tumor cells, but fortunately has proved a less significant issue with suicide gene therapy than with other forms of cancer gene therapy as cells are generally killed before plasmids are eliminated. Both limitations of DNA-mediated gene delivery have been addressed by repeating the transfection process. Following nonviral transfection, permanent incorporation of suicide genes into the tumor cell genome rarely occurs *in vitro* and has not been reported to occur *in vivo*. Despite its limitations when prolonged gene expression is required in tumor cells, this phenomenon has the advantage of not causing a permanent alteration of the host cell genome. Hence, if healthy host cells are inadvertently transfected, the potential for toxicity is low.

25.6.2 RETROVIRUS-MEDIATED SUICIDE GENE DELIVERY

Retroviral vectors can be divided to those derived from the murine leukemia virus and only replicate in dividing cells and to those derived from lentiviruses that do not have this limitation [117,118]. Historically, retroviruses were popular as vectors in early human trials of suicide gene therapy because they had a number of advantages. First, retroviral particles can be engineered to deliver the gene of interest without containing viral genes or viral gene products. Second, long-term gene

expression is possible due to the ability of retroviruses to insert genes into host cell chromosomes. Third, retroviruses and the cell lines from which they are produced can be engineered for maximal host cell safety.

At the same time, limitations associated with retroviral vectors have prevented more extensive clinical use. As expected, insertion of viral genes into host cell chromosomes is associated with risk of carcinogenesis. Recently, Themis et al. reported a high incidence of tumorigenesis in mice transfected with a lentiviral vector, raising concerns about the safety of this vector family [119]. Furthermore, transfection efficiency of retroviral vectors remains poor for a number of reasons. First, because some of these vectors insert genes into actively dividing cells, only a fraction of tumor cells can be transfected. Second, it is difficult to achieve high titers of retroviral vectors. To overcome this problem, retroviral vectors themselves have to be delivered within their human or murine packaging cell line. Third, delivery of retroviruses within cells raises the issue of immunogenicity of murine cells, which can lead to murine cell killing within the host, thereby reducing transfection efficiency. Finally, the susceptibility of different tumors to retroviral infection varies.

25.6.3 ADENOVIRAL GENE TRANSFER

Adenoviruses are a second family of viral particles that can be used to introduce suicide genes into tumor cells. In contrast to retroviruses, they do not integrate genes into host cell chromosomes, reducing the risk of mutagenesis. This is advantageous in terms of their safety profile but leads to shorter duration of suicide gene expression, lasting from one to several weeks [120,121]. As previously explained, duration of gene expression is not considered a significant limitation of the efficacy of suicide gene therapy [36]. Further advantages of adenoviral vectors are that they can be produced in 10,000-fold larger titers than retroviruses and their ability to transfect both dividing and nondividing tumor cells *in vivo* [122]. However, hemopoietic cells are not susceptible to adenoviral gene transfer.

First-generation adenoviral vectors were replication-incompetent but retained the ability to produce viral proteins after entering the host cell, which are immunogenic and can induce inflammation and cell lysis [102,123]. These disadvantages of adenoviral transfection were addressed by genetically engineering adenoviral particles to produce second-generation vectors that persist in the host cell, have reduced viral gene product expression, and tend to induce milder inflammatory reactions [124,125]. However, adenoviral transfection remains immunogenic, leading to antiviral antibody formation that limits the efficacy of repeat transfections.

25.6.4 ONCOLYTIC VIRUSES

Until recently, viral vectors were all replication-incompetent to ensure safety to normal host tissues. However, the ability of some viruses to infect and lyse cells releasing numerous new viral particles is potentially useful in cancer therapy if directed

specifically against malignant cells. Improved understanding of cancer genetics and viral replication have allowed the development of viruses able to selectively infect and kill malignant cells. Due to their ability to replicate and release more vectors that will infect new cells, oncolytic viruses offer improved gene delivery to tumor cells compared to replication-deficient viruses and are currently regarded as a superior transfection method [102,126]. Furthermore, they achieve tumor cell lysis independent of their ability to deliver suicide genes [102].

The Onyx-015 adenovirus, also known as dl1520, was the first oncolytic virus used in a human clinical trial. This vector is characterized by deletion of a gene coding for E1B-55kDa, a p53-binding protein that permits viral replication in cells with intact copies of the p53 gene. Hence, mutant viral particles will not replicate in normal host cells, but will do so in the majority of human cancers where the p53 is mutated [127,128].

25.6.5 OTHER VIRAL VECTORS

Additional viruses might have potential as transfection vectors. Adeno-associated virus (AAV) is a nonpathogenic, naturally replication defective virus of the parvovirus family, with a single-stranded DNA genome [102]. Treatment of AAV can replace the majority of its genome by the therapeutic gene of choice [129], making such particles less immunogenic and able to transfect mammalian cells with prolonged expression of therapeutic genes. They have the added safety feature of integrating their genome at a specific locus on chromosome 19, leading to reduced potential for mutagenesis. Although engineered AAV have lost this property of predictable gene insertion, raising the possibility of carcinogenic potential, there is currently no evidence for AAV-mediated carcinogenesis [102,130,131]. A further factor that complicates the use of adeno-associated virus is the requirement for wild-type virus to be present during the vector production process. The recombinant vector then has to be purified from wild-type viral particles before amplification and *in vivo* use. This renders the vector production process inefficient and reduces the maximal viral titers that can be achieved. Furthermore, AAV does not specifically infect tumor cells and targeting techniques have to be used to obtain tumor specificity [102]. AAV has been used to transfect hepatoma cells *ex vivo* with TK and direct expression of this gene using the α -fetoprotein gene enhancer and albumin gene promoter [132]. Although growth of xenografts of such cells was suppressed following prodrug administration, the *in vivo* tumor specificity of the AAV vector was not evaluated [102].

HSV is another virus with potential use as a transfection vector and has the potential for indefinite intracellular persistence in a latent state. Replication-defective HSV particles able to express recombinant gene products in animals have been produced [133]. However, such particles retain the ability to produce viral gene products toxic to host cells, which has limited clinical use of HSV vectors.

Other viruses under investigation for use as transfection vectors include human papilloma virus, vaccinia virus, avipox virus, and baculovirus. Continued modification of existing viruses simultaneously with examination of new viral vectors will increase the number of viral vectors available for use in suicide gene therapy.

25.7 CURRENT SUICIDE GENE THERAPY TRIALS

Since the first human gene therapy trial started in 1989 and until January 2007, a total of 850 cancer gene therapy clinical trials had been initiated or completed worldwide. Excluding those that were withdrawn or never initiated, suicide gene therapy trials account for 105 of these. In turn, 74 of suicide gene therapy trials are being conducted in the United States.

With respect to vectors utilized, retroviruses and adenoviruses were the commonest, accounting for 51 and 42, respectively, of the 105 suicide gene therapy trials conducted. These trials have confirmed that both viral and nonviral transfection methods used in suicide gene therapy are safe and can achieve expression of suicide genes in tumor cells. However, despite mostly encouraging results, these have to be cautiously interpreted as phase I and phase I/II trials accounting for 64 and 32 of these trials, respectively [133].

26.1 INTRODUCTION

26.1.1 USE AND CHOICE OF SELECTABLE MARKERS

One of the major problems with current approaches to gene therapy is the instability of expression of genes transferred into recipient cells. Homologous recombination or use of artificial chromosomes can stabilize sequences with wild-type regulatory regions. Several studies have recently demonstrated the potential of such approaches to gene therapy using human cell lines and mice models [1–5]. However, clinical trials have not been undertaken yet. In most high-efficiency DNA transfer in current use in intact organisms, selectable markers must be used to maintain transferred sequences; in the absence of selection, the transferred DNAs or their expression is rapidly lost.

There are several different selectable markers that might be used for *in vivo* selection, including genes whose expression has been associated with resistance of cancers to anticancer drugs. Examples include: (a) methotrexate (MTX) resistance due to mutant dihydrofolate reductase (*DHFR*) [6]; (b) alkylating agent resistance due to expression of methylguanine methyltransferase

(*MGMT*) [7]; and (c) the expression of the multidrug transporting proteins P-glycoprotein (P-gp, the product of the *ABCB1/MDR1* gene) [8], *ABCC1/MRP1* (multidrug resistance associated protein 1) [9], and *ABCG2/BCRP* (breast cancer resistant protein) [10] (see Table 26.1). In this chapter, we will detail our experience with the *ABCB1/MDR1* gene.

The resistance of many cancers to anticancer drugs is due, in many cases, to the overexpression of several different adenosine triphosphate (ATP)-dependent transporters (ABC transporters), including the human multidrug resistance gene *ABCB1/MDR1* [23], *ABCC1/MRP1*, the multidrug resistance-associated protein [24,25], other MRP family members [26,27], and *ABCG2/MXR* [28] (for reviews, see Szakacs et al. [29] and Gillet et al. [30]). *ABCB1/MDR1* encodes P-gp, which is a 12-transmembrane (TM) domain glycoprotein composed of two homologous halves, each containing six TM domains and one ATP-binding site (see Figure 26.1) [31–33]. P-gp recognizes a large number of structurally unrelated hydrophobic and amphipathic molecules, including many chemotherapeutic agents, and removes them from the cell via an ATP-dependent transport process [31–33].

Glutathione transferase Yc	Melphalan, mechlorethamine, chlorambucil	Letourneau et al. (1996) [17]
Aldehyde dehydrogenase	Cyclophosphamide	Magni et al. (1996) [18]; Moreb et al. (1996) [19]
O ⁶ -methylguanine methyltransferase (<i>O⁶-MGMT</i>)	Nitrosourea (BCNU)	Allay et al. (1995) [20]
Gamma-glutamylcysteine synthetase	L-buthionine- <i>S</i> , <i>R</i> -sulfoximine (BSO)	Lorico et al. (2005) [21]; Rappa et al. (2007) [22]

ABCB1 has many obvious advantages for use as a selectable marker in gene therapy. It is a cell surface protein that can be easily detected by flow cytometry or immunohistochemistry. Cells expressing P-gp on their surfaces can be enriched using cell sorting or magnetic bead panning technologies. The very broad range of cytotoxic substrates recognized by P-gp makes it a pharmacologically flexible system, allowing the investigator to choose among many different selection regimens with differential toxicity for different tissues and different pharmacokinetic properties. Furthermore,

as will be discussed in detail in this chapter, *ABCB1* can be mutationally modified to increase resistance to specific substrates and alter inhibitor sensitivity.

26.1.2 LESSONS FROM TRANSGENIC AND KNOCKOUT MICE

Certain evidence supports the concept of using *ABCB1* as a selectable marker in human gene therapy (see Figure 26.2). Transgenic mice expressing the *ABCB1* gene in their bone

FIGURE 26.1 Hypothetical 2-D model of human P-gp, based on hydropathy analysis of the amino acid sequence and its functional domains. In this diagram, each circle represents an amino acid residue, with black solid circles showing the positions of mutations that alter the substrate specificity of P-gp (for clarity, only the mutations discussed in the manuscript are shown). The ATP sites are circled, with Walker A, B, and C regions indicated as A, B, and C, respectively.

FIGURE 26.2 ABCB1-transduced cell using a retrovirus. (A) The pHaMSV/MDR1 retroviral vector is composed of: (i) sequences from bacteria, including an origin of DNA replication (*colE1*) and an antibiotic resistance gene (*amp^r*); (ii) VL30 sequences containing *cis*-acting packaging elements; and (iii) an *ABCB1* transgene cassette. (B) The retrovirus consists of an envelope, a matrix, and a capsid, which contains the RNA genome. (C) In the host cell nucleus, the DNA either integrates into a specific site on chromosome 19, persists episomally, or integrates randomly into other chromosomes. In this example, *ABCB1* encoding the multidrug transporter P-gp confers the ability to the cell to be resistant to a wide panel of drugs.

marrow are resistant to the cytotoxic effects of many different anticancer drugs [34–38]. *ABCB1* transgenic bone marrow can be transplanted into drug-sensitive mice and the transplanted marrow is resistant to cytotoxic drugs [39,40]. Mice transplanted with bone marrow transduced with the human *ABCB1* cDNA and exposed to taxol show enrichment of the *ABCB1*-transduced cells [41–43], and this transduced marrow can be serially transplanted and remains drug-resistant [41]. Recently, this ability to select transduced bone marrow with taxol has been demonstrated in canine and mice bone marrow transplantation models [44,45].

The mouse *mdr1a* and *mdr1b* genes have been insertionally inactivated in mice [46–49]. These animals, although otherwise normal, are hypersensitive to cytotoxic substrates of P-gp. This hypersensitivity is due in part to the abrogation of the *mdr1a*-based blood brain/nerve barriers [50–53] and to enhanced absorption and decreased excretion of *mdr1* substrates [54]. These studies demonstrate the critical role that P-gp plays in drug distribution and pharmacokinetics and argue that specific targeting of P-gp to tissues that do not ordinarily express it (as in gene therapy) will protect such tissues from cytotoxic *mdr1* substrates.

26.1.3 NANOSYSTEMS FOR GENE-DRUG DELIVERY: EMERGENCE OF A NEW TECHNOLOGY

A critical factor in gene therapy is the vector used for delivery of the transgene. Viruses have been extensively studied for use as vectors. Although they are able to mediate gene transfer with high efficiency, the size of the transgene that viruses can carry [55], the method used for the virus production and shedding of viral proteins are all serious concerns and challenges [56–59]. Nonviral methods using chemical or physical approaches have also been thoroughly investigated. However, most of these methods are less efficient or not always reproducible compared to virus-based delivery vectors and have limitations for *in vivo* gene delivery; for a review, see Gao et al. [60].

An expanding, multidisciplinary field has developed in the last few years based on nanotechnologies that apply engineering at the molecular level in a range from 1 to 100 nm. In medicine, nanoparticles have broad applications including molecular diagnostics, molecular imaging, targeted therapy, and gene therapy. These applications and particularly drug delivery devices are currently in clinical trials (see National Nanotechnology initiatives: <http://www.nano.gov>).

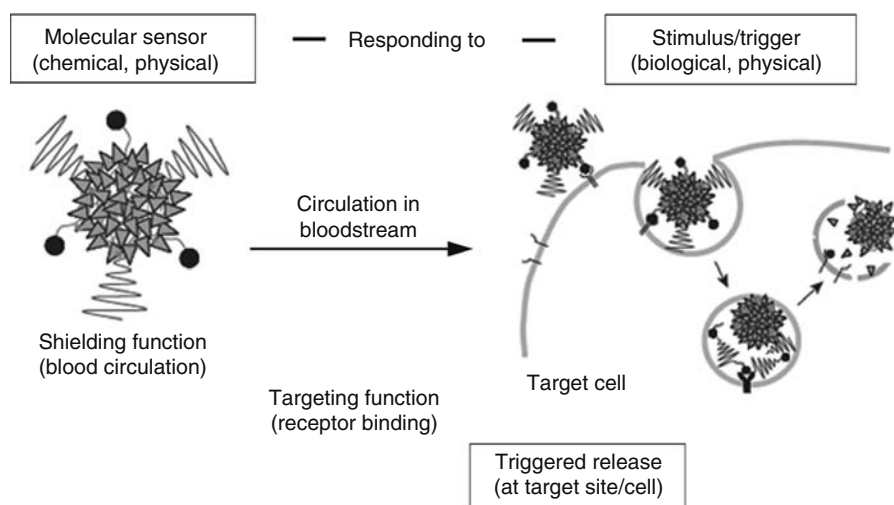

FIGURE 26.3 Nanosystems for programmed drug delivery. Preprogramming of nanoparticle properties by molecular sensors that respond to biological or physical stimuli during the drug delivery process. Timely operation of multiple tasks (e.g., circulation in blood, target binding, cell entry, and intracellular transport and drug release) is required. (From Wagner, E., *Expert Opin. Biol. Ther.*, 7, 588, 2007. With permission.)

Programmed nanostructured systems, a novel and elegant approach to gene therapy, have the ability to deliver both drug and gene in a controlled fashion. These systems are able to respond in a timely way to biological (i.e., pH variations of biological compartments, difference in redox potentials through the cell membrane, etc.) or physical stimuli (i.e., heat, light, ultrasound, electric or magnetic fields) (see Figure 26.3) (for a review, see Wagner [61]). Programmed nanoparticles can be easily used to deliver a transgene such as *ABCBI* to protect bone marrow, reducing technical and safety issues associated with the use of viruses.

26.2 SELECTABLE MARKERS FOR GENE THERAPY OF MALIGNANT HEMATOPOIETIC SYSTEM AND NONMALIGNANT DISEASES

Protection of chemosensitive cells from toxic compounds may be particularly helpful in the case of the hematopoietic system because most cells in blood and bone marrow are highly susceptible to antineoplastic compounds. Hematopoietic progenitor cells do not express glutathione-S-transferases [62] and only very low levels of endogenous *ABCBI* gene are expressed in myeloid and erythroid progenitor cells [63,64]. These low expression levels are not capable of providing protection from the cytotoxicity of anticancer drugs. Conversely, the high susceptibility of normal hematopoietic cells to cytotoxic agents allows selection strategies exploiting drug resistance genes if sufficient levels of resistance can be conferred.

Gene therapy, although thought to bear the potential of curing genetically determined diseases, has long been limited by low gene transfer efficiency to hematopoietic stem cells. In diseases where overexpression of the therapeutic gene does not confer a survival advantage, bicistronic vectors encoding

the therapeutic gene and a selectable marker gene such as drug resistance genes can provide a selective *in vivo* survival advantage.

26.2.1 *ABCBI* GENE AS A SELECTABLE MARKER

As briefly mentioned in Section 26.1, several studies on human *ABCBI* transgenic mice established that constitutive overexpression of this gene protects animals from antineoplastic agents and thus could be useful as a selectable marker in human gene therapy. Indeed, it has been demonstrated that drugs can be administered safely at dose levels several-fold higher than those possible with mice of the respective background strains [34,36,37]. To demonstrate the specificity of this protection, verapamil, an inhibitor of P-gp, was coadministered, resulting in reversal of drug resistance [38]. Other studies have shown that retroviral transduction with a full-length *ABCBI* cDNA promoted by long-terminal repeats (LTR) of the Harvey sarcoma virus protects normal, clonogenic hematopoietic precursors, or erythroleukemia cells from anticancer drugs [65,66]. Furthermore, transduced cells were found to be resistant to multiple drugs including taxol, colchicine, and daunomycin. Murine hematopoietic stem cells originating from fetal liver [67], peripheral blood following mobilization with the use of growth factors [68], or from bone marrow [69] were also efficiently transduced with retroviral *ABCBI* vectors. Finally, it was shown that transplantation of *ABCBI*-transduced murine bone marrow cells into mast-cell-deficient (*W/W^v*) mutant mice [43] or lethally irradiated normal syngeneic mice [42] resulted in significant gene expression in the bone marrow of recipient animals. In both of these studies, investigators detected elevated levels of *ABCBI* expression after treatment of recipient mice with taxol, favoring the idea of a selective *in vivo* advantage of hematopoietic cells overexpressing the *ABCBI* transgene. This observation was in

marked contrast to previous studies with selectable markers such as genes conferring resistance to neomycin, puromycin, or hygromycin. Because of their pharmacological or pharmacokinetic characteristics, such compounds cannot be used for *in vivo* selection. Further support for the potential usefulness of drug resistance genes for *in vivo* selection was provided by experiments in which *ABCBI*-transduced bone marrow was first transplanted into recipient mice [41]. After taxol treatment of recipient mice, their bone marrow was then retransplanted into a second generation of recipient mice. In several cycles of retransplantation and taxol treatment of recipient animals, increasingly higher levels of drug resistance were generated *in vivo*. Mice of the fifth and sixth generation survived doses of taxol (ranging from 15 to 20 mg/kg) that were lethal for mice that had not undergone bone marrow transplantation. Recently, Maier et al. reported that *ABCBI* overexpression may protect normal tissues from radiation- or chemotherapy-induced damage during tumor treatment. Indeed, several genes implicated in detoxification and exocytosis showed an increase from 1.4- to 4-fold in *ABCBI*-transduced cells compared to control counterparts. In addition, proapoptosis genes were downregulated, while the antiapoptotic gene *AKT3* was upregulated [70]. They subsequently corroborated the effect of *ABCBI* overexpression on apoptosis signaling in functional assays by showing reduced rates of apoptosis in response to irradiation in TK6 cells transduced with *ABCBI*. Therefore, the resistant phenotype of *ABCBI*-mediated P-gp-overexpressing cells seems to be associated with differential expression of genes coding for metabolic and apoptosis-related proteins.

Bunting et al. [71] reported that transduction of murine bone marrow cells with pHAMDR1 retroviral vector enables *ex vivo* stem cell expansion, which might help account for the ability of transduced cells to survive multiple cycles of transplantation. However, the biological safety of expansion of transduced stem cells is currently under scrutiny. When *ABCBI*-transduced progenitor cells are expanded with growth factors for extended periods (up to 12 days), uncontrolled proliferation occurs, as has been observed in one study [71]. The authors concluded that the finding was related to the *ABCBI* transgene because the development of a myeloproliferative syndrome was not observed either with a control DHFR vector or mock-transduced cells. Subsequent data confirmed and extended these earlier observations and provided further evidence that enforced *ABCBI* transporter function can alter the replicative behavior of stem cells [72]. Previous studies have not observed this adverse effect after *ABCBI* transfer to murine hematopoietic cells [42,43,73]. More importantly, comparable studies in nonhuman primates, using identical vectors but less efficient gene transfer conditions, did not reveal perturbations of myelopoiesis despite systemic challenge with growth factors [74]. However, the vector used by Bunting and colleagues in their stem cell expansion experiments was modified to reduce cryptic mRNA splicing within the *ABCBI* coding sequence [75,76] and likely expressed greater amounts of P-gp than the vectors used in the other studies. In a recent study, Modlich et al. [77] hypothesized that retroviral vector insertions near a proto-oncogene or

another locus involved in regulating cell growth and proliferation may contribute to leukemogenesis, especially when collaborating with signal alterations evoked by the retrovirally encoded transgene product [78,79]. They found that when there are four or more copies of the transgene, *ABCBI*-associated leukemias are more likely to develop. *ABCBI* overexpression alone did not lead to this development. In addition, one leukemia developed after transduction with multiple copies of a vector expressing a fluorescent protein, strongly suggesting that combinatorial vector insertions can be sufficient to induce carcinogenesis [77]. The exact contribution of *ABCBI* to leukemia incidence under conditions of dose escalation and the possible synergy of *ABCBI* overexpression with insertional gene alterations have not been established.

Predictive preclinical models are thus required, both for risk assessment and prevention. The work of Modlich et al. mentioned above has revealed that studies involving dose-escalation of vectors are an important step in this direction, potentially allowing the establishment of a therapeutic index for retroviral transgene delivery. Du et al. reported that insertional mutagenesis can identify genes that promote the immortalization of hematopoietic cells, which normally have only limited self-renewal [80]. Taking advantage of this study, Modlich et al. developed new mutagenesis assays based on primary murine bone marrow cells that were transduced with a known multiplicity of infection (MOI) [81]. Self-inactivating (SIN) retroviral vectors do not contain the terminal repetition of the enhancer/promoter (at the opposite of their LTR counterparts), theoretically attenuating the interaction with neighboring cellular genes. Their study revealed that SIN retroviral vectors carrying a strong internal enhancer/promoter may transform primary hematopoietic cells by insertional mutagenesis though with significantly lower frequency than their LTR-driven counterparts usually used for stable gene transduction into hematopoietic cells [81].

Based on experiments in tissue culture and animal models, early clinical trials on transfer of the *ABCBI* gene to hematopoietic progenitor cells have been conducted [82–84]. Bone marrow or peripheral blood progenitor cells from patients suffering from advanced neoplastic diseases were retrovirally transduced and reinfused after high-dose chemotherapy [85–87]. These studies revealed that transduction efficiencies using *ABCBI* vectors as detected in bone marrow or peripheral blood of patients tended to be low and varied from one patient to another. Notably, in two studies enrichment of *ABCBI*-transduced cells was observed following treatment with etoposide or paclitaxel [88,89]. These studies confirm that the human multidrug resistance gene can serve as a drug-selectable marker gene *in vivo* in the hematopoietic system. However, gene transfer procedures and selection strategies need to be improved to efficiently protect human hematopoietic cells from the cytotoxicity of drug treatment.

These concerns have prompted new investigations with vector systems other than retroviruses. For instance, SV40 pseudovirions allow for highly efficient *ABCBI* gene transfer to hematopoietic cells [90,91]. Alternatively, Epstein–Barr virus-based (EBV) vectors can be designed that contain the

ABCBI cDNA episomally in target cells [92]. With such vector systems, lifelong expression cannot be achieved because they fail to integrate into the genome. Conversely, for protection of hematopoietic cells during a series of chemotherapy cycles, sustained expression may not be required. Loss of *ABCBI* expression after the period of chemotherapy might in fact increase the safety of *ABCBI* gene therapy (see Section 26.3).

26.2.2 OTHER DRUG RESISTANCE GENES AS SELECTABLE MARKERS

Different patterns of chemoresistance can be attributed to various drug resistance genes. For instance, the *ABCCI* gene is genetically and functionally related to *ABCBI*. Retroviral transfer of *ABCCI* resulted in resistance to doxorubicin, etoposide, and vincristine [9]. However, since binding and transport of inhibitors to *ABCBI* may be different from *ABCCI*, transfer of this gene may be useful if naturally occurring resistance due to *ABCBI* overexpression in cancer cells has to be overcome to allow for effective chemotherapy of an *ABCBI*-expressing cancer.

As has been seen with *ABCBI*, chemoprotection of hematopoietic progenitor cells and a selective advantage *in vitro* were demonstrated following transduction by mutated DHFR cDNAs that confer resistance to MTX and trimetrexate (TMTX) [6,93–99]. Williams et al. [100], Cline et al. [101], and Vinh and McIvor [102] demonstrated the protection of recipient animals from lethal doses of MTX. These studies cannot be carried out in humans because the high doses necessary could be toxic.

Mice transplanted with DHFR-transduced hematopoietic cells display resistance against high levels of TMTX, which can be transferred to a second generation of transplant recipients [12]. Interestingly, mice can be transplanted with low amounts of DHFR-transduced cells following mild total body irradiation at a reduced dose of 1 Gy (Gray) and acquire MTX resistance by treatment with this drug for 60 days following transplantation [103]. Retransplantation experiments performed with DHFR [104] gave results comparable to those obtained with *ABCBI* [41]; both genes facilitate increased levels of resistance after several cycles of transplantation and drug treatment of recipient animals.

In vivo selection of retrovirally transduced hematopoietic cells has convincingly been demonstrated with the DHFR as a selectable marker [105]. In this study, mice were transplanted with DHFR-transduced bone marrow cells. Drug treatment resulted in significantly increased expression in granulocytes, erythrocytes, platelets, and T- and B-lymphocytes. Secondary recipients revealed that selection had occurred at the stem cell level. Recently, a complete tumor regression has been shown in mice after transplantation with mutant DHFR (L22Y)-transduced hematopoietic stem cells (HSC) followed by combined chemotherapy (MTX) and immunotherapy (anti-CD137) treatment [106].

Resistance to alkylating agents is multicausative and several genes may be useful as selectable markers. Retroviral transfer of a rat glutathione-S-transferase Yc cDNA to hematopoietic

cells conveyed moderate resistance to melphalan, mechlorethamine, and chlorambucil [17]. Resistance to cyclophosphamide or 4-hydroperoxycyclophosphamide, respectively, could be conferred on hematopoietic cells by transfer of aldehyde dehydrogenase with the use of retroviral vectors [18,19]. Leukemic or primary hematopoietic cells were rendered resistant to 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU) by retroviral transfer of a human *MGMT* cDNA, a gene encoding *O*⁶-alkylguanine-DNA-alkyltransferase (AGT) [7,20,107]. Transplantation of transduced bone marrow cells rescued recipient animals from the toxicity of nitrosoureas [108]. In particular, nitrosourea-induced severe immunodeficiency can be overcome by transduction of immature progenitor cells [108,109]. However, Allay et al. demonstrated that the survival advantage to BCNU treatment in *MGMT*-transduced cells is modest and thus limits its therapeutic potential [20]. Indeed, in this report, *MGMT*-transduced cells were only twofold more resistant than the mock-transfected cells to BCNU treatment. In the meantime, it has been shown that G156A and P140A *MGMT* mutations are able to render the protein 240- and 40-fold more resistant to *O*⁶-benzylguanine (BG), an inhibitor of *MGMT*, than the wild-type protein in cell-free extract [110], while P140K *MGMT* mutated protein has been shown to be over 1000-fold more resistant to BG [111]. These results have been confirmed using retroviral transduction of this mutant into human stem cells, which confers an increased resistance to combined treatment with BG and BCNU [112]. Furthermore, an *in vivo* study performed on mice demonstrated that transplantation of G156A *MGMT*-transduced bone marrow cells resulted in animal survival from lethal doses of BG and BCNU and in prolonged enrichment of the transduced cells [113]. Another mutation (P140K *MGMT*) [114] showed similar effects after transfer of the mutant gene into hematopoietic stem cells [115,116].

Upon overexpression in target cells, drug-resistant genes may also protect them from environmental toxins such as carcinogens in addition to amelioration of anticancer chemotherapy [117]. For instance, transfer of *MGMT* increases repair of DNA damage in sensitive cells. *In vitro* and *in vivo* studies confirmed this aspect of the function of drug resistance genes [118,119]. Liu et al. [120] showed that rapid repair of *O*⁶-methylguanine–DNA adducts in transgenic mice protected them from *N*-methyl-nitrosourea-induced thymic lymphomas. This protection from carcinogens can be targeted to other organs such as the liver or the skin by suitable promoter systems [121,122].

To widen the range of anticancer drugs to be inactivated by gene therapy, vectors have been constructed for coexpression of two different drug resistance genes. For instance, a vector containing *ABCBI* (or *ABCCI*) and *MGMT* rendered human erythroleukemia cells resistant to the *ABCBI* substrates, colchicine and doxorubicin, as well as to alkylating agents, *N*-methyl-*N*-nitrosourea and temozolomide [123–127]. Other examples include the use of *ABCBI* with DHFR, which confers MTX resistance [128], *ABCBI* plus *MGMT*, which confers resistance to certain alkylating agents, and *ABCCI* plus gamma-glutamylcysteine synthetase, which confers

resistance to alkylating agents as well [129]. More recently, studies demonstrated the effect of mutant *DHFR*/mutant *thymidylate synthase* [130] and mutant *DHFR/cytidine deaminase* [131] fusion genes in conferring resistance to pemetrexed and both MTX and cytarabine, respectively.

A different approach to utilize vectors that allow for coexpression of two genes is to include a second gene that may enhance the efficacy of a selectable marker gene. This has been shown by construction of a vector that contained an *ABCC1*-cDNA and a cDNA encoding γ -glutamyl-cysteine synthetase (GCS), the rate-limiting enzyme of glutathione biosynthesis [129]. The transduced cells were resistant to substrates of *ABCC1* and also to alkylating agents including melphalan, chlorambucil, and cisplatin [129]. A follow-up study showed that *ABCC1* overexpression results in an intracellular decrease of glutathione (GSH) levels and in an increased GSH synthetic rate, increased steady-state GSH intracellular levels and normalization of the turnover time of GSH [132]. Furthermore, the report highlighted that *ABCC1*-overexpressing cells were hypersensitive to L-buthionine-S,R-sulfoximine (BSO) [132], an inhibitor of γ -GCS, enhancing the cytotoxicity activity of alkylating agents, platinum compounds, and irradiation [133]. However, a resistance to BSO treatment rather than hypersensitivity has been shown in *ABCC1*/catalytic subunit of γ -GCS transduced cells [132]. These results, along with previous reports discussing the ability of BSO to reverse drug resistance, especially doxorubicin resistance, mediated by *ABCC1* overexpressing experimental tumors [134,135], suggest that treatment with BSO could exert an anticancer effect and also modulated the anticancer activity of *ABCC1* substrates and alkylating agents in *ABCC1*-overexpressing tumors.

26.2.3 DRUG RESISTANCE GENES AS SELECTABLE MARKERS FOR GENE THERAPY OF NONMALIGNANT DISEASES

Selectable bicistronic vectors provide great flexibility in coordinating expression of a selectable marker, such as *ABCBI*, and a therapeutic gene. The low translation efficiency of the internal ribosome entry site (IRES) results in asymmetric expression of genes positioned before and after the IRES. This asymmetric expression pattern makes it possible to alter the relative expression level of a therapeutic gene and P-gp to achieve maximum therapeutic effects while applying minimal selective pressure using a cytotoxic drug. By choosing different configurations, i.e., placing *ABCBI* before or after the IRES, we can select cells expressing a therapeutic gene at either a low level (*ABCBI* before the IRES) or a high level (*ABCBI* after IRES).

Lysosomal storage deficiencies such as the Gaucher and Fabry disorders are well-characterized single gene disorders and are not subject to complex regulation mechanisms. In addition, an enzymatic activity around 20% of the normal level is sufficient for clinical efficacy. These characteristics make lysosomal storage disorders good candidates for gene therapy.

Gaucher disease is characterized by accumulation of a glucosylceramide in glucocerebrosidase (GC)-deficient hematopoietic cells. These patients suffer from skeletal lesions, severe hepatosplenomegaly, anemia, and disorders of the central nervous system. While it is possible to efficiently transduce a GC cDNA to hematopoietic progenitor cells [136,137], expression levels tend to decrease after several weeks or months *in vivo* because of silencing or the limited lifespan of the transduced cells' progeny. To increase expression of GC *in vivo*, Aran et al. [138] constructed a transcriptional fusion between *ABCBI* and the GC gene. Increased expression of this gene was achieved by selection with cytotoxic substrates of P-gp. Appropriate selection strategies allowed complete restoration of the underlying genetic defect in cells from Gaucher patients [139]. Transduction of such bicistronic vectors into hematopoietic stem cells might allow treatment of patients by chemotherapeutic elimination of nontransduced cells that continue to synthesize or store glucosylceramide. Moreover, following chemotherapy, the numbers of genetically corrected hematopoietic progenitor cells should increase in the bone marrow to maintain physiological numbers of mature granulocytes, monocytes, and lymphocytes in peripheral blood. Havenga et al. demonstrated an *in vivo* selection for cells expressing GC with a vector containing the selectable marker gene, *DHFR* [140].

To demonstrate coexpression of a dominant selectable marker with a therapeutic gene using a bicistronic vector, the authors have coexpressed P-gp with GC [138,141], α -galactosidase A [142], adenosine deaminase (ADA) [143], a subunit of the NADPH oxidase complex [45,144], the shared gamma chain of the interleukin receptors [145], and a hammerhead ribozyme targeted to the U5 region of HIV-1 LTR [146]. In those experiments, *ABCBI* served as a selectable marker linked to the target gene by an IRES from encephalomyocarditis virus (EMCV) and constructed in a retroviral vector containing Harvey sarcoma virus LTR [147]. Two configurations, in which *ABCBI* is placed either before or after the IRES, have been examined in some cases. As demonstrated in those experiments, P-gp and the target gene are coexpressed in the cells selected using cytotoxic P-gp substrates, such as colchicine or vincristine; the expressed target proteins are functional as detected using *in vitro* or *ex vivo* analysis. In one case, using subcellular fractionation, we have demonstrated that P-gp and GC are translocated separately to the cell plasma membrane and lysosomes, indicating correct intracellular protein trafficking [138]. The demonstration that a noncoding RNA, such as a hammerhead ribozyme, can function even though tethered to an mRNA encoding a functional *ABCBI* provides an additional powerful way to use bicistronic vectors [146].

Using an IRES to generate a bicistronic mRNA ensures coexpression of two different proteins. However, IRES-dependent mRNA translation (or cap-independent translation) is less efficient than cap-dependent translation so that the two proteins are not expressed in equal amounts. It has been shown that in a monocistronic vector, insertion of an IRES upstream from an open reading frame of either *ABCBI* or *DHFR*

reduces the translation efficiency by 2- to 10-fold [148,149]. Using a bicistronic vector, expression of *neo* in the position downstream from the IRES is 25% to 50% of that observed when *neo* is in the upstream position [150]. The asymmetric expression pattern of the bicistronic vector results in a significant difference in *ABCBI* transducing titer between a configuration with *ABCBI* placed before the IRES and a configuration in which *ABCBI* is placed after the IRES. We have found that the apparent titer of a bicistronic vector containing *ADA-IRES-ABCBI* was only 7% of the titer of a bicistronic vector containing *ABCBI-IRES-ADA* [143]. Similar reductions in *ABCBI* transducing titer and in expression of the nonselected downstream gene were seen with *ABCBI-β-galactosidase* bicistronic vectors [142]. The apparent *ABCBI* transducing titer of the retrovirus is based on the drug resistance conferred by expression of P-gp as the result of retroviral infection; thus the viral titer is proportional to the P-gp expression level. Insufficient expression of P-gp is unable to protect the cells from cytotoxic drug selection. To achieve P-gp expression at the same level, the lower efficiency of translation would have to be compensated for by a higher level of transcription, which can occur only in a minority of the cells in the transduced population. This may account for the apparent lower *ABCBI*-transducing titer of bicistronic vectors with a configuration of P-gp placed after the IRES. On the other hand, when cells express P-gp at the same level (i.e., the cells survived vincristine or colchicine selection at the same concentration), ADA expressed from *ADA-IRES-ABCBI* is 15-fold higher than the ADA expressed from *ABCBI-IRES-ADA*. This difference is probably due to a combination of the lower translation efficiency of ADA located downstream from the IRES and the high transcription level of *ADA-IRES-ABCBI* as the result of vincristine selection. A similar asymmetric expression of P-gp and human β -galactosidase A is also observed in NIH3T3 cells, where the difference is about eightfold.

IRES-dependent translation is a complex process in which mRNA-containing IRES interacts with various cellular proteins, including IRES-transacting factors (reviewed by Hellen and Sarnow [151]). The efficiency of IRES-dependent translation can be affected by the cell type [152], IRES origin [153,154], and the size and structure of a particular mRNA molecule. We have found that the titer of retrovirus containing pHa-*ABCBI* was higher than pHa-*ABCBI-IRES-ADA*, even though P-gp translation was cap-dependent in both cases. P-gp expressed from pHa-*ABCBI* was also at a higher level in a vincristine-resistant cell population than the P-gp expressed from pHa-*ABCBI-IRES-ADA*. A possible explanation for the relatively low retroviral titers observed is RNA instability or alternative splicing, since no DNA rearrangement was detected by Southern blot analysis of the transduced cells using an *ABCBI* probe.

High expression of the target gene can be selected using cytotoxic drugs, cytotoxic drugs combined with chemosensitizers, or the vector configured to place the target gene before the IRES. However, those approaches also reduce the overall number of cells that can survive the selection. Nevertheless, using a minimum concentration of drug, the selectable

bicistronic vector provides options for selecting a large population of cells with low expression of the target gene, or a small population of cells with high expression of the target gene. Both options may be useful for gene therapy. For instance, ADA levels in normal individuals occur over a very broad range. Heterozygous carriers can be immunologically normal even with as little as 10% of the normal amount of ADA (reviewed by Blaese [155]). Expression of ADA at a low level in a large number of cells may prove sufficient to treat severe combined immunodeficiency (SCID). On the other hand, high ADA-expressing lymphoid cells, even though present as a small percentage of total cells, are also able to correct the SCID syndrome due to a beneficial bystander effect [156].

A different strategy to exploit the *ABCBI* gene as a drug selectable marker for correction of ADA deficiency was described by Germann et al. [157]. In this study, both genes were fused to a single cDNA encoding a bifunctional chimeric protein. This approach, however, cannot be used if the two proteins are physiologically located in different cellular compartments.

In gene therapy applications, the choice of the approach depends on the therapeutic strategy for a specific disease. Experiments on animal models are essential to prove the concepts that underlie gene therapy using selectable markers such as *ABCBI*. Detection of the function of transferred genes may be difficult if normal animals are utilized because of the activity of the respective endogenous gene product. To circumvent this difficulty, "knock-out" animals whose gene has been inactivated by targeted disruption can serve as useful models. For instance, mice whose β -galactosidase gene has been disrupted may be helpful to characterize a bicistronic vector in which *ABCBI* is combined with the respective human gene for correction of Fabry disease [158]. Another alternative is to use marking genes that are not physiologically expressed at high levels in normal tissues. To characterize bicistronic vectors containing *ABCBI*, this gene has been coexpressed with a green fluorescent protein or β -galactosidase [159]. These model systems should help to improve protocols for efficient drug selection and to identify strategies for selection at limited systemic toxicity. For instance, addition of P-gp inhibitors at low concentration to cytotoxic drugs may increase the stringency of drug selection, thereby allowing the use of anticancer drugs at low concentrations for selection [141]. Indeed, in the presence of a P-gp reversing agent, most P-gp-expressing cells are killed by the cytotoxic drug unless they express a large amount of P-gp to overcome the inhibitory effects. Using a combination of cytotoxic drug and chemosensitizer allows selection of cells expressing the therapeutic gene at a high level without need for a high concentration of cytotoxic drug. This strategy is especially desirable for an *in vivo* selection in which avoiding systemic toxicity is essential.

Another system in which selectable markers may be useful is in the skin. It is possible to grow keratinocytes in culture and introduce the *ABCBI* gene via retroviral vectors. Such keratinocytes are resistant to MDR drugs *in vitro*, and when transplanted on keratinocyte "rafts" to recipient animals, they remain resistant to colchicine, which can be applied

as an ointment. If colchicine is withdrawn, transplanted keratinocytes are gradually replaced by nontransduced host skin; in the presence of selection, the transplanted keratinocyte graft is maintained. It should be possible in such a system to introduce other nonselectable genes via bicistronic vectors to serve as a source of protein to treat a genetic defect in the skin or elsewhere in the host [160,161].

26.3 AAV, SV40, AND EBV: EPISOMAL VECTORS EXPRESSING SELECTABLE MARKERS

Efficient delivery of a therapeutic gene to the appropriate target cells and its subsequent maintenance and expression are important steps for successful gene therapy. Genes introduced into cells are rapidly lost unless there is a mechanism to retain these genes within the nucleus and to ensure that the genes are also replicated and partitioned into daughter cells during cell division. Long-term expression of the transgene within cells can be achieved either via the integration of the transferred DNA into the host genome or maintenance of the introduced DNA as an autonomously replicating extrachromosomal element or episome. In either case, inclusion of a drug-selectable marker, such as the *ABCBI* gene, in the construct would ensure that rapidly dividing cells containing the transgene are given a selective growth advantage.

Delivery modalities can be viral or nonviral. Retroviral gene transfer, one of the most exploited systems for gene transfer into actively dividing cells, has been discussed earlier in this chapter while liposomal gene delivery will be discussed later in the chapter. In this section, nonretroviral and/or episomal vectors expressing selectable markers will be described.

26.3.1 AAV

In addition to retroviruses, adeno-associated virus (AAV) can also facilitate integration of the transgene into the host genome. Unlike retroviruses, AAV was found to integrate preferentially into a specific site on chromosome 19 [162]. AAV is a naturally defective, nonpathogenic, single-strand human DNA parvovirus. For productive infection and viral replication, coinfection with helper viruses, e.g., adenovirus, herpes virus, or vaccinia virus are required. In the absence of a helper virus, AAV establishes latency in the host by integrating itself into the host genome. AAV has a broad host range and is also able to infect both dividing and nondividing cells [163]. Hence recombinant AAV (rAAV) vectors have been exploited as alternative vehicles for gene therapy.

AAV-based vectors [164] are simple to construct, requiring only that the viral inverted terminal repeat (ITR) (which are 145 nucleotides each) is upstream from the gene of interest. Other important viral genes such as *rep* (involved in replication and integration) and *cap* (encoding structural genes) can then be supplied in *trans*. One disadvantage with such rAAV vectors is that site-specific integration of the gene of interest into the host genome is not observed [165]. This is probably because the *rep* gene, which is important for

mediating site-specific integration in the absence of helper viruses, is not included in the construct with the gene of interest. Nonetheless, rAAV has been successfully applied to the delivery of various genes into a variety of tissues and persistence of transgene expression in these nondividing tissues was reported [166–171]. Baudard et al. [165] demonstrated that in rapidly dividing cells, continuous selective pressure is necessary to sustain gene expression in cells. *ABCBI* was used as the selectable marker in this study. Being among the smallest DNA animal viruses (~20 nm in diameter), another disadvantage of the AAV system is its limited packaging capacity since it can accommodate only approximately 4.7 kb of the gene of interest. As such, a small and efficient promoter would be required to drive the expression of large genes. One such promoter is the AAV p5 promoter, which, together with the ITR, forms a 263-base pair cassette capable of mediating efficient expression in a CF bronchial epithelial cell line [166,167]. Baudard et al. further demonstrated that the reduction of the p5 promoter-ITR cassette to 234 bp was also able to promote efficient gene expression [165].

As mentioned above, although AAV has many features that render it a useful gene transfer vehicle, its small packaging capacity poses a challenge for AAV-mediated gene therapy in many inherited diseases such as cystic fibrosis (CF), hemophilia A, or Duchenne muscular dystrophy. In these diseases, the therapeutic expression cassette exceeds the viral packaging limit. Transsplicing AAV (tsAAV) vectors is a newly developed technology to double AAV packaging capacity. In this approach, the therapeutic gene is split into two parts and each part is carried by an AAV virion. After coinfection, the full-length gene is reconstituted through head-to-tail vector genome recombination. Therapeutic protein is expressed after the viral junction is removed from the mature mRNA by the cellular splicing machinery (reviewed by Duan et al. [172]). Lai et al. generated a set of *trans*-splicing vectors and achieved widespread expression of a truncated but functional dystrophin gene (exon 17–48) in skeletal muscle of mdx mice, a model for Duchenne muscular dystrophy. The dystrophic phenotype was ameliorated in both adult and aged mice [173]. The same group has recently demonstrated for the first time whole-body transduction using tsAAV vectors [174].

26.3.2 SV40

Vectors that facilitate extrachromosomal replication have some advantages; among these is high gene expression. This could be a result of vector amplification, promotion of nuclear localization and retention, as well as transcriptional activation by viral genes involved in episomal replication. However, selective pressure using selectable markers such as the *ABCBI* gene is necessary to maintain these episomes in actively dividing cells. In some cases, i.e., SV40 and retroviruses, chromosomal replication does occur followed by integration into the genome. This integration can produce mutations. At least two participants involved in a recent gene therapy trial for SCID developed leukemia after retroviral insertion [175]. Thus, another potential advantage of using

episomally replicating vectors is the ability to extinguish expression at will by withdrawing selective pressure to replicating cells. One such example is the expression of the human *ABCBI* cDNA, which can be repressed by tetracycline and induced in its absence [176]. Episomally replicating vectors can be easily created by the inclusion of replicons into the vector design. These replicons can be derived from DNA viruses such as Simian virus 40 (SV40) [177], EBV [178], BK virus [179–181], vaccinia virus, canarypox virus, and Newcastle disease RNA virus [175]. The replicons are usually comprised of a viral origin of replication as well as a viral gene product that is important for maintaining extra-chromosomal replication.

SV40 is a DNA polyomavirus that is a nonenveloped virus. Wild-type SV40 (wt SV40) virus is a double-stranded circular 5.2 kb DNA simian virus. The SV40 capsid is composed of 72 pentamers of the major capsid protein VP1 that are connected through their carboxy termini. The minor capsid proteins VP2 and VP3, which share 234 amino acids at their carboxy termini, connect the minichromosome core to the axial cavities of VP1. It has been suggested that correct interpentamer bonding is facilitated by host chaperones [182]. This interaction of the minor capsid proteins VP2 and VP3 with the major capsid protein VP1 is integral for viral infection. Amino acid residues of the three capsid proteins of SV40 have been studied and the residues required for protein interaction and infection of cells have been defined [183].

SV40 infection begins with the virus binding to its primary receptor, the major histocompatibility complex class I (MHC class I) without internalization of the receptors. The virus also binds to GM1 gangliosides, which act as plasma membrane receptors and travel with it to the endoplasmic reticulum (ER) [184]. After binding, SV40 enters cells through pinocytosis [185]. Transport of the virus to the ER, where the virus is disassembled, occurs in coated carrier vesicles (named COPI and COPII, [186]). Beta-COP, a component of COPI vesicles, is required for the retrograde retrieval pathway from the Golgi apparatus to the ER [187]. This transport to the ER is mediated by caveolae and facilitated by ER chaperones. Following disassembly, nuclear pore complexes assist in delivery of the viral DNA to the nucleus for replication. Nuclear membrane disassembly is not required for this delivery [187]. Infection of nonmonkey cells with wt SV40 can result in the integration of viral DNA into the host chromosome, permitting transmission of expression to daughter cells [188]. While human cells are semipermissive to wt SV40 replication, rodent cells are nonpermissive to viral replication; therefore, no progeny virions can be produced in these cells [189]. Nonlytic infection with wt SV40 enables the virus genome to persist as a self-replicating minichromosome due to the presence of the T antigen (Tag) [190].

Alternatively, when SV40 infects its host, it undergoes a lytic replication cycle, through which Tag is produced and is necessary for viral DNA replication and thus for the production of the capsid proteins. The binding of the large T antigen (LT) to the tumor suppressor proteins p53 and pRb may induce cellular immortalization *in vivo* [191].

The two major SV40 delivery systems are vectors that use SV40 sequences or the wt virus as a helper prepared *in vivo* (the SV40 delivery systems that are prepared using cell lines are defined here “*in vivo*” and those without helper virus and packaging cell lines are defined “*in vitro*”), and vectors that are packaged *in vitro*, with no SV40 sequences and in which the wild-type virus is not present. In *in vivo* preparation, replacing the late or early region with a reporter gene can generate SV40 recombinant viral particles (rSV40 [185,188,192–198]). These are then propagated using either wild-type, or a temperature-sensitive mutant of SV40 as helper via a viral producer cell line, COS7. The packaging cell line COS7 stably expresses an origin-defective SV40 mutant and is capable of supporting the lytic cycle of SV40. Present SV40 vectors prepared *in vivo* have most of the viral coding sequences removed, retaining only the packaging sequences, the polyadenylation signal, and the early promoter of the virus, thus increasing the capacity for DNA to 5.3 kb. “Gutless” vectors, devoid of the SV40 sequence [190], can also be packaged in COS7 cells, for those do not require a helper virus or cotransfection with other plasmids. In this approach, the maximal DNA packaged in the rSV40 vector is 5.7 kb. Arad et al. [199] reported the use of COT18, a packaging cell line, with minimal sequence identity to the wild-type vector that unlike the Tag replacement vectors does not result in reacquisition of the Tag gene. An immune response and recombination with wt SV40 sequences are thus prevented.

The *in vitro* method of preparing helper-free SV40 vectors utilizes the SV40 viral late proteins, VP1, VP2, VP3, and agno or VP1 only [200–203]. The inclusion of VP1 in the vectors is essential and, due to its calcium-binding residues, VP1 participates in the assembly of the capsid and maintains viral integrity. Li et al. [204] demonstrated the involvement of calcium ions in viral entry to the cell and nucleus, controlling virion formation and structural alterations. In this method of *in vitro* packaging (IVP), nuclear extracts of VP1-baculovirus-transduced *Spodopterafrugiperda* (Sf9) insect cells are incubated with supercoiled plasmid DNA lacking SV40 sequences (i.e., the origin of replication, 182) or with siRNA [205] in the presence of 8 mM MgCl₂, 1 mM CaCl₂, and 5 mM ATP [90]. Such *in vitro* assembly allows larger DNA plasmids (up to 17.6 kb) to be packaged very efficiently with no need for SV40 sequences. In this delivery system, it is possible to package large genes together with the *ABCBI* gene (4.7 kDa) as a selective marker. Recently, new conditions for IVP have been defined and tested also for *ABCBI*: a scaled-up procedure for IVP of plasmid DNA, a procedure for concentrating virion volume without loss of activity, and a method that yields a great number of transduced cells [206].

SV40 has numerous advantages as a gene-delivery vehicle [91,194,207]:

1. *Tropism*. The virus is able to infect a wide variety of mammalian cells, including human cells, and to express its genes in these cells. Pseudovirions can transfer the gene of interest to a variety of cells (including hematopoietic cells) with high efficiency.

When using the SV40 *in vivo* delivery system, injections of the vectors into a specific organ or an organ's blood supply leads to the transduction of other organs as well [190]. However, when using the pseudomonas exotoxin (PE)-SV40 *in vitro* delivery system to reduce the size of adenocarcinomas in mice, there was no evidence of toxin expression in other tissues [208].

2. *Nucleic acid delivery.* The vector system is able to deliver untranslated RNA products [205].
3. *Expression persistence.* The gene expression may be transient or stable in cell lines depending on the specific SV40 system that is used. *in vivo* preparation results in long term expression: Strayer et al. [188] found evidence for integration of the recombinant gene or parts of it, a few days after transduction in random sites, which might explain the long-term expression. It has been demonstrated that when the large Tag gene is replaced with a reporter gene, replication-deficient recombinant SV40 viruses can be produced and can mediate gene transfer *in vivo*. Reporter gene expression was detectable for about 3 months without selection. Through IVP one can achieve short-term expression; selection with *ABCBI* can prolong expression. While expression of *ABCBI* and green fluorescence protein (GFP) are transient, lasting up to 21 days, it can be extended to 3 months under colchicine selection for *ABCBI*. When selection is withdrawn, expression is lost [90].
4. *High titers.* Multiple infections, in the preparation of the *in vivo* system, result in higher titers of the virus—up to 10^{10} infectious units/ml. However, the *in vitro* system produces a maximum 10^6 infectious units/ml. It should be noted that a comparison of rSV40 vector titers is problematic because there is no consensus on the titration method. While some researchers use a modified *in situ* polymerase chain reaction (PCR) [196], others use a real-time quantitative PCR method of titration [209] and yet others determine titers by quantifying luciferase activity in vectors carrying this transgene [199].
5. *Expression levels.* Using the SV40 *in vivo* system, episomal replication in the SV40 virus requires the SV40 replication origin as well as the large Tag, which activates the replication origin. Such episomal replication can generate more than 105 copies per cell of recombinant plasmids [210]. Introduction of the *in vitro*-packaged genes at 24h intervals also results in greater expression than a single transduction [206].
6. *Inflammation and immunogenicity.* The replacement of the large Tag with firefly luciferase, controlled by the SV40 early promoter, results in expression of luciferase without causing inflammation [211]. Unlike other viral vectors, rSV40 was not reported to elicit antibody formation. Since rSV40 vectors lack Tag, which induces cell-mediated immunity, and often lack capsid genes encoding for capsid proteins that produce antibody-mediated immunity, probably

only slight immune response is generated. It should also be noted that the entry pathway for SV40 is different from that of most viruses. It does not fuse with the cell membrane because it does not contain an envelope, nor is it phagocytosed. The viral capsid proteins, the potential targets for the immune system, are only processed at a later stage [185]. Transport of the virus to the ER in coated carrier vesicles and caveosomes bypasses endosomes and the Golgi apparatus [212]. Damm et al. [213] describe an alternative, faster entry pathway through which the virus travels to the ER without clathrin or caveolin and thus bypasses endocytic organelles. *in vitro* blocking of the ER continues to show GFP expression, thus suggesting that other pathways of viral entry to the nucleus exist [214]. In an attempt to identify the limiting step in the *in vitro* entry pathway of SV40 pseudovirions into the nucleus, Kimchi-Sarfaty et al. [214] showed that most of the DNA is not incorporated into the nucleus, but is trapped in the ER. Some of it moves back to the cytosol and is possibly degraded [215].

7. *Capacity.* *In vitro*-packaged SV40 vectors that do not contain an SV40 sequence permit packaging of plasmid DNA up to 17kb in size. In order to determine the cloning capacity of IVP SV40 vectors, expression of ABC transporter genes carried by packaged plasmids ranging from 4.2 to 17.7 kb was measured. In addition to delivery of the *GFP* gene as a reporter, very efficient delivery of the *ABCBI*, *ABCG2*, and *ABCC1* genes was achieved along with multidrug resistance on virtually all cell types (human, murine, and monkey cell lines, [216]). The expression of both *ABCBI* and *GFP* genes is dose-dependent. The alteration in the level of expression suggests that MHC class I receptors play an important role in determining the efficiency of transduction. However, in IVP system high levels of MHC class I receptors are not necessary, nor are they sufficient for viral expression [216].
8. *Safety.* *In vitro*-packaged SV40 vectors that contain only capsid proteins and no viral sequences are as safe as nonviral vectors [216].

Application of SV40 in gene delivery is widely reported in the literature. Rund et al. [91] demonstrated very efficient delivery [217] of the drug-selectable marker, *ABCBI*, into various murine and human cell types including primary human bone marrow cells. *ABCBI* constructs that carried a promoter with an intron demonstrated higher expression than those without the intron. In low-expressing MHC class I cell lines, the CMV promoter expressed more P-gp compared with the SV40 promoter. *In vitro*-packaged *GFP* vectors that carried the CMV promoter consistently confirmed higher expression than those that carried the SV40 promoter [216].

Gene expression through IVP is usually limited in its duration. The short-term expression of the SV40/*ABCBI*

in vitro vectors may be an advantage for use in chemoprotection. Long-term expression beyond the chemotherapy period is undesirable, and may put patients at risk for treatment-induced myelodysplasia or secondary leukemia. The SV40/*ABCBI* vectors that are prepared *in vitro* may provide not only a safe vehicle for gene delivery but will also potentially avoid the problem of persistent bone marrow drug resistance in cancer patients.

Resting cells as well as dividing cells can express genes delivered through the SV40 delivery system [190]. Human mesenchymal stem cells (MSCs) in various stages of differentiation can be efficiently transduced by SV40 IVP vectors. When these cells are grown in medium containing factors that promote differentiation, high levels of GFP expression are achieved. While mouse-enriched bone marrow cells transduced with a retrovirus express MDR on the cell surface, a significantly greater amount of MDR is expressed by SV40-transduced cells 35 days posttransduction. This implies that *ABCBI* transduction of patient bone marrow through the SV40 delivery system may provide a strategy for chemoprotection during chemotherapy (unpublished data).

The involvement of SV40 in cancer therapy prompted the idea of delivery of lethal genes through the SV40 delivery system. SV40 pseudovirion delivery of *Pseudomonas* exotoxin A (PE38) was found to be effective in the treatment of human adenocarcinomas growing in mice either by direct injection or systemically. Using a combined treatment of SV40-PE38 with doxorubicin reduces the side effects of chemotherapy [208].

SV40 vectors efficiently deliver HIV-1-inhibitory RNAs using pol II or III promoters [218]. Vectors that encode a variable fragment antibody that recognizes HIV-1 integrase inhibit HIV-1 infection in SCID mice [218]. Neuronal apoptosis induced by HIV-1 gp120 can be reduced *in vivo* through the delivery of superoxide dismutase (SOD1) and glutathione peroxidase (GPx1) by rSV40 injected into rat brains [218]. While antiretroviral therapy penetrates the CNS poorly, rSV40 delivery to microglial cells is effective and can be used for the delivery of anti-HIV therapy, thus protecting from HIV-induced brain injury [219].

In conclusion, rSV40-based vectors have great potential in gene therapy. rSV40 delivery systems are highly efficient vehicles for the delivery of chemoprotective agents, such as members of the ABC transporter genes, into a wide variety of cells. The use of the *ABCBI* selective marker in these vectors along with large genes (total plasmid size of 5.7 kb in *in vivo* "gutless" SV40 delivery and 17.7 kb in *in vitro*-packaged delivery, lacking the SV40 sequence) enables well-controlled, long-term as well as short-term gene expression.

26.3.3 EBV AND OTHER EPISOMAL VECTORS

Episomal vectors based on EBV are also being developed for gene therapy purposes. EBV is a human B-lymphotropic herpesvirus that resides asymptotically in more than 90% of the adult human population by establishing latency and maintaining its genome episomally [220]. The life cycle of EBV comprises two phases, a lytic and a latent phase. During the

lytic phase, EBV DNA replicates via a rolling circle intermediate to achieve a 1000-fold increase in copy number. The origin of replication, Ori Lyt, and the transacting element ZEBRA are required for the lytic replication. Rolling circle replication results in the formation of linear head-to-tail concatamers. The presence of the EBV terminal repeat (TR) sequence causes cleavage of the concatemered DNA to molecules of about 150–200 kbp, which are then packaged into virions. Upon infection into a permissive cell, the viral DNA circularizes by ligation of TR. Latency is established in the cells by episomal replication of the circular DNA.

Episomal replication in EBV is maintained by two elements interacting to ensure that the viral genome is retained within the nucleus, efficiently replicated and partitioned into daughter cells. Although the copy numbers of episomal viral DNA vary from 1 to 800, only between 4 and 10 episomal copies per cell are usually observed using vectors containing EBV OriP and EBNA-1 [221]. Unlike other episomal vector systems, very low rates of spontaneous mutation have been observed with EBV-based episomal vectors [222]. The *cis*-acting element responsible for episomal replication is a 1.8 kb OriP while the transacting element is EBNA-1. OriP comprises two distinct sequence motifs, the dyad symmetry (DS) motif from which replication is initiated and the family of repeats (FR) that serve as a replication fork barrier. Interaction of EBNA-1 with DS initiates bidirectional replication, while binding of EBNA-1 to FR enhances transcription from the episome and terminates DNA replication. EBNA is reported not to be oncogenic nor immunogenic. It evades the host immune system via the presence of the repeat motif, Gly-Ala, which was found to interfere with antigen processing and MHC class I-restricted presentation [223]. These EBV episomal vectors replicate once per cell cycle [224] and are capable of stably maintaining human genomic inserts of sizes between 60 and 330 kb for at least 60 generations [225].

Vos and colleagues [226] developed a helper-dependent infectious recombinant EBV to evaluate the feasibility of using such a vector system to correct hereditary syndromes in B-lymphocytes already harboring the EBV virus latently. The EBV-containing target B-lymphocytes will supply EBNA-1 *in trans* for the episomal maintenance of the transgene. Hence only minimal *cis*-EBV elements for episomal replication (OriP), viral amplification (Ori Lyt), and packaging (TR) are included in their construct. The hygromycin resistance gene was included as a selectable marker in their vector. Infectious virions are generated by the producer cell line HH514. They demonstrated successful transfer of such infectious virions carrying the therapeutic gene, Fanconi anemia group C (FA-C) cDNA, into HSC536, an FA-C patient cell line. Upon selection with hygromycin, long-term (at least 6 months) correction of the Fanconi phenotype *in vitro* was observed, as determined by cellular resistance to the crosslinking agent, diepoxybutane. They also observed that in the absence of selective pressure, their episomal vector is retained in rapidly dividing cells at a rate of 98% per cell division translating to a half-life of 30 days in cells doubling every 20 hours.

The authors have explored the use of EBV episomal vectors containing only the OriP and EBNA-1 and carrying the selectable marker *ABCBI* as potential gene therapy vectors. Using the liposome formulation, DOGS/DOPE (1:1) [227], we successfully delivered the vector to various cultured cells as well as human stem cells. *ABCBI* was found to be expressed at a higher level in the episomal vector compared to its non-episomal counterpart and more drug colonies were obtained upon selection. Episomal plasmids could be recovered in drug-selected cells for many weeks [92].

Other episomally replicating vectors can be derived from BPV viruses [228] or BK virus [180]. Unfortunately, BPV vectors cannot be reliably maintained as episomes, as they exhibit a high spontaneous mutation rate (~1%), frequently undergoing integration, deletion, recombination, and rearrangements [229]. Furthermore, BPV has a limited host range and BPV vectors cannot be efficiently maintained in human cells. Not much is known about BK-virus-derived episomal vectors. Nonetheless, successful stable maintenance of episomal gene expression was reported in human transitional carcinoma cells using BK-based vectors but not EBV-based vectors, probably due to the differential tropism of BK and EBV viruses for human uroepithelial cells [179].

Various chimeric viruses have been developed to improve the efficiency of gene transfer as well as the maintenance of gene expression within target cells. These chimeric virus systems attempt to combine the favorable attributes of each vector system and overcome the limitations associated with each system. The episomal replication ability of EBV was exploited to produce both rapid and long-term high-titer recombinant retroviruses (up to 10^7 TU/ml) for efficient gene transfer into human hematopoietic progenitor cells [230,231]. A novel adenoviral/retroviral chimeric vector was also reported in which an adenoviral delivery system was utilized to efficiently deliver both the retroviral vector and its packaging components, thereby inducing the target cells to function as transient retroviral producers capable of infecting neighboring cells. This system capitalizes on the superior efficiency of adenoviruses to deliver genes *in vivo* and the integrative ability of retroviruses to achieve stable gene expression [232]. An EBV/HSV-1 amplicon vector system was also described that combines the efficiency of HSV-1 virus to transfer DNA into various mammalian cells, including the postmitotic neuronal cells and the ability of EBV to maintain genes episomally. This vector system contains the HSV-1 origin of DNA replication (*oriS*) and a packaging signal, which allow replication and packaging of the amplicon into HSV-1 virions in the presence of HSV-1 helper functions as well as EBV *oriP* and EBNA-1 [233]. Another report describes the use of a similar HSV-1 amplicon system for efficient gene transfer, but AAV was included in their vector to achieve stable expression. This HSV/AAV hybrid vector contains *OriS* and packaging sequences from HSV-1, a transgene cassette that is flanked by AAV ITRs as well as an AAV *rep* gene residing outside the transgene cassette to mediate amplification and genomic integration of ITR-flanked sequences [234]. An HVJ-liposome vector system reported by Dzau et al. [235] was utilized to

improve the efficiency of liposome-mediated transfer of an EBV-episomally maintained transgene [236,237]. This system exploits the fusogenic properties of the hemagglutinating virus of Japan (HVJ or Sendai virus) since envelope proteins of inactivated HVJ were found to mediate liposome-cell membrane fusion and facilitate cellular uptake of packaged plasmid DNA, bypassing endocytosis and lysosomal degradation.

One of the limitations with using viral episomal systems is the limited host range of such vectors. Although EBV episomal vectors replicate well in various human and primate cells, they are unable to replicate in rodent cells, limiting their utility in gene therapy since they cannot be tested in rodent models. Nonetheless, it was found that large fragments of human genomic DNA (between 10 and 15 kb) can mediate autonomous replication if there is also a mechanism to retain them in the nucleus [238]. Such vectors based on a human origin of replication were also found to be capable of replicating in rodent cells [239], probably due to the common host factors that drive their replication. A hybrid class of vectors was thus developed, which employs a human origin of replication to mediate vector replication as well as the EBV FR and EBNA-1 gene product to provide nuclear retention functions (see Calos [240]). EBNA-1 binding to the FR of the vector DNA causes the adherence of this complex to the chromosomal scaffold in a noncovalent fashion, thus retaining the vector DNA in the nucleus [241]. These vectors were reported to replicate somewhat in synchrony with chromosomal DNA once per cell cycle. Maintenance of these vectors within cells is related to the frequency of cell division [240]. Such vectors have been reported to persist in cells for at least 2 months under no selective pressure [238,242].

Ultimately, the development of a true mammalian artificial chromosome (MAC) without dependence on viral elements will be the key to obtaining stable episomal replication without dependence on selective pressure. Functional elements in mammalian cells important for maintaining DNA episomally as a minichromosome include a replication origin to promote autonomous replication, telomeres to protect ends of linear DNA and replicate DNA termini, and a centromere to facilitate correct segregation of the construct during mitotic division. Various mammalian chromosomal DNA replication initiation sites have been identified (reviewed in DePamphilis [243]) and found to comprise a 0.5–11 kb primary origin of bidirectional replication flanked by an initiation zone of about 6–55 kb. These sequences show characteristics of DNA unwinding, a densely methylated island, attachment sites to the nuclear matrix, and some palindromic sequences.

Vectors utilizing human genomic sequences that promote extrachromosomal vector replication have already been successfully applied as mentioned above. Telomeres that are required for the stability and integrity of the eukaryotic chromosome have been well characterized. In mammalian cells, the telomeric tracts comprise 2–50 kb of tandem TTAGGG repeats. Human centromeres, necessary for proper chromosome segregation at mitosis and meiosis, have been localized cytogenetically as primary constrictions of the chromosomes.

They are thought to consist of up to several megabases of highly repetitive DNA belonging to the alpha satellite DNA family and are attached to microtubules [244]. Until recently, the functional isolation of the centromere has been a great hurdle in the progress toward the construction of an MAC. The group of Willard et al. developed the first generation of human artificial microchromosomes (HAC) by creating synthetic alpha satellite arrays ~1 Mb in size [245]. They found that such an HAC, which is about 6–10 Mb in size, is mitotically and cytogenetically stable for up to 6 months in culture in the absence of selective pressure. Nonetheless, the technical challenge of assembling an MAC is still formidable, as cloning and manipulating such large constructs are not trivial using conventional bacterial cloning systems, and transfer to mammalian cells is difficult.

26.4 NANOPARTICLE-BASED DRUG AND GENE DELIVERY: A NEW PROMISE FOR GENE THERAPY

Occasionally, a new technology/field comes along that represents an emerging and novel scientific trend. Although nanotechnology has become very popular in the last few years, the concept is not new. Richard P. Feynman pioneered the field in the late 1950s when he introduced the concept of manipulating individual atoms: “there is plenty of room at the bottom.” Developing nanoparticles depends on understanding the limitations and advantages of nanoscale studies. Despite Feynman’s early vision, working at nanometer scale has only recently been conceivable.

Nanotechnology is a multidisciplinary field ranging from materials science to personal care application. Among these disciplines, nanomedicine has the potential to revolutionize diagnostics and therapeutics, two main applications that currently are in clinical trials (see National Nanotechnology initiatives: <http://www.nano.gov>). As mentioned in Section 26.1, a critical factor in gene therapy is the delivery vector. Therapeutics-based nanomedicine raises the opportunity to circumvent the issues related to present systems (including low transducing efficiency, toxicity, etc.) or at least to improve the gene and/or drug delivery process (reviewed by Emerich and Thanos [246] and Nie et al. [247]).

One type of nanoparticle is the liposome, which consists of a lipid shell surrounding a core containing a therapeutic gene or drug. Liposome-mediated gene transfer is a safe and noninvasive method of DNA delivery into cells. The use of lipids, specifically cationic lipids, as tools for the delivery of nucleic acids into cells has certain advantages over other gene delivery methods such as viral transfection vectors. These advantages include safety, simple preparation and handling, robust production of vectors, and the ability to inject large lipid:DNA complexes [248]. When liposomes are used for gene delivery, cationic lipids interact with the DNA spontaneously by noncovalent binding to form lipoplexes. These can infect a wide variety of cells *in vitro* with varied efficiency. Some have been reported to infect more than 70% of the cells [249]. Lipoplexes do not limit

the size of the DNA transferred, unlike viral vectors, and were not shown to induce an immunological response, thus allowing multiple dose regimens [250].

The major shortcoming of liposomal methods for gene delivery that makes them inferior to viral vectors is their low and variable efficiency and nonstable expression *in vivo*. A possible explanation for this is that organism complexity and systemic barriers alter the cationic lipid transfection efficiency observed *in vitro*. Systemic barriers can be overcome by peptides (oligomers with N-substituted glycines [251]) and lipoplex formulation methodologies. The incorporation of nonlipid substances, such as proteins or peptides [250], into the lipoplex can also assist in transport through cell barriers. Pharmacokinetic properties of lipoplexes can be altered by the use of PEGylated liposomes (attachment of polyethylene glycol). While expression is enhanced and renal clearance reduced, the efficacy and safety of these systems are compromised. Repeated *in vivo* administrations cause a long-term antibody response against PEG [252]. This response may be minimized by modifying the alkyl chain of the PEG–lipid conjugate. Through the change in pharmacokinetic properties, more constant and sustained plasma concentration can be achieved. In turn, this results in increased clinical effectiveness and decreased side effects [253]. Lipoplexes are characterized by their size, surface charge, DNA and lipid organization, DNA accessibility, and colloidal stability. It has been shown that certain lipoplex characteristics can influence transfection efficiency [249]. Of these, lipoplex size is worth mentioning [254], as well as charge ratio of the cation to anion and cell type.

Like liposomes, calcium phosphate nanoparticles are an alternative to viral gene delivery systems. Experimentation with this system has yielded high vector transfection efficiency, with no adverse effects from the carrier particles [255].

The use of the human *ABCBI* gene as a selectable marker may allow for the selection and enrichment of the recipient cells and may be useful in the future for the long-term maintenance of the cationic liposome:DNA complex. Previous studies have shown that a liposomal delivery system can mediate successful *ABCBI* transfection of mouse bone marrow cells and *in vivo* expression of functional P-gp in hematopoietic cells [256]. The introduction via liposomes into hematopoietic cells of an *ABCBI* gene driven by Harvey murine sarcoma virus LTR sequences (Ha-MSV-LTR) can be achieved in two ways: either “directly” by intravenous administration into mice or “indirectly” by adoptive transplantation of previously *in vitro*-transfected bone marrow cells. In these studies, using a cationic liposome complex consisting of dioctadecylamidoglycyl spermidine (DOGS) and dioleoylphosphatidyl ethanolamine (DOPE, a popular colipid), *ABCBI* transfection was detected in up to 30% of unselected and 66% of vincristine-preselected murine bone marrow cells. This was demonstrated by drug resistance in an *in vitro*, colony-forming unit assay. Transfection into human bone marrow cells is likely to be much less efficient. However, obtaining drug-selectable mouse bone marrow progenitor cells through liposome-mediated gene transfer may eventually prevent bone marrow toxicity in cancer patients undergoing

chemotherapy. Liposome-mediated gene transfer can also be used for *in vivo* delivery of adeno-associated-vectors (AAV)-*ABCBI*-based vectors. Baudard et al. [165] report drug-selected coexpression of both P-gp and GC with an AAV vector containing the *ABCBI*-IRES-GC fusion delivered to NIH 3T3 cells by lipofection. Moreover, 7 weeks after a single intravenous injection of this bicistronic vector complexed with cationic liposomes, GC and *ABCBI* sequences were detected by PCR in all recipient mice organs tested.

For nonintegrating DNA vectors such as EBV-based systems (see Section 26.4) and the AAV system [165], liposome-based gene delivery usually results in transient transgene expression. This can be explained by the episomal nature of the transfected plasmid and the loss of the plasmid when the cells proliferate [257,258]. Use of a selectable marker such as *ABCBI* may make it possible to maintain nonintegrated episomal forms in proliferating cells (see Section 26.4). Combining liposomes with AAV- or EBV-based vectors and *ABCBI* as a selectable marker may make it possible to expand the population of expressing cells by *ABCBI*-drug selection.

Polymer nanospheres are also being investigated (reviewed by Uchegbu [259]). Perez et al. constructed poly(lactic acid)/poly(ethylene glycol) (PEG) composite nanospheres (diameter <300nm) and showed modulation of release with the addition of either poly(vinyl alcohol) or poly(vinylpyrrolidone) alone or in combination [260]. Putnam et al. demonstrated the complexation of polyhistidine-PEG nanoparticles to DNA by forming micelles of DNA/polyhistidine surrounded by a hydrated shell of PEG and showed that they could achieve similar efficiency of transfection to polylysine DNA conjugates, but lower than polyethyleneimine [261]. Dendritic and hyperbranched polymers are other nanoparticles developed for gene delivery (reviewed by Paleos et al. [262]). These polymers form electrostatic interactions between the negatively charged phosphate group on the DNA backbone and the positively charged amino groups on the polymer. Polyamidoamines (PANAM) are the most often used and characterized dendrimers for gene delivery and several groups have demonstrated their efficacy. One of them, Maksimenko et al., reported successful transfection of several cell lines by pCMV β -gal plasmid-dendrimer complexes in the presence of anionic oligomers including oligonucleotides or dextran sulfate [263]. The size and the charge of the additive affected the transfection efficiency, with 35–50 phosphate group oligonucleotides providing the highest efficiency.

Although further investigation is required to study the potential toxicity of nanoparticles, this novel technology opens interesting avenues for gene therapy. Nanoparticles could soon replace viral systems for gene delivery and circumvent some of the present difficulties involved in gene therapy.

26.5 ENGINEERING VECTORS TO IMPROVE EFFICIENCY OF DRUG SELECTION

26.5.1 NOVEL SEQUENCES AND DELIVERY VECTORS

Almost all coding eukaryotic mRNA molecules are monocistronic. Initiation of translation of eukaryotic mRNA is mediated

by a cap-binding protein that recognizes a methylated guanosine cap at the 5' terminus of mRNA. However, some viral mRNA molecules transcribed in eukaryotic cells are polycistronic. They can use a cap-independent mechanism to initiate translation in the middle of mRNA molecules. For picornavirus, this cap-independent internal initiation of translation is mediated through a unique IRES within the mRNA molecule [264,265]. Identification of IRES sequences has led to the development of bicistronic vectors that allow coexpression of two different polypeptides from a single mRNA molecule in eukaryotic cells [148,150]. Using a bicistronic vector containing an IRES to coexpress a target gene and a selectable marker has several advantages. First, since two polypeptides are translated from the same mRNA molecule, the bicistronic vector guarantees coexpression of a selectable marker and a second protein. Secondly, bicistronic mRNA allows two polypeptides to be translated separately. Thus, this system does not compromise the correct intracellular trafficking of proteins directed to different subcellular compartments. In addition, using a bicistronic vector, expression of a target gene is proportionate to the expression of a selectable marker. Hence, expression of a target protein can be achieved quantitatively by applying selections of different stringencies.

In addition to IRESes derived from viruses, several IRES elements have been identified in human genes. Those IRESes play important roles in cell cycle-dependent or stress-response translation regulation (reviewed in Sachs [266]). In contrast to viral IRESes, human IRESes are shorter and are complementary to 18s rRNA (reviewed in Mauro and Edelman [267]). It has been found that a 9-nt sequence from the 5'-UTR of the mRNA encoding the Gtx homeodomain protein can function as an IRES. Ten linked copies of the 9-nt sequence are 3- to 63-fold more active than the classical EMCV IRES in all 11 cell lines tested [268]. Similarly, an IRES isolated from the human EIF 4G gene also exhibits 100-fold more IRES activity than EMCV IRES in four different cell lines [269]. In addition to higher efficiency and smaller size, translation from a human IRES can be regulated by cellular events [269], which may be advantageous for certain cancer gene therapies.

Another approach to the use of *ABCBI*-based bicistronic vectors is to develop "suicide" vectors for cancer gene therapy. Using *ABCBI* to protect bone marrow cells from cytotoxic drugs represents a promising approach to improve cancer chemotherapy. However, contaminating cancer cells may be inadvertently transduced with *ABCBI*, or transduced bone marrow cells may accidentally develop new tumors. In those cases, overexpression of P-gp could cause multidrug resistance in inadvertently transduced tumor cells that contaminate bone marrow, or in any transduced cells that later become malignant. A bicistronic "suicide" vector developed by the authors links P-gp expression with herpes simplex virus thymidine kinase (TK) expression [270,271]. Thus the cells containing this vector can be eliminated through ganciclovir treatment.

Using the multidrug resistance gene, Metz et al. [272] showed that retroviral vectors derived from Harvey viruses can be substantially shortened without reduction of gene

transfer efficiency, thereby increasing the maximum size of the packaged gene of interest. By systematic analysis of the U3-region of various 5'-LTR, Baum et al. [273] optimized *ABCBI* transfer to hematopoietic cells. Notably, transfer to immature hematopoietic progenitor cells, which are generally difficult to transduce, was improved [274]. Subsequent improvements of posttranscriptional processing led to a vector that reliably ensured *ABCBI* expression and drug efflux in human hematopoietic cells following an *in vivo* passage in immunodeficient mice [217]. Other vector systems used for chemoresistance gene transfer to hematopoietic cells include AAV vectors [165], liposomes [256], and new nanosystems (see Sections 26.3 and 26.4).

New vector constructs increase the efficiency of gene transfer to hematopoietic cells but do not necessarily ensure gene expression for sustained periods. A major obstacle to long-term gene expression is the limited lifespan of some transduced cell clones. Since only hematopoietic stem cells have the capability of self-renewal, the lifespan of progeny generated by more differentiated progenitor cells is limited. Berger et al. [275] have shown that expansion of cells with cytokines, particularly with interleukin-3 (IL-3), reduces the frequency of long-term culture-initiating cells (LTC-IC), which correlated with reduction of Rhodamine-123 efflux from immature progenitor cells. In accord with these findings, Schiedlmeier et al. [276] reported that IL-3-stimulated hematopoietic cells engrafted more poorly than cells grown in the presence of other growth factor combinations. Both studies resulted in efficient retroviral *ABCBI* transfer to primitive human progenitor/stem cells.

Alternatively, a dominant-positive selectable marker gene can be coexpressed with a negative selectable marker such as thymidine kinase from Herpes simplex virus (HSV-TK) [270,271]. The latter approach allows selective elimination of transduced cells. Such an approach may increase the safety of gene transfer if cancer cells contaminating hematopoietic cell preparations are inadvertently rendered drug-resistant, or if transduced cells become malignant [71,277]. Selective killing of *ABCBI*-HSV-TK transduced cells *in vivo* has been demonstrated [271]. TK may not only facilitate selective killing of cancer cells but instead increase the efficacy of certain selectable marker genes. A bicistronic vector in which TK was combined with DHFR displayed enhanced resistance as compared to a construct that contained a neomycin phosphotransferase instead of TK [278].

To increase the safety of gene therapy of cancer, drug resistance genes may be combined with cDNAs that specifically eliminate cancer cells. This has been demonstrated for chronic myeloid leukemia (CML), which is characterized by a specific molecular marker, the BCR/ABL gene fusion. A vector has been constructed that combined a MTX-resistant DHFR with an antiBCR/ABL antisense sequence [279]. Transfer of this vector to CML cells led to the restoration of normal cellular function of BCR/ABL cDNA + cells due to reduced levels of transcripts while conferring drug resistance.

26.5.2 *ABCBI* MUTATIONS AND SNP STUDIES LEAD TO IMPROVED DRUG TREATMENT EFFICACY

One of the hallmark characteristics of the multidrug transporter is its extremely broad substrate specificity. Over the past several years, the identification of specific domains and amino acid residues involved in substrate recognition has contributed to our present understanding of the mechanism of action of P-gp. The major sites of interaction have been shown to reside in TM domains 5 and 6 in the N-terminal half of the protein and in TMs 11 and 12 in the C-terminal half and the loops that conjoin them [280–284]. For the purposes of chemoprotection, the design of a P-gp that has increased resistance to chemotherapeutic agents compared to endogenous P-gp and/or decreased sensitivity to inhibitors would be most useful because increased doses of the agent could be administered without harming the bone marrow cells expressing the exogenous P-gp molecule, and naturally occurring resistance of cancer cells could be reversed while still allowing protection of bone marrow by transfected P-gp. This increased resistance and decreased sensitivity to inhibitors can be achieved by generating *ABCBI*-mutant transporters.

Mutations in TM domains of P-gps from both rodents and humans have demonstrated significant alterations in substrate specificity [8,285,286]. An F338A mutation in hamster P-gp enhances resistance to vincristine, colchicine, and daunorubicin but has little impact on resistance to actinomycin D [287,288]. An F339P mutation in the same molecule only increases actinomycin D resistance. However, the double F338A/F339P mutant demonstrates an increased level of resistance to actinomycin D and vincristine but a lowered level of resistance to colchicine and daunorubicin [287,288]. Of these mutants, the F338A may prove most useful because it confers increased resistance to a wider range of chemotherapeutic agents. In human P-gp, however, a homologous mutation at F335 confers greater resistance to colchicine and doxorubicin but causes a severe reduction in resistance to vinblastine and actinomycin D [289,290]. Additionally, cells expressing a Val > Ala mutation at position 338 also exhibit preferential resistance to colchicine and doxorubicin but are severely impaired for vinblastine [290]. Resistance to actinomycin D, however, is unaffected. Mutation of proline 223 to alanine in the fourth TM segment of human P-gp decreased the affinity for colchicine, whereas the affinity for vinblastine remained unchanged [289]. Alanine scanning of TM 11 in mouse P-gp encoded by *mdr1a* revealed that two mutants, M944A and F940A, show an increase in resistance to doxorubicin and colchicine while maintaining wild-type levels of resistance to vinblastine and actinomycin D [291]. For certain treatment protocols, it is conceivable that increased resistance to certain agents would be desirable, and the reduction in levels of resistance to other compounds would not be problematic, especially if a well-defined chemotherapy regimen was being employed.

Although the majority of residues that increase resistance to various chemotherapeutic agents reside in the TM domains,

a number of residues in the putative cytoplasmic loops also have been implicated in defining drug resistance profiles for cytotoxic drugs. The best characterized of these mutations is the G185 V mutant that confers an increased resistance to colchicine and etoposide but decreased resistance to actinomycin D, vinblastine, doxorubicin, vincristine, and taxol [292–295]. Interestingly, and perhaps relevant clinically, when this mutation is made in conjunction with an Asn > Ser mutation at residue 183, increased resistance to actinomycin D, vinblastine, and doxorubicin is achieved without loss of increase in colchicine resistance [293]. Mutations of Gly-141, 187, 288, 812, or 830 to Val in human P-gp increase the relative resistance of NIH3T3 cells to colchicine and doxorubicin but do not alter resistance to vinblastine [296]. Only the mutations at positions 187, 288, and 830 confer decreased resistance to actinomycin D to cells in culture.

Due to its broad substrate specificity, P-gp not only interacts with chemotherapeutic compounds but also with reversing agents and inhibitors. In combination chemotherapies, reversing agents increase the efficacy of cytotoxic agents in *ABCBI*-expressing cancers. Two of the most potent reversing agents currently in use or in clinical trials are cyclosporin A and its nonimmunosuppressive analog PSC833. Recently, a number of mutants have been described that affect sensitivity to these agents. Cells expressing a human P-gp containing a deletion at Phe335 or Phe334 are substantially resistant to cyclosporin A and PSC-833 [297]. A similar phenotype has been observed for a transporter containing five mutations in the region including TM 5 and TM 6, namely Ile299Met, Thr319Ser, Leu322Ile, Gly324Lys, and Ser351Asn [298] (see Figure 26.1). Additionally, in hamster P-gp, the substitution of an alanine at position 339 with proline results in a transporter that confers lowered sensitivity to cyclosporin A [288]. From these studies, it appears that TM 6 plays an important role in the recognition of cyclosporin A and its analogs. The decreased sensitivity to these reversing agents observed in cells expressing the TM 6 mutations could help protect bone marrow stem cells transduced with the mutant *ABCBI* gene from the toxic effects of chemotherapy given with reversing agents to sensitize *ABCBI*-expressing tumors.

The *cis*- and *trans*-isomers of flupentixol, a dopamine receptor antagonist, have also been shown to inhibit drug transport and reverse drug resistance mediated by P-gp [299,300]. The substitution of a single phenylalanine residue with alanine (F983A) in TM 12 affects inhibition of P-gp-mediated drug transport by both isomers of flupentixol [301–303]. Both isomers were found to be less effective at reversing P-gp-mediated drug transport of daunorubicin and bisantrene. However, the inhibitory effects of other reversing agents such as cyclosporin A were not affected. The reduced sensitivity of the F983A mutant to this compound coupled to the apparent lack of clinical toxicity of (*trans*)-flupentixol [299], suggests that this mutant may be useful in combining *ABCBI* gene therapy with chemotherapy including *trans*-flupentixol as a chemosensitizer. This approach, in theory, should allow for effective treatment at lower doses of chemotherapeutic agents while maintaining bone marrow protection.

The assembly of gene delivery vectors that incorporate the *ABCBI* gene as a selectable marker should take into consideration common polymorphisms along the gene that are known to alter P-gp expression or function. This knowledge is of great importance when one attempts to create a P-gp molecule that enables high resistance or sensitivity to MDR1 substrates. Different single-nucleotide polymorphisms (SNPs) are linked to drug efficacy and disease susceptibility.

Five nonsynonymous SNPs in positions N21D, F103L, S400N, A893S, and A998T showed no differences in P-gp expression and function *in vitro* when compared to wild type [304]. In contrast, three SNPs in positions 12/C1236T, 21/G2677T, and 26/C3435T, frequently appearing in various populations, might have clinical implications. Although no differences in mRNA or protein levels are observed in transient infection–transfection studies, there is evidence that this haplotype is associated with a conformational change that results in altered substrate and inhibitor recognition. The haplotype protein has been shown to be relatively resistant to the inhibitory effects of cyclosporin A and verapamil. This is of particular interest, since two of these three polymorphisms are synonymous and do not change the amino acid sequence. The mechanism of this resistance appears to be altered protein conformation resulting from a change in the kinetics of translation of the polymorphic P-gp [305]. In lymphoblastoid cell lines derived from HIV positive Japanese patients, higher concentrations of nelfinavir (protease inhibitor, PI) were found in individuals with the T/T genotype in location 3435, when compared to the C/C genotype [306]. This suggests higher P-gp expression for the C wild-type allele. Furthermore, this SNP is associated with a predisposition to refractory Crohn's disease and ulcerative colitis and to a reduction in the risk of developing Parkinson's disease [307]. Another common SNP influencing P-gp expression is in exon 21, 2677G > T. This SNP, much like the former, has been correlated with a greater risk for resistance to chemotherapy [308]. It has also been linked to tacrolimus-induced neurotoxicity in Japanese liver transplant patients [309]. Moreover, chemotherapy efficiency in acute myeloid leukemia patients has been associated with this SNP, i.e., homozygous patients (2677GG/TT) exhibit a worse prognosis than heterozygous patients [310]. Similarly, clinical implications have been reported for the SNP at location 12/1236C > T. This conformation has been linked to a greater export of protease inhibitors in the treatment of HIV and to CD4 cell count recovery during PI treatment [306]. These studies suggest that one should take into consideration possible SNP-genotype-phenotype correlations when constructing vectors carrying the *ABCBI* gene as a selectable marker.

26.6 CONCLUSIONS AND FUTURE PROSPECTS

We have argued in this review that drug-selectable marker genes may be helpful for gene therapy in two ways: first, to protect bone marrow progenitor cells (and other sensitive cells) from the cytotoxicity of anticancer drugs, thereby allowing safe chemotherapeutic treatment at reduced risk of severe side effects, and second, to enrich the expression of otherwise

non selectable genes in drug-sensitive cells to overcome low or unstable gene expression *in vivo*. Given the current instability of expression of genes from existing vectors, especially episomal vectors, such selectable markers may be an essential component of gene therapy protocols. The variety of selective markers with different drug resistance profiles that are now available make it possible for gene therapy to be used to overcome myelotoxicity in cancer chemotherapy.

We are still in the early stages of vector development, and until transduction efficiencies into human tissues such as bone marrow are improved and shown to be safe, long-term human gene therapy will not be feasible. The combination of more efficient gene transfer, targeted vector systems and effective, relatively nontoxic selection systems to maintain gene expression may make long-term correction of human genetic defects feasible and safe.

Finally, a new era for drug/gene delivery has arrived with the development of nanotechnology. Nanoparticles could soon replace viral systems for gene delivery and circumvent some of the present difficulties involved in gene therapy. Although further investigation is required to study the potential toxicity of nanoparticles, this novel technology has the potential to revolutionize medicine and especially, gene therapy. Moreover, the analysis of SNPs or engineered mutants, coupled with our knowledge of the current set of anticancer and reversing agents, offers an opportunity to begin designing novel and promising vectors.

27.1 INTRODUCTION

Humans have been fascinated by the possibility of biological regeneration since ancient times. The ancient Greeks may have known something about it, as they named the liver, one of the few organs that has the capacity to regenerate, *hēpar* after the Greek word for “repairable.” And this is evident, of course, in the famous myth of Prometheus, who was forever condemned to have his liver pecked out by an eagle, only for it to regenerate by the next day [1].

We can see evidence all around us to suggest that other organisms can undergo substantial regeneration; for example, if the limbs of amphibians such as salamanders and newts are amputated, they will simply grow new ones. We too can regenerate—most parts of our bodies can heal and regenerate to a certain degree, but not as spectacularly as we might hope. For this reason, natural philosophers, physicians, and more recently, scientists have tried to understand how the body heals, how they can encourage it to heal, and how we may devise new ways of making substitute body parts.

Transplantation is one of the more familiar ways to achieving this and there are sporadic reports of transplantation throughout history, some undoubtedly mythical, but others which are bona fide. For example, an Italian surgeon, Tagliacozzi, was performing autografts in the sixteenth century [2]. But it was not until just over 100 years ago that organ transplantation was pioneered by the French Nobel Prize winning surgeon, Alexis Carrel, who took lessons from a seamstress in order to perfect his work. Problems with rejection, however, meant that it was not until 1954 that the first successful organ transplant was performed [3]. In the interim, transplantation has become a routine and successful procedure for the replacement of many defective tissue and organs. Its success now has almost become a burden: there simply are not enough replacement body parts to go round.

In addition to transplantation, surgeons have investigated synthetic materials as potential replacement body parts. For example, a group in Brazil recently showed that the ancient Incas used gold plates to repair skull defects [4]. Many medical implants have been developed in more modern times, such as artificial heart valves and stents, cardiac pacemakers, and artificial joints. Such developments have brought a substantial improvement in the quality of life for many, but this success is tempered by the often limited lifespan of the implants.

So, to improve on these developments, a new area of research has emerged in recent years—tissue engineering—which seeks to “apply the principles of engineering and life sciences toward the development of biological substitutes for the repair or regeneration of tissue or organ functions” [5]. In other words, tissue engineers are faced with the challenge of making tissues and organs from scratch, using cells, scaffolds, and matrices as building materials. This approach brings modern scientists and engineers from many disciplines together. For example, material scientists must design novel, biocompatible scaffolds, on which biologists are faced with growing cells, and eventually tissues, that can function in the intended manner. Increasingly, biologists are investigating stem cells. These cells have the potential to “self-renew” or to differentiate into more than one cell type, like those cells that give rise new limbs in salamanders. The recent isolation of embryonic stem cells (ESCs) from early human embryos [6] has suggested tantalizingly that we may be able to make any cell type for therapeutic purposes since these cells ultimately develop naturally into all of the cells and tissues found in the adult.

Here we will review the need for cell therapy and tissue engineering, how cells, and in particular ESCs, can be used in cell therapy, and we will discuss some of the materials and scaffolds that may be combined with these cells to create replacement body parts.

27.2 WHY IS REGENERATIVE MEDICINE NEEDED?

Tissue engineering and cell therapy aims to provide therapies for any disease in which a tissue or organ is lost and so its remit covers a wide range of degenerative diseases. The need for tissue engineering strategies is becoming especially

marked in the developed world, where an ageing population means that tissues and organs become worn out and need replacing to ensure quality of life. Similarly lifestyles, which increase the risk of other diseases such as heart disease and diabetes, are also contributing to burdens on health services, which increase the need for novel therapies.

27.2.1 NEURODEGENERATIVE DISEASES

Age is one of the foremost risk factors for neurodegenerative conditions. For example, more than 100,000 people in the United Kingdom suffer from Parkinson's disease, and this costs the National Health Service €1 billion annually [7]. This disease involves the loss of the cells of the substantia nigra of the brain, which secrete dopamine. Currently, this disease is treated with drugs that increase dopamine in the brain, but these drugs are not ideal, having often unpleasant side effects and benefits that decline with use [8]. The transplantation of cells from aborted fetuses has been used, but there are ethical questions concerning this procedure; effects are often variable and tissue is limited. Similarly, Huntington's disease, Alzheimer's disease, and stroke (the third highest killer in industrialized countries) [9] all result in significant neuronal death in the brain, which could be partially rectified by cell transplantation. And, of course, spinal cord injuries are particularly debilitating and are usually irreversible, causing lifelong paralysis. Axons do have the capacity to regenerate, but are prevented from doing so by scarring at the injury site [10]. Cell transplantation may help to improve the prognosis of people with these injuries.

Another degenerative neural disease that is increasing as our societies age is age-related macular degeneration (ARMD). It is estimated that 30 million people worldwide suffer from this condition and it is the leading cause of blindness in people over 60 in the United States [11]. This disease is caused by the death of the photoreceptors in the retina due to a decrease in blood supply, but there is interest in using cell transplantation to help correct these diseases, although research is at an early stage.

27.2.2 CARDIOVASCULAR DISEASE

Cardiovascular disease causes 40% of all deaths in the United States each year [12]. Many treatments, including pharmacological, lifestyle, and surgical, are available for coronary heart disease, but as yet there is no treatment other than transplantation that can cause repair of damaged heart muscle. The survival of patients aged 45 years and over following myocardial infarction was only around 60% in the United Kingdom when measured in 2005 [13], although the number is declining slightly. Alternatives to transplant are being considered, including xenotransplantation and artificial mechanical hearts [14], but new treatments that can repair or replace damaged tissue in the heart are desperately needed.

27.2.3 DIABETES

A report in 1997 estimated that there were over 120 million diabetic people worldwide and predicted that this would

increase to 220 million before the year 2010 [15]. The increased incidence of diabetes is especially marked in the developing world, with obesity and decreased physical activity being high risk factors for the development of type 2 diabetes. Aside from the poorer health and quality of life that diabetic people suffer, the economic cost for society is huge. In most countries, more than 3% of the annual health budget is spent on diabetes, of which around 75% is accounted for by the associated long-term complications [16]. Studies in the United Kingdom forecast significant increases in these costs due to the aging population [17]. As the incidence of diabetes increases, so do the associated diseases that it causes. For example, end-stage renal disease therapy cost \$25 billion in the United States in 2002. Cell therapies that replace pancreatic β cells in type 1 diabetes and augment their effect in type 2 diabetes would lighten the economical and social burden considerably.

27.2.4 MUSCULOSKELETAL DISEASE

Although bone has a remarkable capacity to heal itself, disease or injury often results in severe damage that must be corrected surgically. Autologous grafting is considered the “gold standard” treatment, but it is not ideal: these treatments can cause pain and tissue damage at the donor site [18]. Allogenic grafts are also used, but are from cadavers. This brings the risk of poor quality or necrotic tissue, which may carry infectious agents [19]. Artificial joint replacements have had great success in the treatment of arthritis and joint disease and injury over the past few decades, and currently nearly 500,000 knee and hip replacements take place in the United States each year [20]. But these implants have a limited lifespan, which is a particular problem in the treatment of young patients. New treatments that replace damaged cartilage and bone are urgently required.

27.2.5 OTHER DEGENERATIVE DISEASES

Lung and liver diseases are two other prominent diseases that may benefit from stem cells and tissue engineering. It is estimated that one in seven people in the United Kingdom are affected by lung disease, and for many chronic conditions, transplantation is the only eventual cure. Similarly, although the liver has a substantial capacity for self-repair, in many cases, such as in cirrhosis and hepatitis, liver tissue must be replaced to ensure survival.

27.3 CELL SOURCES

Cell therapies and tissue engineering, which aim to replace cells that are lost in the diseases described above, obviously require a source of transplantable cells. In the ideal situation, the relevant cells would be isolated from the patient, grown in culture to a volume sufficient to correct the disease, and implanted back into the patient. But in practice, these cells may be reduced or absent, difficult to isolate, or difficult to grow or maintain in culture. In addition, most somatic cells in

an organism are terminally differentiated, which means that they cannot divide further. Others, such as fibroblasts, may become senescent, which makes the growth of sufficient number of cells with the correct phenotype difficult to achieve. For these reasons, and because many tissues like skin, liver, and bone have the capacity to heal and regenerate, researchers have speculated that stem cells or progenitor cells exist in the body that can contribute to new tissue formation after injury.

27.3.1 HEMATOPOIETIC STEM CELLS

Hematologists can probably lay claim to being the pioneers of stem cell research. During the 1950s and 1960s, cells were discovered in the bone marrow, which had the potential to generate a new immune system in mice in which the old one had been destroyed. These cellular entities were designated hematopoietic stem cells (HSCs) [21], and shortly later, Mathé et al. showed that transplants of these cells could replace a cancerous blood system in humans and hence cure leukemia [22]. The precise identity of these cells has been somewhat elusive, and there has been a great deal of debate on how they are actually identified. For instance, it is not possible to culture a pure population of HSCs. But there is now some consensus on the pattern of surface markers that these powerful stem cells express.

27.3.2 MESENCHYMAL STEM CELLS

As with HSCs, there does not appear to be a consensus in the literature on what precisely constitutes a mesenchymal stem cell (MSC). In most instances, the term “marrow stromal cell” (which conveniently has the same initials) is a more accurate term. They were first noticed by Friedenstein et al., who saw that rare cells ($c0.001\%$) in bone marrow aspirates adhered to the culture substratum and formed colonies [23]. These cells were found to be highly proliferative and could be maintained in tissue culture for 20 to 40 passages before senescence. Like HSCs, these cells are multipotent and can differentiate readily into cells of the connective tissue such as osteoblasts, adipocytes, and chondrocytes [24] under the correct culture conditions. More recently, other groups [25,26] have shown that they can differentiate into many other lineages, not limited to mesoderm tissue. MSCs are intrinsically primary cell cultures, and are not clonal, raising the question that the observed differentiation might be because the initial cell population is mixed, containing cells at various stages of commitment. But a journal article published in 1999 [27] demonstrated, by isolating individual cells from MSC cultures, expanding them, and differentiating these new cell culture “strains” into three lineages, that at least some of these cells do have true multipotency. MSCs are hotly investigated cells in musculoskeletal tissue engineering since they can be isolated as autologous cells for tissue transplantation. But it is important to note that they do have limited proliferative potential (which decreases with age), and it might not be possible to expand enough cells for regenerating large tissue defects, as is often the case in this field of medicine.

27.3.3 TISSUE-SPECIFIC STEM CELLS

Stem cells are thought to exist in many other niches throughout the body apart from the bone marrow, but are perhaps best studied in the brain and the skin. Reynolds and Weiss [28] and Richards et al. [29] demonstrated in the 1990s that single cells from the brains of adult rodents could be grown in suspension culture as clusters of cells, which were named “neurospheres.” Neural stem cells (NSCs), as they became to be known, could be isolated from these neurospheres and selectively differentiated into the three main cells of the brain—neurons, glial cells (astrocytes), and oligodendrocytes (see Ref. [30] for an excellent review). More recently, it has been shown that NSCs can also differentiate into other cell types, for instance blood [31], and when they are combined with early embryos, they can contribute to the formation of an organism, subsequently being found in tissue such as kidney, heart, and liver [32]. NSCs may have an important role to play in the treatment of many neural diseases. Transplantation of fetal cells, which are in scarce supply, is known to improve the condition of people with Parkinson’s disease [33,34], and recently Redmond et al. have shown that undifferentiated NSCs can be effective in a primate model of Parkinson’s disease [35].

Skin also has a population of stem or progenitor cells and the molecular processes that govern the renewal and differentiation of these cells are well studied (see Ref. [36] for a review). Stem cells are also thought to occur in niches in other tissues in the body such as liver [37] and kidney [38], which act to maintain the population of functional, terminally differentiated cells in these tissues. These cells are rather different from HSCs and MSCs, however, in that they exist in small numbers *in vivo*, but cannot be isolated or expanded in large numbers, so their potential in regenerative medicine and tissue engineering is not yet clear.

27.3.4 EMBRYONIC STEM CELLS

ESCs have the potential to grow indefinitely and can differentiate into all cell types of the adult. They have had and continue to have widespread public appeal, probably because of the controversial way in which they are generated, but more importantly because of the significant potential that they have in medicine. They are derived from the preimplantation blastocyst, a ball of around 50 cells, which develops several days after conception in humans. The blastocyst is a spherical fluid-filled structure, composed of a layer of outer cells called the trophectoderm that goes on to form the placenta, and a ball of cells attached to the inner wall of this structure called the inner cell mass that goes on to form the embryo proper. It is these latter cells from which ESCs are derived. These cells have the advantage over other cell types of being truly pluripotent, i.e., they have the potential to develop into all three “germ layers” of tissues found in the adult organism. It is this property, which suggests that we may be able to derive any cell type from them, that interests biologists. The germ layers comprise the ectoderm, which goes on to form the neural tissue and the skin; the mesoderm, which gives rise to the

bones, blood, muscles, and other connective tissues; and the endoderm, which gives rise to the cells that line the gut as well as the internal organs, including liver, lungs, and pancreas (Figure 27.1).

ESC research has its origins in the rather obscure study of tumors called teratomas. These morbidly fascinating tumors occur predominantly in the germline tissues and may be comprised of a wide range of misplaced tissues such as teeth and hair. In the most bizarre cases, even more advanced tissue may be present, such as in fetaform teratoma, where highly developed structures such as rudimentary limbs sometimes develop [39]. Several groups found that cells from teratomas, which were named embryonal carcinoma (EC) cells, could be isolated and grown indefinitely in culture [40]. When these cells were then reintroduced into adult mice, further teratomas were generated and, most intriguingly, when introduced into mouse blastocysts, these cells could survive, differentiate, and eventually contribute to some of the tissues found in the adult mouse. Because it seemed possible to grow these cells in their undifferentiated state *in vitro*, the scientists working on them reasoned that it may be possible to isolate and expand cells from the early mouse embryo. And in 1981, Evans and Kaufman at Cambridge [41], and Martin [42], who had previously worked with Evans at Cambridge, reported the derivation and extended culture of pluripotent cell lines from mouse blastocysts. Most tellingly, three years later, Bradley et al. [43] demonstrated that when these cells were injected into mouse blastocysts, they could contribute to all of the tissue types present in the adult, including the germline. This last point was particularly important since this new technology meant that it became theoretically possible to make a mouse, albeit in the second generation, which was wholly derived from *in vitro* cultured cells. And this was the advance that led to transgenic mice: growing ESCs could be genetically manipulated *in vitro*, introduced into a mouse blastocyst, grown to adulthood, and mated to create heterozygous mice and eventually homozygous mice [44]. This approach has proved invaluable in many areas of research, particularly in identifying the functions of genes through “knockout” mice over the last 15–20 years.

There has also been a great deal of interest in the molecular mechanisms that keep a cell from differentiating. Initially, it was necessary to culture mouse ESCs either in a medium conditioned by EC cells or, like EC cells, on a cell layer derived from embryonic fibroblasts. The discovery of a molecule called leukemia inhibitory factor (LIF) by two groups in 1988 [45,46] paved the way for feeder-independent culture of ESCs, and this also led to further identification of the genes involved in maintenance of cells in the undifferentiated state, such as *Oct3/4* and *Nanog*. More recently, it has been found that ESCs can be grown in the absence of serum if bone morphogenic protein (BMP) is included in the growth medium [47]. Identification of the genes and molecular pathways involved in pluripotency led in 2006 to the genetic reprogramming of adult cells so that they are virtually indistinguishable from ESCs. In these studies, Yamanaka’s group showed that the retroviral introduction of only four genes, *Oct3/4*, *Sox2*,

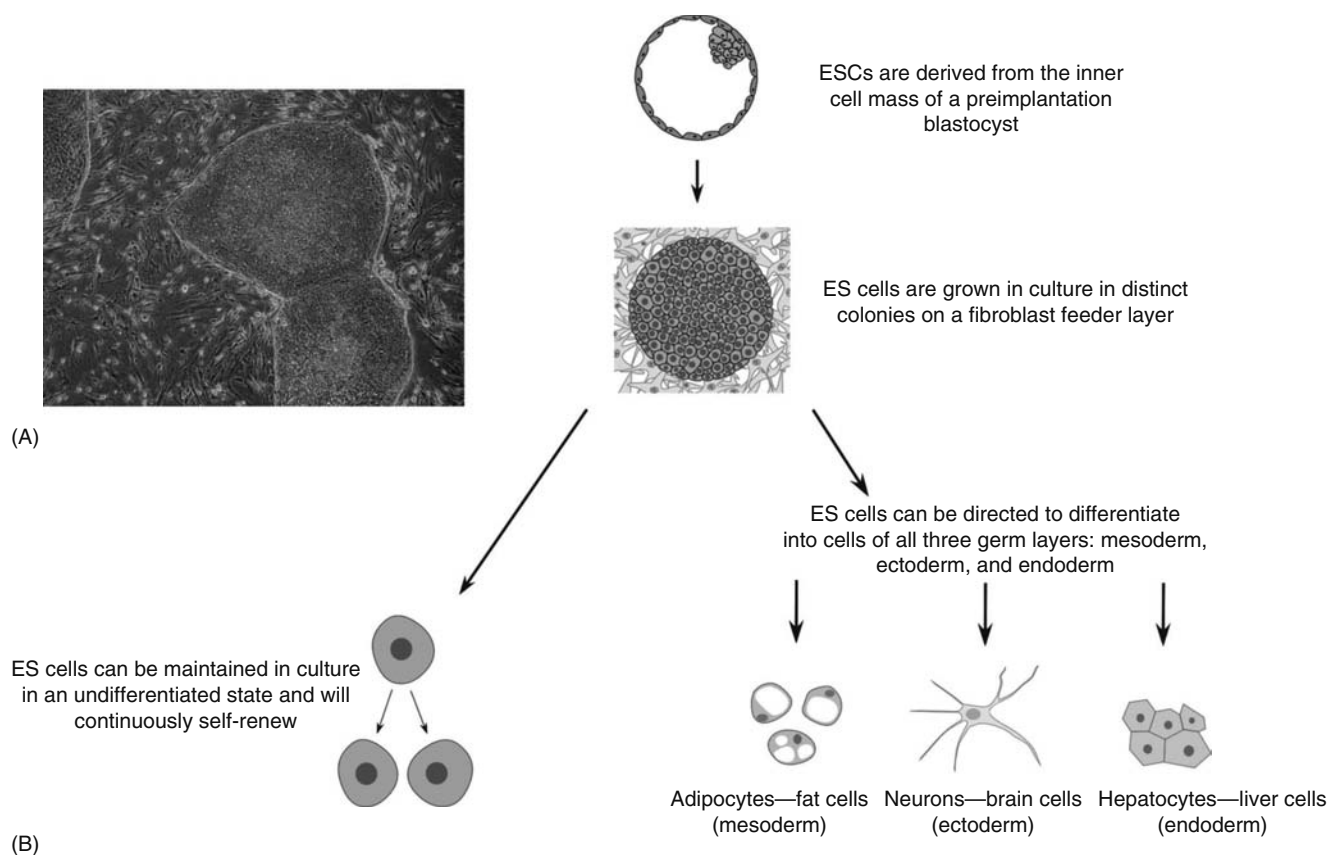

FIGURE 27.1 (A) Phase contrast microscope image of undifferentiated human ESCs (H1 cell line) grown on a layer of embryonic fibroblast feeder cells. (B) Schematic illustration of derivation, differentiation, and maintenance of ESCs. ESCs are able to self-renew or to differentiate into cells of all three mammalian germ layers.

c-Myc, and *Klf4* (albeit at multiple copy number), caused embryonic and adult fibroblasts to revert to an “induced pluripotent” state [48]. Initially, these cells could not form chimaeras in mice, but more recently this technique has been refined so that, remarkably, it now appears possible to make not only chimaeras, but also mice that are comprised wholly of cells that were, previously, ordinary fibroblasts growing in culture [49,50].

Probably due to the lack of available embryos, and also because of the intrinsic reticence of the cells themselves, it was not until 1998 that the first human ESCs were derived [6]. Like mouse ESCs, human ESCs can be grown in an undifferentiated state *in vitro* and, when implanted in an immunodeficient mouse, form teratomas comprised of all three germ layers. But there remain important differences between hESCs and mESCs. For instance, there are differences in the proteoglycan cell surface markers that they express and hESCs cannot be maintained in an undifferentiated state through the addition of LIF (interestingly LIF appears to be an evolutionary adaptation to allow mouse embryos to survive in the uterus when implantation is delayed by the presence of a still-suckling litter [51]). Instead hESCs can be maintained in an undifferentiated state with the addition of two other signaling molecules, activin and fibroblast growth factor (FGF) [52]. From a technical perspective, one of the most infuriating

aspects of hESC culture for scientist, or a business, working on them is that they propagate poorly as single cells and must be manually dissected rather than by trypsin addition. The reason for these differences has remained something of an enigma, though Brons et al. have recently shed some light on the matter [53]. They found that cells isolated from postimplantation mouse blastocysts (named “epiblast stem cells” [EpiSCs]) behaved similarly to hESCs, indicating that the mESCs that have been studied for the past 25 years may represent a developmentally earlier state than hESCs, and possibly that human development is more advanced at implantation. The study of how cells control differentiation is not only academically interesting, but also has great bearing on the real therapeutic applications that ESCs might have, the ability to differentiate them into functional, mature tissue for transplantation.

27.4 DIFFERENTIATION OF ESCs *IN VITRO*

As with derivation, the control of differentiation of ESCs owes much to work done in the 1970s on EC cells. Like with EC cells, differentiation can be induced by the culture of ESCs as cellular aggregates called “embryoid bodies” (EBs) in suspension on nonadherent substrata [54]. In this way, intercellular communication appears to spontaneously induce

differentiation in a way analogous to that occurring in the embryo in its natural environment. Initially in mESCs, an outer layer of endoderm develops in the EB, followed by an interior rim of ectoderm [55]. Later, mesodermal cells also begin to differentiate and when EBs are plated onto tissue culture plastic, cells with the properties of many different cells, including cardiomyocytes, neurons, and hepatocytes, begin to appear. But unlike in embryos, the tissues that form in EBs are disorganized and no polarity is established. The main aim of differentiating ESCs *in vitro* is to reduce this complexity, or at least to be able to control it predictably so that cells of the required type can be grown and isolated for their intended use.

In vivo, the process of development from a single cell to a mature organism is, of course, an enormously complicated process and is much better understood in simple model organisms than in mammals. In the nematode worm, *Caenorhabditis elegans*, Sulston and Horvitz [56] used light microscopy to painstakingly map the fate of every cell that arose through cell division. In this way, they were able to generate a “family tree” of all the 959 specialized cells that arose, and to begin to analyze the precise spatial and chemical cues that were required to generate a particular type of cell. The process is certainly much more complex in the mammal. Delineating the precise developmental path of every single cell may well prove impossible. Biologists have, however, used a variety of techniques to preferentially generate cell types of interest. These include culturing cells in a medium designed for the target cell type; growing the cells on a specific extracellular matrix (ECM); coculturing ESCs with another cell type; and introducing transcription factor or selection genes into cells to either promote differentiation or to enable cell selection.

27.4.1 ECTODERM TISSUES

Arguably, differentiation of ESCs into cell types of the ectodermal lineage, skin, and nerve tissue has had the most success. Ectodermal differentiation appears, in fact, to be the default differentiation pathway of ESCs [57]. In 1995, several groups [58,59] found that neuronal cell types, including glial cells and neurons, could be generated from EBs. This differentiation was induced by retinoic acid (RA), previously known to be an important signaling molecule in the central nervous system (CNS) [60]. Serum removal [61,62], coculture with stromal cells [63], and addition of growth factors such as basic FGF and epidermal growth factor [64], as well as incubation

with neuronal survival factors [65], were also found to increase the number of neuronal cells derived from ESCs. Furthermore, the complexity and ill-defined nature of EB-based differentiation have been circumvented by the development of more controlled monolayer differentiation protocols [66]. A genetic approach was also used, where an antibiotic selection marker was introduced under the control of the neuroepithelial-specific *Sox2* promoter. In this way, all cells that did not express this gene could be eliminated in culture, resulting in reasonably pure populations of neuronal cell types.

In these studies, all three of the main neural cell types, neurons, astrocytes, and oligodendrocytes, were found in the expanded populations. More recent efforts have sought to more precisely control which of these cell types are isolated. Kim et al. [67] engineered an ESC line that over expressed *Nurr1* and showed that midbrain dopaminergic neurons, the type of cells that are lost in Parkinson's disease, could be selectively generated. And Wichterle et al. [68] used an ESC line with enhanced green fluorescence protein (EGFP) under the control of the *HB9* promoter to isolate cells with the characteristics of motor neurons.

Similar approaches have been used by Smith's group to find genes that are implicated in neuronal differentiation from ES cells. For instance, by producing a knock-in ESC line with GFP under the control of the *Sox1* promoter, and using it to screen many possible genes for neuroinduction, these authors demonstrated that inhibition of the Wnt signaling pathway could promote neural differentiation [69].

In parallel with these developments on mESCs, many groups have also shown that human ESCs have the potential to differentiate into neuronal cells and that hESC derived neural progenitors can be selectively differentiated into the three main neural cell types [70]. As with mESCs, coculture, combinations of growth factors, and ECM proteins can all increase NSC differentiation, and that, like with NSCs, human ESC-derived neural progenitors could be maintained in culture as neurospheres [71].

Other ectodermal cell types have also been generated in culture. Bagutti et al. [72] demonstrated that keratinocytes could be generated from mESCs and later, Green et al. [73] have shown cytokeratin-expressing cells can be generated from human ESCs. In another study, Coraux et al. [74] have shown that, by culturing ESCs on a matrix derived from a skin cell line, a tissue with the complexity and organization of embryonic skin can be generated (Figure 27.2).

FIGURE 27.2 (See color insert following blank page 206.) Hematoxylin/eosin staining of sections of 17.5-day-old mouse embryo skin (left) and of tissue formed from ESCs grown on a matrix secreted by a skin cell line (right). 27.4.2 MESODERM TISSUES

Similar principles to induce differentiation have been used for cells of the mesoderm lineage, which include connective tissues such as cartilage and bone, as well as muscle and blood. For example, by initially aggregating ESCs as EBs, plating them, and then growing them in a medium containing β -glycerophosphate, ascorbate, and dexamethasone (usually used for the osteogenic differentiation of cell lines), Buttery et al. [75] and Bielby et al. [76] have demonstrated that ESCs form calcified deposits on the cell culture substratum called bone nodules, and preferentially express bone-specific genes (Figure 27.3). Others have investigated further the means by which this happens, finding that vitamin D [77] and compactin, [78] as well as BMPs [79,80] and coculture with a liver carcinoma cell line [81] can regulate bone formation. In similar ways, others have demonstrated formation of chondrocytes, adipocytes, and muscle.

There is a glut of papers in the literature on cardiac differentiation, probably because cell therapies for cardiac disease are considered to be urgently needed. Cardiomyocytes commonly develop in EBs in the presence of serum and can be easily identified by the fact that they beat. They have also been characterized and express many of the proteins found in adult cardiomyocytes, such as sarcomeric proteins [82], and they are similar electrophysiologically [82,83]. These cells have been isolated, like in neural cells, by modifying them to express either antibiotic resistance genes or fluorescent proteins under the transcription control of cardiac-specific promoters. For example, Klug et al. [84] engineered an ESC line to express an α -MHC-dependent neomycin gene, while Muller et al. [85] engineered GFP under the control of the myosin light chain 2v promoter. Such fluorescent cells could then be isolated by

FIGURE 27.3 (See color insert following blank page 206.) Phase contrast and fluorescence composite image of murine ESCs grown for 21 days in the presence of osteogenic supplements (β -glycerophosphate, ascorbate, and dexamethasone). Bone nodules are indicated by areas that stain positively for alizarin red S, which fluoresces when bound to calcified ECM.

fluorescence-activated cell sorting (FACS). The factors that induce cardiomyogenesis have also been widely studied. BMP2 and FGF2 [86] and ascorbate [87] appear to promote cardiomyocyte differentiation. Mummery's group has shown that coculture with a visceral endoderm cell line, END-2, can promote cardiomyogenic differentiation [88,89]. As with mESCs, human ESCs also differentiate into cardiomyocytes under similar conditions, although these cells appear to have properties of fetal cells rather than adult cells [90].

Differentiation to cells of the blood system has also been well studied, mostly because ESCs offer an ideal model system to investigate development of the blood system, but also because it was suspected ESCs might offer an unlimited source of HSCs for transplants. Keller has written an extensive review on this subject [91]. As early as 1985, Doetschman et al. noticed that red hemoglobin-containing cells were evident in EBs [55]. Later, Keller and colleagues showed that under the correct culture conditions, the majority of ESCs could be induced to express Flk-1, a marker of vascular and hematopoietic cells [92]. Furthermore, specific cell types of the blood are evident in hematopoiesis, such as erythrocytes, macrophages, and neutrophils. Despite this, however, the isolation of hematopoietic stem cells from ESCs (which have the critical property of ability to reconstitute the immune system of an irradiated animal) has yet to be achieved reproducibly (see Ref. [91] for an exhaustive review).

The early events that control mesoderm development are only beginning to be understood, but by investigating the effects of various growth factors in the absence of serum, researchers are starting to precisely define the series of steps that occur. It is especially important to determine precisely when and what changes in gene expression occur when differentiating ESCs become committed to each of the three germ layers. This process occurs at "gastrulation," a series of organizing events in which the specification and position of cells becomes determined. At this point in development, the cells that are committed to the mesoderm and the endoderm begin to express a characteristic series of genes. In an attempt to mark cells committed to the mesoderm lineage, Fehling et al. made an ESC line expressing GFP under the control of the *Brachyury* gene, thought to be one of the earliest markers of mesoderm [93]. They were then able to demonstrate that the hemangioblast, the putative precursor of both the blood cells and endothelial cells, could be derived from *Brachyury*⁺ cells in the primitive streak. Surprisingly, these *Brachyury*⁺ cells were also found to have the potential to form endoderm, with a greater capacity when activin was included in the differentiation media and when serum was omitted [94]. In fact, serum, which is an undefined mixture of growth factors and other chemicals, was found to inhibit endoderm formation, a point that illustrated the problems with using ill-defined factors in a supposedly reductionist approach of understanding a biological process. Subsequently, the *Brachyury*-GFP cell line has been further modified to include the CD4 surface receptor protein under the control of the *Foxa2* gene, which is thought to be an early endoderm marker [95]. This has allowed Gadue et al. to establish signaling pathways and positional differences

involved in the very early development of mesoderm and endoderm by isolating these cells by FACS.

27.4.3 ENDODERM TISSUES

The differentiation of ESCs to the endodermal lineage has mainly focused on generating hepatocytes and pancreatic β cells for therapies treating liver disease and type 1 diabetes, respectively. Again, these tissues were known to form in teratomas when ESCs were introduced into severe combined immunodeficient (SCID) mice, and therefore researchers used similar protocols to those used for mesoderm and ectoderm. An early protocol for generating pancreatic beta cells involved a complex five-step protocol in which ESCs were grown for four days as EBs, transferred to adherent culture in the absence of serum, then following the expression of nestin in these cells, FGF was added. Its removal several days later resulted in the onset on pancreatic differentiation [96]. But since this paper was published, doubt has been cast on the conclusions that were drawn; another group demonstrated that the insulin-positive cells in this experiment may, in fact, have been absorbed by the cells in culture [97]. Drug resistance genes inserted under the control of the insulin promoter have been used to select cells that have subsequently been shown to have some of the properties of pancreatic β cells, such as glucose-dependent insulin release [98]. Other genes have also been investigated: the transcription factors *Pax4* [99] or *Pdx1* [100] are necessary for the development of β cells. Overexpression of these genes has been investigated as a mechanism to create β cells from ESCs with some moderate success [101,102]. When Micallef et al. [103] attempted to select *Pdx1*+ cells from cultures of ESCs using GFP as a marker, they found that these cells did indeed appear to be of the endoderm lineage, but did not express any other markers of pancreatic maturation. More recently, Jiang et al. [104] have employed a serum-free differentiation protocol to generate cultures of cells of which 15% express C-peptide, a β -cell-specific marker, which must be expressed endogenously and cannot be taken up from the growth medium.

Both liver and lung cells have also been shown to develop from ESCs. Hamazaki et al. [105] showed early and late hepatic markers in differentiating ESCs and subsequently the differentiation of liver cells to bile duct epithelial and oval cells has been demonstrated. Recently Soto-Gutierrez et al. [106] demonstrated that these ESC-derived liver cells could metabolize chemicals such as ammonia at a rate two-thirds that of primary liver cells. Alveolar cells of the lung have also been derived from ESCs by selecting cells that express GFP under the control of the *Spc* gene [107,108].

27.5 ESC THERAPIES

ESCs have several advantages that make them attractive as potential cellular therapies. As previously noted, they can divide indefinitely, so are potentially unlimited as a tissue source, and have been shown to differentiate into many different tissues. But like any transplanted cell source, ESCs would

first need to be tissue-matched to a potential donor to avoid the problems of rejection. Because ESC cells are derived from embryos, this raised the possibility that cloned ESC could be derived by somatic cell nuclear transfer (SCNT). This involves introducing DNA from an adult cell into an ovum from which the host DNA has been removed and growing the embryo to blastocyst stage. ESCs can then be derived from the inner cell mass and, because the DNA is from an adult cell, these stem cell lines might be used to treat the person from whom the DNA was originally isolated. Hwang et al. reported the derivation of such lines in 2004 and 2005 [109,110] to worldwide media attention, but this work was later found to be fraudulent. This approach remains viable, however, but the likely costs and time involved in such a procedure are likely to be too prohibitive for SCNT to be used as routine treatments. Others have suggested that ESCs might be genetically engineered to reduce their immunogenicity [111] or ESC-derived white blood cells might be derived and implanted prior to a transplant to modulate any immune response [112]. More realistically, however, ESCs, like blood cells, might be banked and could then be selected based on their human leukocyte antigen (HLA) type. An interesting recent study by Taylor et al. [113] has shown that a bank of only 150 ESC lines, which is a realistic possibility in the light of the recent establishment of the U.K. stem cell bank, would provide an acceptable HLA match for around 80% of the population (Figure 27.4).

It is, however, something of an understatement to say that several safety issues and technical difficulties with ESCs need to be overcome before they can be used in a clinical setting. For instance, many researchers consider that the derivation and growth of ESCs in the presence of animal products, such as serum, feeder cells, and other reagents, is an obstacle to therapeutic use. For instance, one ESC line culture in serum was found to express a mouse-derived sialic acid [114]. This has been used as an argument to promote the further derivation of ESCs in a precisely defined, xeno-free environment [115]. Another problem with ESCs is their potential to form teratomas when implanted into animals. And, of course, any cell type derived from ESCs must be functional and able to do its job *in vivo*. For these reasons, there is a wealth of information in the literature on the implantation of ESC-derived cells into animal models of disease.

27.5.1 CARDIAC DISEASE

Many studies have investigated the effect of bone marrow transplantation on heart repair in humans. For example, Bittira et al. [116] have shown that MSCs can contribute to heart repair by homing to the site of injury. Because of safety issues, to date there have been no studies investigating the effect of ESC transplantation for heart disease. But there have been several animal studies. In 1996, Klug et al. [84] were able to select ESC-derived cardiomyocytes by fusion of the cardiac-specific α -MHC gene with a drug resistance gene. These cells were then implanted into mice, were able to integrate into the host tissue, and were able to survive for at least 8 weeks. Since this study, other groups have investigated ES transplantation

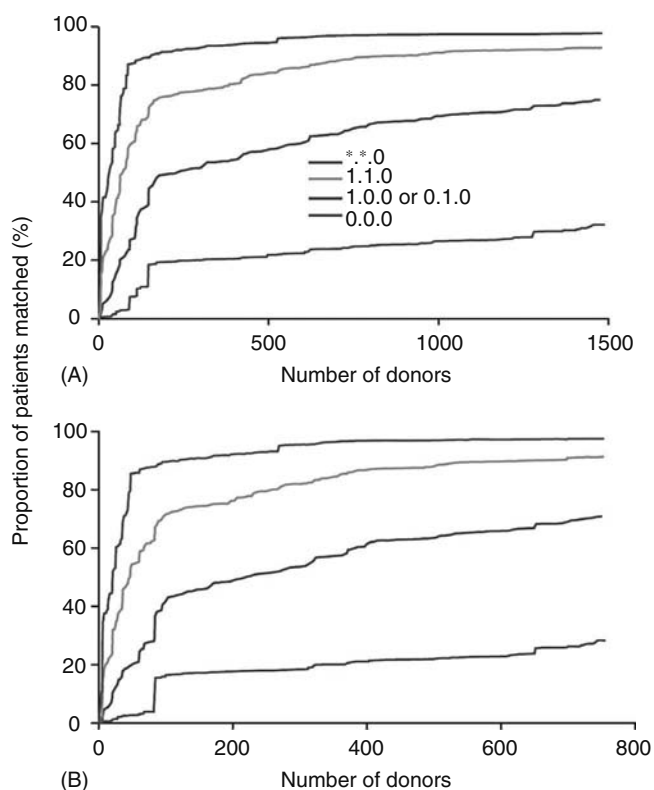

FIGURE 27.4 (See color insert following blank page 206.)

Graphs of estimates of how many ESC donors are required to provide different degrees of HLA matching in potential recipients. (0,0,0) indicates a zero HLA-A, HLA-B, and HLA-DR mismatch; (1,0,0 or 0,1,0) indicates a zero HLA-DR mismatch with no more than a single HLA-A or HLA-B mismatch; (1,1,0) indicates a zero HLA-DR mismatch with no more than a single HLA-A and a single HLA-B mismatch; and (**, 0) indicates a zero HLA-DR mismatch. (A) was obtained using data from 1500 consecutive cadaveric organ donors and (B) 760 consecutive blood-group-O cadaveric organ donors. (From Zhan, X., Dravid, G., Ye, Z., Hammond, H., Shablott, M., Gearhart, J., et al., *Lancet*, 364, 163, 2004. With permission.)

and have shown improvements in cardiac function. While most studies have investigated the effect of implanting cells differentiated *in vitro*, others have looked at the implantation of undifferentiated cells [117]. The expected outcome of this treatment would be the formation of a teratoma, but remarkably in these studies, the host environment appears to direct the cells to a cardiac phenotype. These findings are contested by others who have shown teratoma formation under similar conditions [118,119]. There has been significantly less work published on the implantation of human ESCs, although recently Laflamme et al. reported that a combination of cardiomyocytes enriched from ESCs and a cocktail of “survival” factors could restore heart function and remuscularize myocardial infarcts in mice [120].

27.5.2 TYPE 1 DIABETES

There have been several examples of the implantation ESC-derived β -cell-like cells into animal models of diabetes, such as mice treated with streptozotocin. In a report in 2000,

Soria et al. reported the correction of hyperglycemia in mice implanted with such cells [98]. This is a commonly used method of testing the functionality of β cells produced by many groups working on differentiation strategies. There has been some controversy in this area of research; some researchers suggest that the insulin-producing cells obtained in such experiments may be more closely related to nerve cells than to endocrine cells [121]. The most recent study at the time of writing claimed that euglycemia was restored in 30% of streptozotocin-treated mice implanted with ESC-derived β cells [104]. Until the characteristics of the “pancreatic” tissue produced from ESCs are better defined, the application of ESCs for clinical correction of type 1 diabetes remains a distant prospect.

27.5.3 MUSCULOSKELETAL DISEASE

There are few reports of the use of ESC-derived cells to correct disease models of musculoskeletal disease, and it is not yet clear whether ESCs could give rise to functional bone or cartilage tissue. It is important to bear in mind that, more so than in many other stem cell-based therapies, it is the functional properties of the tissue as a whole rather than the individual cells, which is of primary importance. This means that stem cell research into the generation of bone and cartilage is linked intrinsically to tissue engineering. Most stem cell-based research in this field has been concentrated on MSCs, which can differentiate into both osteoblasts and chondrocytes, and various studies have shown that a combination of MSCs and a suitable scaffold can rectify bone injuries in animals (for example, Ref. [122]). But MSCs do have their disadvantages, including limited replication potential especially in the elderly, and so the importance of ESCs cannot be understated, even if their application is still some time away yet. A demonstration that ESCs could be used to correct an animal model of bone or cartilage disease would be a significant step forward in this field.

27.5.4 NEURODEGENERATIVE DISEASE

Early studies by Brustle et al. [123,124] demonstrated that ESC-derived neural cells could form all three brain cell types in rat brains and that oligodendrocytes could form myelin sheaths around host neurons in an animal model of multiple sclerosis. In another study, Kim et al. [67] found that ESCs overexpressing the transcription factor *Nurr1* could cause a significant improvement in the condition of a rat model of Parkinson's disease. Several other studies have had similar findings, although there are still risks of tumor formation that should be taken into account before such transplants can be considered in people. More recently, Bühnemann et al. [125] have shown that ESC-derived neural cells can repopulate previously ischemic areas of rat brain (a model of stroke), with cell survival for 12 weeks and differentiation into cells expressing many neural markers, while in a similar study Yanagisawa et al. [126] have shown an improvement in the behavior of recipient rats. There have also been studies

investigating the implantation of ESCs for motor neurone disease and spinal cord injury. Lee et al. [127] showed that ESC-derived neurons could engraft successfully in chick embryos, and most importantly, project axons into peripheral host tissues a significant distance away from the area of engraftment. In a rat model of spinal injury, Deshpande et al. [128] showed that ESCs, engrafted at the site of damage, could send out axonal projections to muscle, partially restoring movement in these animals.

27.5.5 OTHER DISEASES

ESC-derived hepatocytes have also been shown to be able to contribute to host tissue following implantation into a host animal. Wang et al. [129] isolated fluorescent cells from cultures of ESCs expressing GFP under the control of the albumin gene promoter and showed engraftment in the injured liver, while Moriya et al. [130] showed an improvement in liver fibers in ESC-treated animals. In another study, an implanted bioartificial liver containing ESC-derived hepatocytes was shown to improve whole-animal liver function following a 90% hepatectomy [106]. Recently, Lane et al. [131] have injected pneumatocyte-enriched ESCs systemically into mouse models of lung disease and shown that these cells selectively engraft in the lungs when compared to other organs. This suggests that ESCs might be used as a cell source for such diseases as cystic fibrosis.

27.6 ESCs FOR SCREENING

ESCs are not only important for their application in cell therapy and tissue engineering, but also as a source of cells for testing for the toxicity of compounds produced in the pharmaceutical industry. Currently new drugs must be screened either using animal models that are expensive, which the governments in Europe are trying to limit for ethical and political reasons, or using human primary cell lines. Of particular interest are cardiac and liver cells lines; two of the main causes of failure in preclinical drug trials are from cardio- and hepatotoxicity. But these cells lines are often limited because of a lack of healthy donors and may have variations from batch to batch, which limit the accuracy of such tests. ESCs may be useful in such circumstances as they are unlimited in supply and culture protocols and testing procedures might be standardized (see Ref. [132] for a review). Several companies are focusing on deriving and differentiating human ESCs under defined conditions for toxicity testing; for example, Cellartis in Sweden is planning to sell cardiomyocytes for testing while Geron in the United States has produced hepatocytes. Another advantage that ESCs have is that they might intrinsically carry, or be made to carry, specific genetic disease. For example, Pickering et al. have derived an ESC line that carries a genetic lesion associated with cystic fibrosis [133]. Although technically challenging currently, there is no reason to suggest that in time, it will become easier to genetically engineer human ESCs, making it possible to study the effect of drugs on

many genetic lesions, which cause disease in people. Hwang's studies in the mid-2000s initially seemed to show it was possible to create ESCs that were clones of adult donors. This work was, of course, subsequently shown to be faked, but in theory, this technique remains possible. Experimentation on SCNT is limited by the supply of human eggs, so to circumvent this problem researchers in the United Kingdom asked for permission to create hybrid ESC lines, i.e., using animal eggs rather than human eggs. After some initial controversy and political posturing [134], this license was recently granted [135]. If successful, this may mean that ESC lines will be produced that carry a whole range of human diseases and that it will be possible to model the effect of drugs on these diseases.

27.7 SCAFFOLDS

In many cases, ESC therapies might be delivered by cell transplantation alone. For example, ESC-derived β cells or dopaminergic neurons could potentially be directly injected into a recipient for the treatment of type 1 diabetes or Parkinson's disease, respectively. Cell therapy may also benefit a host of other diseases where injected cells might engraft and improve function in damaged tissue such as heart, liver, and lung disease. Often the area of degeneration may require the transplant of a significant volume of tissue, including the diseases mentioned above, but particularly in musculoskeletal disease. In these cases, it may be necessary to generate a significant volume of ESC-derived tissue prior to implantation. Tissue engineering emerged as a discipline in the 1980s [5] in response to this need and is focused on developing implants that combine materials with a source of cells. Skin tissue engineering is an example of where this approach may provide a simple, reliable therapy, and it is today available commercially as a treatment for burns and ulcers (Dermagraft, Apligraf). In these examples, human fibroblasts, derived from neonate foreskin, are expanded *in vitro* and seeded onto a collagenous matrix, a simple cell "scaffold," which is then implanted in the recipient. Luckily, keratinocytes and fibroblasts lack MHC antigens and are therefore immunoprivileged, so rejection is minimized. Similarly, Atala et al. [136] recently generated functional, artificial bladders. In this case, biopsies of the patients' bladders were taken, cells were expanded on bladder-shaped collagen scaffolds, and the resulting constructs were implanted successfully back into the patients as autologous transplants.

Skin and bladder tissue engineering have the advantage of requiring the growth of relatively thin sheets of cells, which can be easily grown in conventional *in vitro* culture systems. But many applications may require replacement tissue that is much thicker and more complex, and so tissue engineers have begun to devise many ways of achieving this.

27.7.1 CONVENTIONAL SCAFFOLDS

Scaffolds must provide a suitable three-dimensional environment in which tissue can grow and develop. Historically,

biomedical implants were designed to be bioinert, but more recently for tissue engineering purposes, scaffolds are being designed that actively contribute to the development of a tissue, the so-called “bioactive” scaffolds. In some cases, scaffolds may even carry no cellular component; the structure and composition of the scaffolds are designed to be sufficient to encourage cellular in-growth and the formation of new tissue *in vivo* [137].

In cases where cells are added to scaffolds and grown before implantation, it is critical that cells throughout the depth of the scaffold have access to oxygen and nutrients. For this reason, scaffolds have generally been designed to incorporate a porous or permeable structure. Also the scaffolds are usually chosen so that they do not provoke a morbid immune response and provide a physical environment approaching that of the tissue to be replaced. Many materials can be chosen and manipulated in this way. For example, polyesters such as polyglycolide can be foamed up and hardened, or can be molded around grains of salt that can subsequently be dissolved out in aqueous solution, leaving a connected porous network [138]. Many consider these polymers to have the advantage of biodegradability; these materials were originally used in dissolving sutures and often dissolve to yield products such as lactic acid that can be metabolized in the body. Perhaps because of these qualities, there is a vast literature on polymer scaffolds. But these polymers are often not very hydrophilic and do not encourage cell attachment, spreading, and infiltration [139,140], but they can be modified by protein coating, for example, with fibronectin [141,142] or combination with other materials, such as collagen [143]. Such scaffolds have been considered for many applications, including bone, cartilage, liver, and lung.

Because bone has a high mineral content, inorganic materials such as calcium phosphates and hydroxyapatite-based materials have been considered for the tissue engineering of bone. Such materials can be ground up to form small particles, which can then be sintered, i.e., heated and partially melted so that each particle melts slightly into the next. In this way, porous networks are formed [144]. These scaffolds can then be seeded with cells and potentially implanted as scaffolds. Such scaffolds usually are brittle but have high mechanical strength when combined with polymers or natural organic material [145] and so could be beneficial in the tissue engineering of load-bearing bones. Bioactive glasses, composed of various combinations of CaO, P₂O₅, and SiO₂, have also been considered for bone tissue engineering. Like calcium phosphate-based materials, they can be sintered [144], or alternatively can be foamed with a surfactant to form sol gels [146]. It is also well-established that bioactive glass enhances osteogenic activity in several types of cells and can accelerate bone healing.

Artificial and natural hydrogels show great promise in soft tissue engineering. The advantage of this approach is that cells can be mixed in a solution, which can subsequently be gelled and molded without killing the cells. For example, cells can be mixed with polyethylene glycol (PEG) and a cross-linker agent and UV light can be used to solidify the gel [147]. Similarly alginate, a polymer of guluronic and manuronic

acids, which can be isolated from seaweed, can be hardened by the addition of divalent, nontoxic ions such as Ca²⁺ [148]. Like PEG, this material has been considered as an encapsulant in cell therapy for diabetes and has also been used as a space filler to allow *in situ* formation of tissue. Stevens et al. injected alginate into the periosteum of bone and observed *de novo* bone formation [137]. Collagen also has been used in this fashion; gelation of collagen can be achieved by increasing pH. And there are a host of studies investigating collagen gels in many different types of tissue engineering, but particularly in bone, cartilage, and tendon.

One of the main disadvantages with porous scaffolds is that it will prove very difficult to make thick tissues as in an *in vitro* setting, there is no blood supply to ensure the delivery of nutrients to the center of a construct and the removal of waste. As previously mentioned, this problem has largely been tackled by developing porous scaffolds. But pore size is generally a trade-off between maintaining a three-dimensional tissue structure and ensuring nutrient diffusion. That is, if pore size is too great, it is arguable whether cells experience a three-dimensional environment; they merely grow on the curved surfaces of pores in the same way that cells grow on tissue culture plastic. If pore size is too small, on the other hand, nutrients cannot diffuse into the center of the construct. To increase nutrient diffusion, bioreactors or spinner flasks have been used in which either the medium surrounding a construct is forced to flow or the medium is forcibly pumped through the scaffold. Another problem with such scaffolds is that because of the way they are constructed as bulk objects, their precise structure cannot be controlled and so they are poor organizers of tissue growth. For these reasons, many groups are investigating novel scaffolds that can be patterned at a microscale resolution to recreate vascular systems and tissue structure, and at the molecular level to direct cell differentiation and function.

27.7.2 MICRO AND NANO SCAFFOLDS

Photolithographic techniques, introduced from the microelectronics industry, have recently been applied to tissue engineering to allow a form of scaffold patterning at a micrometer scale. Here, raised relief patterns can be produced on flat photosensitive silicon wafers called photoresists by selectively exposing areas to UV light using a mask. Patterned masks of any sort can be made easily on computer drawing programs. A curable polymer, such as polydimethylsiloxane (PDMS), can then be poured over the raised relief pattern, allowed to harden, and then removed. This technique has been employed to great success in the field of microfluidics, where the PDMS is patterned with channels, adhered to glass slides before allowing liquid to flow through the channels (see Ref. [149] for a review). But recently, several groups have realized that other curable material that are more biocompatible, such as collagen, alginate, or PEG, can be first combined with cells, poured over the silicon (or PDMS) molds, and then cured, creating porous, patterned scaffolds (Figure 27.5) [150,151]. In this way, some groups have simulated vascular-like structure, where a central, wide inlet “artery” branches into many

FIGURE 27.5 (See color insert following blank page 206.) Process by which patterned hydrogel scaffolds can be constructed. Silicon photoresists are first patterned by exposure to UV light (A). A curable gel, such as silicone can then be molded over the photoresist (B) and used as a mold to create structure in a biocompatible hydrogel such as alginate that may contain cells (C and D). Channels in the hydrogel can then be perfused with a liquid such as growth medium (E). (From Cabodi, M., Choi, N.W., Gleghorn, J.P., Lee, C.S.D., Bonassar, L.J., and Stroock, A.D., *J. Am. Chem. Soc.*, 127, 13788, 2005. With permission.)

“capillaries” before recombining into another wide “vein” (Figure 27.6) [152,153]. Such scaffolds are advantageous because they can supply cells deeply embedded within a scaffold with nutrients in an organized manner, although it is unclear whether these channels are structurally durable and whether or not there would be an even delivery of nutrients to all parts of the scaffold.

Curable polymers can also be patterned without the need for a mold. In these cases, a layer of cell-containing PEG is exposed to UV light in a pattern determined by a mask, the uncured areas of polymer are removed, and then another layer of cell-polymer mixture can be added above it. In this way, different shapes, possibly containing different cell types, can be patterned to simulate tissue architecture [154].

FIGURE 27.6 Patterns can be produced easily on photoresists to simulate vascular architecture. (A) Illustrates a macroscopic view of such a construct and (B) shows a magnified image of the branching structure. (From Kaihara, S., Borenstein, J., Koka, R., Lalan, S., Ochoa, E.R., Ravens, M., et al., *Tissue Eng.*, 6, 105, 2000. With permission.)

Aside from compartmentalizing cells in this manner, others are investigating scaffolds that are textured or patterned at a nanometer scale. In their natural environment, cells are usually surrounded on all sides by other cells and proteins of the ECM; they live in a truly three-dimensional environment. But in scaffolds with large pores, cells may spread out with growth medium on one side and the material of the scaffold on the other. To try and create a more physiological environment, several novel types of scaffold are under investigation. In one approach, materials, which can be an artificial polymer or a more natural material such as collagen, are extruded rapidly through a fine nozzle under the influence of a high electric field to generate very fine threads of material from around 5 nm to 5 μm in cross-section diameter [155]. Meshes of this material, which resembles cotton wool, can then be seeded with cells and maintained in culture. Cell-binding ligands, such as the triamino acid motif Arginine–Glycine Aspartate (RGD), can be attached to such materials to encourage cell binding and spreading the three dimensions. Another ingenious scaffold technology under investigation includes so-called amphiphilic self-assembling peptides [156]. These molecules function using much the same principle as soap. Each molecule has a highly hydrophobic tail and a hydrophilic amino acid head. In aqueous solution, the hydrophobic tails attract one another and remain hidden; the hydrophilic heads protrude out into the center of the molecules, rather than forming spherical micelles, these peptides form long cylindrical fibers, which when viewed macroscopically, resemble a sticky gel. A particular advantage of these peptides is that they can be added to

FIGURE 27.7 (See color insert following blank page 206.) Amphiphilic molecules can be designed with a hydrophilic peptide “head” (5) and a hydrophobic tail (1) (A). These peptides self-assemble to form thread-like nanofibres (B and C). (From Hartgerink, J.D., Beniash, E., and Stupp, S.I., *Science*, 294, 1684, 2001. With permission.)

a solution that contains cells so that the fiber network forms around the cells rather than vice versa, and that specific cell-recognition peptides can be introduced as the fiber head so that cell function and differentiation can be chemically controlled. The ability of a scaffold to directly control the differentiation of cells and the development of tissue is a particularly important factor when considering stem cells in tissue engineering.

27.8 SCAFFOLDS AND STEM CELLS

In the case of stem cells, it is particularly important that the scaffold should play some role in the differentiation of the cells that grow on and around it and that tissue should form in an organized manner. Perhaps because of the reason that stem cell biologists have concentrated on finding ways to make a specific type of cell from ESCs, there have been surprisingly few studies on the differentiation of ESCs on scaffolds and how these cells differ in three dimensions. Recently, however, there have been a few interesting examples. Levenberg et al. [157,158] have shown that the tissues and cells that form when ESCs differentiate in an ECM-based scaffold, made of Matrigel and polyester, express much higher levels of proteins associated with differentiation than those

differentiated on two-dimensional surfaces. Another group has shown that the chondrogenic differentiation of ESCs cultured in a PEG hydrogel is dependent upon whether or not the cells are exposed to RGD-binding ligands [159]. Gerecht et al. have also investigated the growth of ESCs in three dimensions using either hyaluronic acid or a photocurable hydrogel made of poly(glycerolco-sebacate)-acrylate [160,161].

In future, it will probably be beneficial to investigate the effect of more bioactive scaffolds on ESC differentiation in three dimensions. For example, several groups have begun to investigate bioactive scaffolds on other types of stem cell. Kim et al. [162] created a polyester-based scaffold that could slowly secrete ascorbate and β -glycerophosphate. This could enhance the differentiation of MSCs to osteoblasts. Another group has used a similar principle to make a scaffold that slowly exudes BMP, a growth factor that promotes osteogenic differentiation in MSCs [163]. Interestingly, two groups have recently begun to investigate amphiphilic peptide scaffolds to stem cell differentiation, Silva et al. introduced a laminin-specific peptide at the hydrophilic end of the amphiphiles and demonstrated an increased neural differentiation of cells culture in three dimensions in this scaffold compared with if it was used as a substrate [164]. Such scaffolds may have exciting applications in the study of ESC differentiation in the future.

27.9 CONCLUSIONS AND FUTURE DIRECTIONS

ESCs present us with a possible cure to many diseases in which tissue is lost. Studies on the fundamental processes that govern cellular differentiation, as well as the development of new techniques, which will allow us to produce functional differentiated cells, are vital if we are to produce therapies from these versatile cells. Similarly, if we wish to engineer new tissues for implantation, an understanding of how cells respond to a three-dimensional environment will be necessary. New biomaterials and cell culture techniques are vital to develop this understanding, and in the past two decades, material scientists and cell biologists have begun to collaborate. We are only beginning to see the benefits of this new field of research, and in the future, we may be encouraged that the construction of three-dimensional, intricate replicas of human tissue in the laboratory may become a reality.

28.1 INTRODUCTION

Nano and microtechnologies support a number of biomedical applications including drug targeting. Among the several micron and submicron particles developed for drug targeting, biodegradable polymeric nanoparticles have been widely used to carry different types of drugs including oligonucleotides (ODNs) and small-interfering RNA (siRNA). These short gene fragments are able to control gene expression once they get inside the cell and therefore potentially active to treat oncogene-related cancers, viral infections, or inflammatory diseases. Because of their low intracellular penetration and poor stability in biological fluids, the use of a carrier able to overcome these issues is crucial to exploit nucleic acids in therapeutics. Polymeric nanoparticles offer good potentialities as carriers because of their chemical stability and their ability to achieve tissue and cellular targeting. Besides nanotechnologies, microtechnologies were also applied to the delivery of nucleic acids. Since they produce long-term drug release, they can be used for the local delivery of nucleic acids in body regions that can be damaged if frequent administrations are given (e.g., intraocular delivery). This chapter will

describe the different strategies for designing polymeric particulate systems for optimal administration of ODNs and siRNA.

28.2 BASIC CONCEPT AND MECHANISM OF ODNs AND siRNA

ODNs can be designed to modulate gene expression by different strategies. Antisense ODNs (AS-ODNs) are certainly the more largely investigated ODNs. AS-ODNs are synthetic single-stranded DNA fragments, from 13 to about 25 nucleotides, able to bind to specific sequence (sense) of intracellular messenger RNA (mRNA) strands, forming a short double helix. The resulting short double helix hinders mRNA translation with consequent inhibition of protein synthesis expressed by the targeted gene [1]. The ability of an AS-ODN to form a hybrid depends on its binding affinity and sequence specificity. Binding affinity is a function of the number of hydrogen bonds formed between the AS-ODN and the targeted sequence. The affinity can be measured by determining the melting temperature (T_m) at which 50% of the double-stranded

material is dissociated into single strands. T_m depends on the concentration of the AS-ODN, the nature of the base pairs, and the ionic strength of the solvent in which hybridization occurs [2]. Among several recognized mechanisms, one commonly described is the so-called translational arrest (Figure 28.1). In this mechanism, the AS-ODN binds to the single-strand mRNA by Watson-Crick base pairing forming a double helix hybrid, sterically blocking the translation of this transcript into a protein [3]. In addition, the hybridized mRNA prevents the binding of factors that initiate or modulate the translation and may block the movement of ribosomes along the mRNA [4]. Another mechanism that was widely described involves RNase-H-mediated cleavage of the target mRNA

(Figure 28.1). RNase-H is a ribonuclease that recognizes RNA-DNA duplexes and selectively cleaves the RNA strand. This mechanism is catalytic: once an RNA molecule is cleaved, the AS-ODN dissociates from the duplex and becomes available to bind a second target mRNA molecule [5]. However, this recognition by RNase-H is restricted to a few compounds since it does not occur with most of the chemically modified ODNs.

Direct DNA targeting is also possible by using ODNs (antigen ODNs) (Figure 28.1). These single-stranded ODNs can form triple helices with DNA. The third strand binds in the major groove of the double helix specifically recognizing homopolypurine:homopolypyrimidine sequences present in a number of eukaryotic genes. The third strand of polypyrimidine

FIGURE 28.1 Mechanisms of action of ODNs and siRNA.

binds parallel to the polypurine strand of the duplex DNA by Hoogsteen hydrogen bonds, whereas the third strand of polypurine, which is typically G-rich and antiparallel to the polypurine tract, binds to the purine strand of the duplex DNA via reverse-Hoogsteen hydrogen bonds. Formation of this triplex construct lead to the blockage of the transcription of the target gene [6,7].

An alternative way to modulate gene expression by ODNs is the transcription factor decoy strategy (Figure 28.1). This experimental approach is based on the competition for transcription factors between endogenous *cis*-elements present within regulatory regions of target genes and exogenously added DNA sequences (double-stranded ODNs) mimicking the specific *cis*-elements. The binding of decoy ODN to transcription factors results in an inhibition of the expression of specific proteins [8].

siRNA was discovered by showing that the introduction of long double-stranded RNA (dsRNA) into a variety of hosts could induce post-transcriptional silencing of all homologous host genes or transgenes by a mechanism that is summarized in Figure 28.1 [9–12]. Within the intracellular compartment, the long dsRNA molecules are metabolized to small 21–23 nucleotide-interfering RNAs by the action of an endogenous ribonuclease: dsRNA-specific RNase III enzyme Dicer [11,13,14]. The siRNA molecules then assemble to a multiprotein complex, termed RNA-induced silencing complex (RISC), which contains a helicase activity that unwinds the two strands of RNA molecules, allowing the antisense strand to bind to the targeted RNA molecule [12] and an endonuclease activity, which hydrolyzes the target mRNA homologous at

the site where the antisense strand is bound. RNA interference has an antisense mechanism of action, as ultimately a single-strand RNA molecule binds to the target RNA molecule by Watson–Crick base pairing rules and recruits a ribonuclease that degrades the target RNA [15]. Although there are similarities between AS-ODNs and siRNA, very few molecules of siRNA are needed to inhibit gene expression compared to AS-ODNs [16]. As suggested by Corey [17], the reason might be that, unlike siRNA, there is no evolved mechanism for promoting antisense strand recognition and it is likely that AS-ODNs must find their target unassisted [17].

28.3 CHEMICAL MODIFICATIONS OF ODNs AND siRNA

ODNs and siRNAs are natural phosphodiester compounds (Figure 28.2). However, critical drawbacks such as poor stability versus nuclease activity *in vitro* and *in vivo*, low intracellular penetration, and low bioavailability have limited their use in therapeutics [18,19]. As a result, clinical applications of both types of nucleic acids required chemical modifications with the aim of retaining their capacity to knock down protein expression while increasing stability and cellular penetration.

Replacement of the nonbridging oxygen of the phosphodiester backbone by sulfur resulted in the synthesis of phosphorothioate ODN or siRNA (Figure 28.2) with enhanced stability to enzymatic degradation. For ODNs, although the duplex formed with the target RNA has a lower melting temperature (T_m) (i.e., lower affinity) than the phosphodiester compound, it remains a substrate for RNase H. With siRNA, such

FIGURE 28.2 Chemical structure of natural and modified monomer in ODNs and siRNA.

a modification did not significantly affect silencing efficiency [20]. However, the main disadvantage of the phosphorothioate modification is their binding to certain proteins, inducing undesirable effects [21,22]. Moreover, some authors have shown that these linkages do not significantly enhance siRNA stability versus nucleases and reduce the melting temperatures of the duplexes as compared with unmodified RNA [23]. In another study, a phosphorothioate modification was shown to clearly reduce siRNA activity [24]. Thus, the importance of phosphorothioate modification might have been overestimated.

Other chemical approaches tested on ODNs have been the replacement of the nonbridging oxygen by a methyl group, which results in a methylphosphonate ODN (Figure 28.2) or the replacement of the same oxygen by a borane in ODNs [25] and siRNA [26] (Figure 28.2). Methylphosphonate ODNs have a greater hydrophobicity due to the loss of the negative charge. However, in this case, RNase H activation is also reduced [27]. Boranophosphate ODNs are highly resistant to nucleases, hybridize with both DNA and RNA, and activate RNase H cleavage of complementary RNA [25,28]. Moreover, for these ODNs, no demonstrable toxicity has been shown. Similarly, boranophosphate siRNAs were shown to be more effective than natural or phosphorothioate siRNAs mostly because they are at least 10 times more nuclease-resistant than unmodified siRNAs [26,29]. Other modifications made on the phosphate group have led to the synthesis of phosphoramidates (Figure 28.2). In these molecules, the 3'-oxygen is substituted by a 3'-amino group. This modification creates a highly nuclease-resistant molecule with an ability to form very stable duplexes with RNA by Watson-Crick base pairing. In contrast to phosphodiester, the phosphoramidates also form stable triplexes with double-stranded DNA under near physiological conditions. Although the ability of phosphoramidates to activate RNase-H is weak, they effectively block translation because of the high stability of the DNA/RNA hybrids formed [30,31].

ODN or siRNA sugar moiety can be modified at the 2' position of the ribose by linkage of *O*-methyl (2'-OMe), *O*-methoxyethyl (2'-OMeEt), fluoro (2'-F), and locked nucleic acid (LNA) (Figure 28.2). 2'-*O*-methyl and 2'-*O*-methoxyethyl ODNs have raised a large interest. The RNA/RNA duplex formed with these ODNs is highly stable as indicated by the elevated T_m . However, none of the 2'-*O*-alkyl ODNs derivative can induce RNase-H cleavage of target RNA. For this reason, their antisense effect can only be due to a physical blockage of ribosomal machinery, with consequent reduction of their potency [32,33]. The siRNA motif consisting of 2'-OMe and 2'-F has enhanced plasma stability and increased *in vivo* potency as well [34]. This modification has also been shown to increase the nuclease resistance of siRNA duplexes [24]. Nevertheless, this high potency is being discussed by several authors. Indeed, it was recently shown that siRNA duplexes containing full 2'-*O*-Me-modified sense strands display comparable activity to the unmodified analog of similar sequence [35]. Another interesting study has shown that even though the 2'-F modified siRNAs greatly improve

resistance to nuclease degradation in plasma, this increase in stability did not translate into enhanced or prolonged inhibitory activity of target gene reduction in mice following tail vein injection [36].

LNA, also referred to as inaccessible RNA, is a family of conformationally locked nucleotide analogs that display unprecedented hybridization affinity toward complementary DNA and RNA [37,38]. Commonly used LNA contains a methylene bridge connecting the 2' oxygen with the 4' carbon of the ribose ring (Figure 28.2). This bridge locks the ribose ring in the 3'-endo conformation characteristic of RNA [39,40]. LNA ODNs possess a high stability in blood serum and cell extracts and are able to activate RNase H [37]. LNA ODNs have been shown to inhibit tumor growth in a murine xenograft model [41]. However, they also displayed profound hepatotoxicity as measured by serum transaminases, as well as by organ and body weights [42]. LNA were also compatible with siRNA intracellular machinery, preserving molecular integrity while offering several improvements that are relevant to the development of siRNA technology [23,43].

Chemical modifications have also led to the synthesis of an important class, which is the peptide nucleic acids (PNAs) [44] (Figure 28.2). In this case, the phosphodiester linkage is completely replaced by a polyamide (peptide) backbone composed of (2-aminoethyl) glycine units. These ODNs have high hybridization properties and a good biological stability versus nucleases. Nevertheless, they present some drawbacks such as their poor aqueous solubility and low cellular uptake. In addition, they do not induce target RNA cleavage by RNase-H. PNAs seem to be nontoxic as they are uncharged molecules with a low affinity for extracellular proteins. Another family of nonionic DNA analogs is morpholino ODNs (Figure 28.2) that consist of nucleic acids in which the ribose is replaced by a morpholino moiety and phosphoramidate intersubunit linkages are used as a substitute for phosphodiester bonds. These ODNs are interesting because their affinity for their target is similar to that of natural ODNs and they display a low toxicity [45,46].

28.4 CELLULAR UPTAKE OF ODNs AND siRNA

In order to downregulate gene expression, ODNs and siRNAs must penetrate into the targeted cells and reach the cytoplasm. The exact mechanisms involved in ODN penetration are so far unclear. Uptake occurs through active transport, which in turn depends on temperature [47], structure, concentration of ODN [48], and of course cell type. At present, it is believed that adsorptive endocytosis and fluid phase pinocytosis are the major mechanisms of ODN internalization, with the relative proportions of internalized material depending on ODN concentration. At relatively low ODN concentrations, it is likely that internalization occurs via interaction with a membrane-bound receptor [47]. However, only a limited amount of ODN that enters into cells can escape from endosomes. Also in the case of siRNAs, the mechanism of

internalization into cells is unclear. It is known that they are readily taken up by invertebrate cells such as *Caenorhabditis elegans*. However, they are not taken up by most mammalian cells in a way that preserves their activity. Actually, siRNAs do not readily cross the cellular membrane because of their negative charge and size [49] and therefore the simple addition of naked, unmodified siRNAs to the culture media that over-comes mammalian cells does not result in effective knockdown of the target gene [19].

28.5 PHARMACOKINETIC AND BIODISTRIBUTION OF ODNs AND siRNA

The first pharmacokinetics studies were conducted with a 25-mer natural phosphodiester ODN that was injected intravenously in monkeys. Analysis of blood sample by polyacrylamide gel electrophoresis or capillary gel electrophoresis showed that after 15 min, all the ODNs was degraded [50], with a blood half-life estimated to be about 5 min [50]. Similar results were reported in rats for a 20-mer phosphodiester ODN [51]. The majority of the chemically modified ODNs can improve pharmacokinetics parameters. Indeed in rodent models (rats and mice), phosphorothioate ODNs showed distribution half-lives ranging from 30 to 60 min [52–55]. For 2'-*O*-methyl derivatives, the pharmacokinetics properties were close to those of phosphorothioates [55,56] while the PNAs did not display any increase in the distribution half-life [57]. The plasma clearance depended in some cases on the animal model. In mice, at equivalent doses of phosphorothioates ODNs, plasma clearance was at least twofold more rapid than in monkeys [58]. Plasma clearance was largely attributed to ODN distribution into peripheral tissues. ODNs were mainly distributed to the liver, kidney, spleen, lymph nodes, and bone marrow with no measurable distribution to the brain [50,52,53,59]. The biodistribution pattern depended on the nature of the ODN backbone. The phosphodiester ODNs accumulated highly in the liver, whereas high kidney uptake dominated the phosphorothioates, 2'-*O*-methyl phosphodiester [60], and PNA patterns [57]. ODNs do not only distribute to tissues but also accumulate within cells in tissues [61–63]. At early time points after injection, phosphorothioate ODNs appear to be associated with extracellular matrix and within cells. However, by 24 h, almost all of the ODNs are found within cells in tissues [61]. The mechanisms by which ODNs accumulate within the cells following parenteral administration is currently unknown [64]. Regarding siRNAs, their half-life *in vivo* is as short as for ODNs (seconds to minutes) [65]. This is predominantly due to their rapid elimination by kidney filtration because of their small size (~7 kDa) [65]. Like ODNs, they can also be degraded by endogenous serum RNases with a serum half-life of 60 min. The biodistribution of radiolabeled siRNA in mice showed an accumulation primarily in the liver and kidneys [66]. They were also detected in the heart, spleen, and lung. Both intravenous and intraperitoneal delivery resulted in similar behavior of siRNA *in vivo*. siRNAs levels were relatively stable from 1 to 4 h following injection and

were still detectable for up to 72 h [66]. These patterns closely resemble the characteristics of ODNs.

28.6 NANO AND MICROTECHNOLOGIES FOR THE DELIVERY OF NUCLEIC ACIDS

Despite the continuous synthesis of new entities of ODNs or more recently siRNA, a few issues remain to be solved to optimize their delivery. It is very important to meet all the critical parameters corresponding to an optimal activity: improved stability, increased blood half-life, tissue and cellular targeting, improved cellular penetration, and release of the nucleic acids in the right intracellular compartment. A number of research groups have focused on the design of nanotechnologies that could meet all the requirements mentioned above for an optimal delivery of nucleic acids. Two main approaches were utilized. First, due to their negative charges, ODNs can be complexed through electrostatic interactions with cationic polymers or nanoparticles. Second, the nucleic acids are delivered by nanoparticles that are able to trap them in their inner structure. Moreover, microparticles containing nucleic acids have been investigated extensively mainly for their long-term release effect.

28.6.1 PARTICULATE SYSTEMS BY COMPLEX FORMATION WITH ODNs AND siRNA

Several systems have been developed to enhance the intracellular delivery of ODNs through complex formation. Nucleic acids are negatively charged at physiological pH and can electrostatically interact with cationic charges to form complexes simply by mixing the components at optimal conditions. The positive charges can either come from soluble cationic polymers or cationic nanoparticles. As the complex possesses generally a global positive surface charge, they get easily attached to negatively charged cell surface with subsequent endocytosis. Complexes have shown to improve the cellular uptake of nucleic acids with variable success *in vitro* and *in vivo* [67–69].

28.6.1.1 Poly(ethyleneimine)

Polyethyleneimine (PEI) is a polymer, available in different molecular weights and in linear or branched form, characterized by a high density of positive charges. PEI is largely known to be capable of effective nucleic acid transfer to mammalian cells [67,70] (Figure 28.3). The high transfection efficiency of PEI has been attributed to the buffering effect or the “proton sponge effect” of the polymer caused by the presence of amino groups in the molecule. The strong buffering effect and the consequent endosome rupture should help in rapid and massive diffusion of ODN into the cytoplasm [71]. Cytotoxicity and transfection efficiency of PEI are directly proportional to its molecular weight [72]. Many studies have aimed to reduce the toxicity by synthesis of PEI with graft copolymers such as linear poly(ethylene glycol) (PEG) [73],

FIGURE 28.3 Main cationic polymers and nanospheres used for complexation of nucleic acids.

incorporation of low-molecular weight PEI, and PEI glycosylation [74]. *In vitro* efficacy of PEI to deliver ODNs and siRNAs was clearly demonstrated on different cell populations including nondividing cells [67,75,76]. The medium in which the complex is formulated is of utmost importance to obtain nanosized complexes and subsequent optimal cellular delivery of ODNs [76]. Other authors have tried to reduce complex aggregation by micelle formation using a PEI-PEG conjugate [77]. It was shown that the molecular weight of PEI and the substitution degree of PEG are critical parameters for stability of the complexes with ODNs [78]. More stable complexes are obtained with low-molecular weight PEI containing 10 mol% PEG [78]. A higher degree of substitution leads to a quick decomplexation of the ODNs/PEI complexes [79].

Successful siRNA delivery was observed within a very narrow window of conditions and only with the 25 KDa branched PEI. The ability of PEI to improve the *in vitro* and *in vivo* efficacy of siRNA has been studied by a few authors. While the zeta potential and size of PEI/siRNA complexes correlated to transfection efficacy in some cases, complex instability may have also reduced nucleic acid efficacy [80]. It was shown that complexation of chemically unmodified siRNAs with PEI leads to the formation of complexes that condense and completely cover siRNAs as determined by atomic force microscopy [81]. More importantly, upon complexation with PEI, siRNAs were efficiently protected against degradation both *in vitro* in the presence of RNase and *in vivo* in the presence of serum nucleases [82]. In tissue culture, PEI/siRNA complexes are internalized by tumor cells within a few hours, leading to the intracellular release of siRNA molecules, which display full bioactivity. Grzelinski et al. [81] tested with success the delivery of an siRNA against the growth factor pleiotrophin. The complex was able to generate antitumoral effects in an orthotropic mouse glioblastoma model with U87 cells growing intracranially. In a subcutaneous mouse tumor model, the intraperitoneal administration of complexed, but not of naked siRNAs, led to the delivery of the intact siRNAs into the tumors [82]. The intraperitoneal injection of PEI complexes targeting the HER-2 receptor also resulted in a marked reduction of tumor growth through siRNA-mediated HER-2 downregulation [82]. Ligand-targeted PEI has been used to improve the efficiency of siRNA delivery. Self-assembling nanoparticles with siRNA were constructed with PEI that was PEGylated with an Arg-Gly-Asp (RGD) peptide ligand attached at the distal end of the PEG. The complex was used to target tumor neovasculature expressing integrins and deliver siRNA inhibiting vascular endothelial growth factor receptor-2 expression blocking tumor angiogenesis. Cell delivery and activity of PEGylated PEI was found to depend on the presence of peptide ligand and could be competed by free peptide. Intravenous administration into tumor-bearing mice gave selective tumor uptake, siRNA sequence-specific inhibition of protein expression within the tumor, and inhibition of both tumor angiogenesis and growth rate [83].

As well as for ODNs, the stability of siRNA/PEI complexes is of critical importance for efficient siRNA delivery to

the cytoplasm. The effect of PEGylation on stability was tested by Mao et al. [84]. The stability and size of PEI/siRNA complexes were clearly influenced by PEI-PEG structure, and high degrees of substitution resulted in large (300–400 nm), diffuse complexes, which showed condensation behavior only at high nitrogen-to-phosphorus ratios (N/P) [84]. The stability of siRNA polyplexes against heparin displacement and RNase digestion could be improved by PEGylation. In knockdown experiments using NIH/3T3 fibroblasts stably expressing beta-galactosidase, it was shown that PEG chain length had a significant influence on biological activity of siRNA. PEGylated complexes with siRNA yielded knockdown efficiencies of around 70% higher than with PEI alone. These results were explained by the fact that the high siRNA condensation of PEI might prevent siRNA release in the cytosol whereas the condensation was lower in the case of PEGylated PEI [84].

28.6.1.2 Dendrimers

Starburst polyamidoamine (PAMAM) dendrimers are synthetic branched polymers characterized by a spherical shape and a high charge density surface. Dendrimers are produced in an iterative sequence of reaction steps, in which each additional iteration leads to a higher generation dendrimer (theoretically from G1 to Gn) (Figure 28.3). Transfections of AS-ODNs using dendrimers into clones generated from D5 mouse melanoma and Rat2 embryonal fibroblast cell lines expressing luciferase cDNA resulted in a specific and dose-dependent inhibition of luciferase expression [85]. This inhibition caused approximately 25%–50% reduction of baseline luciferase activity [85]. These results were confirmed by others using G5 dendrimers [86]. Helin et al. [87] studied the intracellular distribution of a fluorescein isothiocyanate-labeled AS-ODN delivered by PAMAM and found that intracellular ODN distribution was dependent on the phase of the cell cycle, with a nuclear localization predominantly in the G2/M phase.

Dendrimers can condense siRNA into nanoscale particles. They protect siRNA from enzymatic degradation and achieve substantial release of siRNA over an extended period of time for efficient gene silencing [88]. The ability of siRNA-dendrimer complexes to deliver siRNA to cells was tested using a model of endogenous gene knockdown. For these assays, A549Luc cells stably expressing the GL3 luciferase gene were used. Efficient gene silencing was observed with the specific GL3Luc siRNA-G7 complex while neither the naked siRNA nor the nonspecific GL2Luc siRNA-G7 complex showed any gene silencing effect [88]. The siRNA-dendrimer complex showed generation-dependent gene silencing behavior: the higher the dendrimer generation, the more efficient the gene silencing was found to be. The best gene silencing results were obtained with G7 at an N/P ratio of 10 to 20 and siRNA concentration of 100 nM [88]. For targeting purposes, PAMAM G5 dendrimer was conjugated to Tat peptide, a cell-penetrating peptide that should increase cellular delivery. Delivery of both AS-ODNs and siRNAs designed to

inhibit MDR1 gene expression in NIH/3T3 cell line was achieved [89]. MDR1 gene expression was partially inhibited by the antisense complex and weakly inhibited by the siRNA complex when both were tested at nontoxic levels of the dendrimer. Conjugation with Tat peptide did not improve the delivery efficiency of the dendrimer [89].

28.6.1.3 Complexation by Cationic Nanospheres

Nanospheres (nanoparticles consisting of spherical polymer matrix) can be used to support complexation of nucleic acids. In this case, the use of cationic nanospheres, made of cationic polymers (Figure 28.3) or nanospheres that are rendered positive through the adsorption of a cationic surfactant (Figure 28.3), is required. In this latest case, nanospheres are composed of synthetic biodegradable polymers such as poly(alkylcyanoacrylate) (PACA) [90] or poly(lactic acid) (PLA) [91,92]. Since ODNs have no affinity for the polymeric matrix, association with nanospheres has been achieved by ion pairing with a cationic surfactant, cetyltrimethylammonium bromide (CTAB) adsorbed onto the nanosphere surface [90]. AS-ODNs bound to PACA nanosphere in this way were protected from nucleases *in vitro* [93] and their intracellular uptake was increased [68]. In addition, nanospheres were able to concentrate intact AS-ODNs in the liver and spleen [94]. Using such a formulation, AS-ODNs were able to specifically inhibit mutated *Ha-ras*-mediated cell proliferation and tumorigenicity in nude mice after intratumoral administration [95].

28.6.2 PARTICULATE SYSTEMS ENCAPSULATING ODNs AND siRNA

The association of nucleic acids to the surface of nanoparticles involves a number of issues. In most cases, the use of an ion pair agent is required to confer a positive charge to particle surface. However, this kind of association was found to be rapidly reversible in the presence of protein-rich biological medium [94]. Moreover, when associated through electrostatic forces, nucleic acids adopt conformations that make them unlikely to hybridize with their biological target [96]. Finally, the use of surfactants, such as CTAB, can contribute to the cytotoxicity of the formulation, as demonstrated by Delie et al. [97]. Thus, for optimal activity, ODNs should not be adsorbed, but entrapped within nano or microparticles, such as nano/microcapsules and nano/microspheres. Nano and microcapsules are vesicular systems in which the drug is confined to a cavity (an oily or aqueous core) surrounded by a unique polymeric membrane (Figure 28.4) whereas for nano and microspheres, the drug is dispersed throughout the polymeric matrix (Figure 28.4). Nanospheres or nanocapsules have a diameter less than 1 μm whereas the diameter of microspheres and microcapsules is larger than 1 μm . Different methods have been developed to prepare micro and nanoparticles for the encapsulation of hydrophilic macromolecules such as nucleic acid. These techniques can be classified into two main categories according to whether the formation of nanoparticles requires a polymerization reaction or it is achieved directly from a macromolecule or a preformed polymer.

FIGURE 28.4 Polymeric particles with a capsular (A) or matrix (B,C) structure. In nanocapsules or microcapsules, the nucleic acid is solubilized in the liquid core surrounded by a polymeric membrane (A). In nanospheres or microspheres, the nucleic acid is dispersed in the polymeric matrix (B) or localized into cavities present within the polymeric matrix (C).

28.6.2.1 Particles Obtained by Polymerization of a Monomer

al Khouri-Fallouh et al. [98] have developed a method to produce PACA nanocapsules made of an internal oily core. They actually proposed to solubilize the monomer in an alcohol phase containing oil, this phase being then dispersed into an aqueous phase containing surfactants. The monomer, insoluble in water, polymerizes at the interface of the phases to form the wall of the nanocapsules. This process, which is simple to apply, was designed to encapsulate lipophilic drugs [99]. To encapsulate hydrophilic drugs, Lambert et al. [100] have designed a method to produce polyisobutylcyanoacrylate (PIBCA) nanocapsules containing an aqueous core for the encapsulation of nucleic acids, such as AS-ODN or siRNA. In this case, an aqueous solution containing the nucleic acids is emulsified within an oily phase containing a surfactant, forming a water-in-oil microemulsion. Following the slow addition of the monomer, polymerization occurs at the water-in-oil interface, thus producing nanocapsule shell (Figure 28.5) [100–102]. PIBCA nanocapsules containing an aqueous core were successfully used for the encapsulation of water-soluble molecules such as peptide and nucleic acids [100,103,104].

AS-ODNs encapsulation into the aqueous core of nanocapsules improved their stability against enzymatic degradation. Their half-life in serum was increased from 3 to 6 h when comparing naked AS-ODNs and AS-ODNs adsorbed onto PIBCA nanospheres, respectively [100]. *In vitro* AS-ODNs release from nanocapsules is generally high in the first 30 min, followed by a linear and almost complete release after 3 h [105]. This effect was explained by the presence of two nanocapsule population with different membrane fragilities. The initial release could be due to a rapid disruption of the polymeric wall occurring in the case of one of the population (probably the larger nanocapsules). The following linear release was instead attributed to the progressive degradation of the more resistant nanocapsule wall by serum esterase. It can therefore be assumed that AS-ODN degradation in serum occurs only after release from nanocapsules [105].

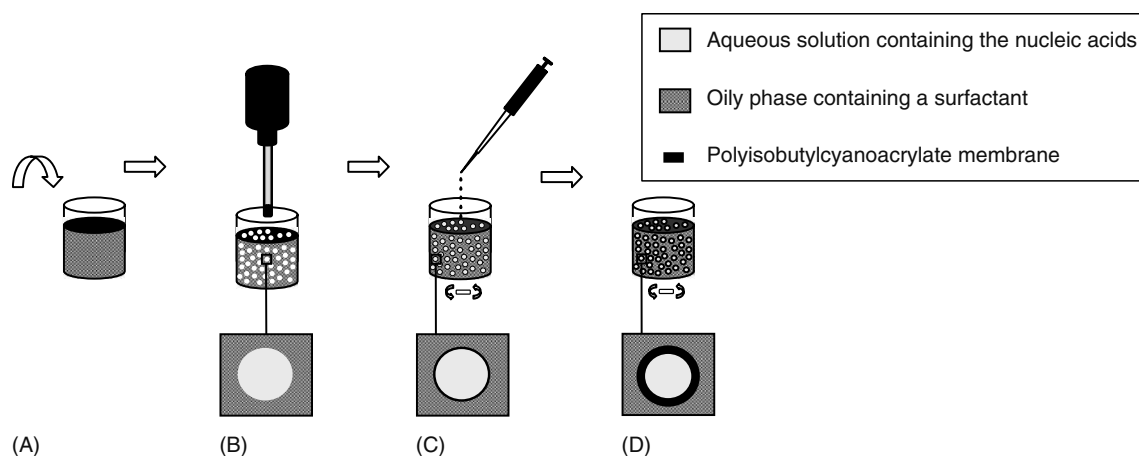

FIGURE 28.5 Preparation of poly(isobutyrylcyanoacrylate) nanocapsules containing an aqueous core obtained by interfacial polymerization. The aqueous solution containing the nucleic acids is emulsified within an oily phase containing a surfactant (generally sorbitan monooleate) (A) to form a water-in-oil microemulsion (B); polymerization occurs for slow addition of the monomer at the water-in-oil interface (C); after about 4 h under stirring, the aqueous droplets are surrounded by a poly(isobutyrylcyanoacrylate) membrane (nanocapsules) (D).

Encapsulation into PIBCA nanocapsules importantly increased cell uptake of both AS-ODN and siRNA. Toub et al. [106] investigated the subcellular distribution of AS-ODNs when incubated under naked or encapsulated form [106]. Incubation of naked AS-ODNs with cultured vascular smooth muscle cells resulted in membrane-bound species higher than the internalized fraction, while the ODN encapsulation led to an inverted profile with an internalized fraction 10 times higher as compared to naked ODN. Toub et al. [106] confirmed that the intracellular fraction of naked AS-ODNs was mainly found in vesicular fraction. AS-ODNs delivered by PIBCA nanocapsules drastically changed the subcellular distribution: less than 40% of ODN remained entrapped into vesicles, whereas about 50% was found in the nuclear fraction. This suggests that PIBCA nanocapsules were able to deliver a substantial amount of its cargo to the cytosolic compartment with further diffusion of the AS-ODNs to the nucleus. Similar AS-ODNs distribution into cells was observed using either fluorescence or radioactivity measurements, confirming the integrity of the internalized compounds [106]. Finally, AS-ODNs accumulation into the nucleus was found to increase as a function of the time, as shown in confocal microscopy experiments performed at different time intervals, ranging from 2 to 15 h [107].

The mechanism by which encapsulated AS-ODNs can escape from endosomes is not yet fully understood. However, detergents such as sorbitan monooleate used in their formulation may play a role in endosomal membrane destabilization [108]. Similar results were obtained for siRNA encapsulated into PIBCA with an aqueous core [104]. Confocal microscopy studies showed that when a fluorescently labelled naked siRNA was added to the culture medium, only a low fluorescence localized on the extracellular matrix was found. On the contrary, when siRNA was encapsulated in nanocapsules, a punctuate fluorescence was observed into the cells, suggesting an endosomal localization of the siRNA [104].

In vivo, AS-ODNs-containing nanocapsules were mainly tested on a murine model of Ewing sarcoma-related tumors targeting EWS Fli-1, a fusion gene resulting from a translocation that is found in 90% of both Ewing sarcoma and primitive neuroectodermal tumor [105]. All treatments were given by the intratumoral route. At a cumulative ODN dose of 14.4 nmol, only AS-ODNs encapsulated within nanocapsules led to a significant inhibition of tumor growth, while only a slight effect was observed with naked AS-ODNs at the same dose. Tanaka et al. [109] observed a significant reduction of tumor growth with injection of 500 nmol naked AS-ODNs. Thus, the use of nanocapsules allowed to obtain a 35-fold reduction of the AS-ODN administered dose. In the same experimental model, the efficiency of AS-ODN-containing nanocapsules was compared with that of the same AS-ODNs adsorbed onto poly(isohexylcyanoacrylate) (PIHCA) nanosphere through interactions with preadsorbed CTAB [110]. In this case, a completely phosphorothioate AS-ODNs and a chimeric phosphorothioate/phosphodiester derivative were tested. Both nanoparticulate systems led to an efficient inhibition of the tumor volume from about 66% to 82%. The antisense effect of the delivered AS-ODN was demonstrated by downregulation of EWS-Fli-1 mRNA. The authors speculate that in the case of the nanoparticles, CTAB can permeate the endosomal membrane, thus inducing a more efficient cytoplasm delivery of the AS-ODN. Using again the same *in vivo* experimental model, Toub et al. showed that PIBCA nanocapsules were efficient to deliver siRNAs into tumor [104]. In particular, a dramatic inhibition of tumor growth was observed, especially when a higher cumulative dose was employed. In particular, a reduction of the tumor volume from about 43% to about 80% with a cumulative dose of 0.8 and 1.1 mg/kg, respectively, were observed allowing with a lower daily and cumulative dose to obtain a better efficacy than for encapsulated AS-ODNs. For both doses, naked siRNA had no inhibitory effect on tumor growth.

28.6.2.2 Particles Obtained by Preformed Polymer

To avoid limitations due to the use of monomers such as the toxicity of eventual residual monomers or the possibility of drug inactivation through the formation of covalent link between the drug and the polymer, particulate delivery systems based on preformed polymers have been proposed. Among the preformed polymers, PLA and its copolymers with glycolic acid (PLGA) have been extensively used in the last three decades. This family of polymers is present in the market at different molecular weights, lactide-to-glycolide ratios, and hydrophilicity (i.e., capped and uncapped end-groups), offering the possibility to choose among very different biodegradation rates. Phosphodiester and phosphothioate AS-ODNs were firstly loaded onto films made of PLA, obtaining a sustained release and an efficient protection against serum nucleases as well as a maintained hybridization capability [111]. However, the use of such polymeric devices needs a surgical implantation. The possibility to formulate these polymers in the form of microspheres offers the advantage to directly inject the delivery system into the administration site. Also when encapsulated into microsphere, AS-ODNs are efficiently protected by degradation upon incubation in serum [112,113].

Encapsulation of ODNs into PLA or PLGA particles was mainly achieved by the water-in-oil-in-water (or multiple) emulsion/solvent evaporation or extraction technique. In these techniques, an aqueous solution of the ODN is emulsified in an organic polymer solution to form a water-in-oil dispersion. This primary emulsion is then dispersed into an aqueous solution containing a hydrocolloid, generally poly(vinyl alcohol), to obtain a multiple emulsion. Solvent evaporation allows polymer hardening with a consequent formation of matrix-like particles in which the ODN is mainly localized in internal cavities of the first emulsion (Figure 28.6). In the case of solvent extraction, a cosolvent is added to the external aqueous phase to accelerate polymer hardening. ODN length and chemistry (phosphodiester or phosphorothioate), ODN loading as well as microspheres size strongly affect encapsulation

efficiency and release properties [112]. Higher drug loading is generally associated with a larger size [114] but is independent of ODN length [112]. *In vitro* release profile of AS-ODN from particles was found to be affected by microsphere size, drug loading, and ODN length and polymer molecular weight. Small microparticles (1–2 μm) released most of the entrapped AS-ODNs within the first 4 days, compared with 40 days for larger particles (10–20 μm) [114]. In the case of larger particles, a triphasic release was observed: a burst release in the first 48 h attributed to the rapid release of the AS-ODN present on or close to the microsphere surface; a sustained release phase (about 25 days) in which an AS-ODN diffusion through pores present in the polymer matrix should occur; a final more rapid release phase (up to a complete release at about 60 days) due to the polymer degradation that should accelerate ODN release rate [112]. In the case of smaller particles, the increased surface area-to-volume ratio results in a greater concentration of ODN at or near to the surface with the consequent more rapid release [112]. An increase of ODN loading also results in a higher burst effect [115,116] and a more rapid release rate [112]. Release profile is only modestly dependent on nucleic acid length, with a release rate higher as the AS-ODN molecular weight is lowered [117]. Finally, a high burst effect as well as the rapid *in vitro* release rate has been related to microsphere porosity. Pores on microsphere surface originate when an osmotically active agent, such as AS-ODN, is added to the internal aqueous phase. The use of an osmotic agent, such as NaCl, into the external aqueous phase allows to reduce microsphere surface porosity, thus reducing the initial ODN burst effect as well as the *in vitro* release rate [113,118,119]. *In vitro* decoy ODN release from PLGA microparticles is dramatically modified at pH different than the physiological value [116]. In particular, it was found that at pH values of 5 and 10, the overall released decoy ODN dramatically reduced. The pH effect was reduced by the incorporation of PEG into the microparticles [116].

AS-ODNs were also coencapsulated with the anticancer drug 5-fluorouracil with a similar loading efficiency. However,

FIGURE 28.6 Preparation of PLA/PLGA particles containing nucleic acids by water-in-oil-in-water emulsion/solvent evaporation or extraction technique. An aqueous solution containing the nucleic acid is emulsified in an organic polymer solution (A) to form a water-in-oil dispersion; this primary emulsion is then dispersed in an aqueous solution containing a hydrocolloid (generally polyvinyl alcohol) (B) to obtain a multiple emulsion (C). Solvent evaporation or extraction allows polymer hardening with a consequent formation of matrix-like particles in which the nucleic acid is mainly localized in the internal cavities (D).

the release profiles were slower when the two drugs were coencapsulated, suggesting an interaction between ODN and 5-fluorouracil [120]. Besides single-stranded AS-ODNs, also double-stranded ODN have been successfully encapsulated within PLGA microspheres [121]. In particular, microspheres encapsulating a decoy ODN against the transcription factor κB (NF- κB) showed a negligible burst effect and a very gradual release profile, with the decoy ODN completely released after about 40 days [121]. A double-stranded siRNA was also encapsulated into PLGA nanoparticles [122] and microparticles [117]. For the same formulation, the *in vitro* release of siRNA was found to be much slower and with a very limited burst effect, compared with that obtained with a single-stranded AS-ODN. The difference between the release profiles was ascribed to the different chemical nature of the two nucleic acids, while only a modest effect was attributed to the different molecular weights [117].

Increase of ODN encapsulation efficiency into PLGA or PLA nano and microparticles, as well as optimization of their *in vitro* release properties, has been achieved by using cationic additives able to complex the nucleic acid within the matrix. The *in vitro* release rate of AS-ODN from PLGA microspheres was slowed down by complexation with zinc acetate [123]. A limited burst effect together with a linear release was observed (70% of the loaded ODN released over 9 days). Our group used the same rationale to design a “Trojan” delivery system that combines the advantages of microspheres (long term release) and of PEI/AS-ODNs complexes that is an enhanced ODN intracellular penetration [113,119,124,125]. Several different types of AS-ODNs were entrapped with the microparticles and depending on the ODNs characteristics and on the experimental conditions in which ODN and PEI are mixed, liquid [124], or solid complexes can be encapsulated [119,125]. ODN complexation with PEI improved AS-ODN encapsulation efficiency [119,124,125], probably by an electrostatic interaction between the cationic ODN/PEI complex and the anionic PLGA [124]. Release rate was shown to be dependent on the porosity of the microparticles, the higher the porosity, the faster was the release and the higher was the burst effect. Using an analytical solution of Fick’s second law of diffusion, it was shown that the early phase of phosphorothioate AS-ODN and phosphorothioate AS-ODN-PEI complex release was primarily controlled by pure diffusion irrespective of the type of microspheres [119].

When incubated with cells, the *in vitro* fate of the encapsulated drug can vary according to particle size. In particular, small PLGA particles (including nanoparticles with a mean diameter lower than 1 μm and microparticles with a mean diameter between 1 and 5 μm) are generally developed to be taken up by cells. It was therefore shown that AS-ODNs entrapped within 1–2 μm -sized microparticles displayed 10-fold improved cell association in murine macrophages, compared with naked AS-ODNs [114]. Cell uptake was enhanced when macrophages were activated with interferon- γ or lipopolysaccharide (LPS) treatment, but decreased significantly in the presence of metabolic and phagocytosis inhibitors. PLGA microparticles loaded with AS-ODNs against the rat

tenascin mRNA was tested on smooth muscle cell proliferation and migration [126]. The study demonstrated a dose-dependent growth inhibition with the AS-ODN-loaded microparticles. Microparticles were found to be able to deliver a fluorescently labeled phosphorothioate AS-ODNs into “nonacidic compartments” of DU145 cells, presumably cytoplasm and nucleus, rather than in the endosome, where naked AS-ODNs are preferentially found [127]. Microparticles with a mean diameter of about 3.5 μm and encapsulating ODN/PEI complexes were efficiently internalized into HeLa cells [128]. In this case, the global positive charge of particles was thought to contribute to the cell/particle interaction. Moreover, formulation with the lower ODN release rate exhibited the better ODNs accumulation into the nucleus [128]. The use of nanoparticles (diameter lower than 1 μm) allowed to improve cell internalization and cytoplasm localization of a platelet-derived growth factor (PDGF) β -receptor AS-ODN [129]. A dose–response antiproliferative effect was found with AS-ODN-encapsulated nanoparticle on rat smooth muscle cells at the dose of 0.5 and 1 μM , while the effect was the same at higher concentration (2 μM). The antiproliferative effect was significantly lower with naked ODN at the same concentration [129]. A higher uptake of nanoparticles containing AS-ODNs against vascular endothelial growth factor (VEGF) was observed by Aukunuru et al. [130] in human retinal pigment epithelial cells. In this case, AS-ODN uptake increased about 4.3-fold by using nanoparticles, compared with naked AS-ODN. These data were confirmed by the efficient inhibition of VEGF mRNA expression together with a significant reduction of VEGF secretion by the cells. Efficient uptake of PLGA microparticles encapsulating adjuvant ODN containing unmethylated CpG motifs was also showed on dendritic cells *in vitro* by confocal microscopy, fluorescence-activated cell sorting (FACS), and scanning electron microscopy (SEM) [131]. In this study, dendritic cells incubated with PLGA nanoparticles containing tetanus toxoid induced significantly higher T cell proliferation when coencapsulated with CpG ODN rather than associated to the adjuvant at the same dose in solution [131].

Only a few studies have been focused on the *in vitro* fate of AS-ODN when delivered with large particles (diameter higher than 5 μm) that are unable to be taken up by cells. Of course, the main aim in this case is to obtain a long-term delivery of the ODN, thus reducing the need of frequent administrations. However, the release rate can play an important role in cellular uptake. In recent studies, we have demonstrated that, at a fixed concentration, ODN cell uptake is enhanced by slow release, compared with ODN administered in naked form [113,121,124]. Confocal microscopy studies showed a significant higher uptake of a single-stranded ODN when slowly released from microspheres of about 30 μm , compared with naked ODN [124]. In another study, a double-stranded decoy ODN against NF- κB was encapsulated in PLGA microspheres with a mean diameter of about 25 μm . Also in this case, an increased ODN uptake into cells was observed by confocal microscopy [121]. The increased decoy ODN uptake fitted with an increased inhibition of NF- κB activation (80-fold higher than with naked

Decoy ODN), as suggested by decreased NO production, iNOS, and tumor necrosis factor alpha (TNF- α) expression as well as reduced NF- κ B/DNA binding [121]. The contemporary release of AS-ODN and PEI resulted in a further improvement of ODN cell uptake with accumulation into the nucleus [113,124]. All these results could be explained by the fact that ODN entry into cells prevalently by a pinocytotic process [132] that is saturated at high concentrations of naked ODN exposing a high dose fraction to degradation by exonucleases. When encapsulated into PLGA microspheres, ODN is efficiently protected from the enzymatic activity; then, when a little amount of ODN is released from microspheres, pinocytotic saturation is not expected to occur and a higher percentage of ODN can enter into cells. For siRNA, only a recent report has used PLGA nanoparticles containing a green fluorescent protein (GFP) gene silencing siRNA with GFP-expressing 293T cells [122]. Significant silencing effect was observed after 1 day incubation and was still persistent 1 week later.

Different studies have investigated the *in vivo* potentialities of PLA/PLGA nano- and microparticles for the delivery of AS-ODN compared with AS-ODN administered in a naked form. The therapeutic effect of PLGA microspheres encapsulating an AS-ODN targeted to the proto-oncogene *c-myc* was demonstrated in two different animal tumor models, human xenograft leukemia and melanoma [123]. In particular, the antitumor effect of microspheres encapsulating ODN/zinc complexes, administered by subcutaneous route, was compared with the efficacy of either subcutaneously or intravenously administered naked ODN at the same doses. The microsphere-based formulation was more effective as shown by reduced tumor growth, decreased number of metastases, reduced *c-myc* expression, and increased survival in melanoma model. A decreased metastatic potential and an increased survival were also observed in the leukemia model [123]. Different AS-ODN distribution in neostriatum of rat brain was observed by comparing a fluorescently labeled AS-ODN administered in naked or in microencapsulated form [133]. In particular, in the case of naked AS-ODN, a punctuate fluorescence was found in the cell cytosol at 24h postinjection, while a weak signal was observed at 48h. In contrast, when administered in microencapsulated form, fluorescently labeled AS-ODNs were still well visible in the neuronal tissue [133]. Biodistribution of tritium-labeled ODN, administered in naked form or encapsulated into microspheres, was investigated after subcutaneous administration in Balb-c mice [117]. In the case of naked AS-ODN, the majority of the radioactivity associated with the nucleic acid was eliminated within 24h. The use of AS-ODNs entrapped within microspheres resulted in high levels of radioactivity at the injection site and a lower level through the body after 24h from the inoculation. After 7 days, the level of radioactivity remains high at the administration site and considerably lower in the liver, kidney, and spleen. Microautoradiography analysis of liver and kidney showed similar biodistribution for naked and microencapsulated AS-ODN [117]. In a rat carotid *in vivo* model, PLGA nanoparticles containing an AS-ODN against PDGF receptor

showed an antirestenotic effect after 14 days from the treatment [129]. In this case, however, the same effect was observed with naked AS-ODN administered at the same dose. It is worthy to note that in the case of nanoparticles only a little amount of the loaded AS-ODN should be released during 14 days; consequently, the naked AS-ODN was effective compared with the encapsulated AS-ODN, but at higher doses [129]. The higher effect of AS-ODN, when administered with PLA/PLGA particles, was also investigated with PLGA nanoparticles containing CpG ODN (used as immunostimulant) [131]. Strong antigen-specific T cell proliferation was observed in Balb/c mice receiving immunogen tetanus toxoid associated to the adjuvant CpG ODN. A comparable stimulation index was observed with naked CpG ODN at a dose of 5 μ g or with CpG ODN encapsulated into PLGA nanoparticles at a dose of 0.05 μ g [131]. The *in vivo* potential of PLGA microspheres as delivery system for a decoy ODN to NF- κ B has been recently tested in a rat model of chronic inflammation. Subcutaneous injection of PLGA microspheres releasing decoy ODN inhibited λ -carrageenin caused leukocyte infiltration and formation of granulation tissue up to 15 days whereas naked AS-ODN, at the same administered dose, showed a similar effect only from 1 day up to 5 days (G. De Rosa, personal communication). The so-called "Trojan delivery system" consisting of PLGA microparticles releasing AS-ODN/PEI complexes was tested *in vivo* [119]. In this study, an AS-ODN against the TGF- β 2 was tested for wound healing after filtration surgery in an animal model of glaucoma. The cryosection of rabbit conjunctiva showed that after 1 day from the subconjunctival injection of microspheres containing AS-ODN/PEI complexes, the AS-ODN was located in the conjunctival stroma. Six days after the injection, AS-ODN was located in conjunctival cells, with accumulation into the nucleus. No conjunctival hyperemia was observed for 6 weeks after the injection. Rabbit treatment with PLGA microspheres releasing anti-TGF β 2 AS-ODN prolong bleb survival for 28 days (50% of the treated eyes) following trabeculectomy compared to control. This effect was significantly higher in the case of PLGA microspheres releasing AS-ODN/PEI complexes with a bleb survival of 42 days on 100% of the treated eyes [119].

28.7 CONCLUSION

It is clear from this review that particle engineering has been extensively applied to the delivery of AS-ODNs and siRNAs. Major successes were obtained *in vitro* and *in vivo* for the delivery of these compounds. However, one issue remains to be solved. How can nanotechnology address specifically its content to the diseased cell? There is therefore a need to develop more targeted systems. A successful tissue-targetable system should have three properties: nucleic acid release into the cell cytosol, protection from nonspecific interactions, and tissue targeting that provides cell uptake. No single material has all of these required properties. Thus, the alternative approach could be the design of nanocapsule material that assembles these multiple properties.

29.1 INTRODUCTION

The expression of transgenes encoding powerful biological mediators or effectors should be limited to the optimal therapeutic window. Multiple gene switches that can be utilized to regulate the temporal expression of transgenes were developed. They typically consist of an artificial (chimeric) transcription factor that is activated or inactivated by a small-molecule ligand and a promoter that is activated or silenced by the transcription factor and is functionally linked to the transgene to be regulated. All systems appear to be, in principle, capable of functioning as on/off gene switches. However, they differ in respect of the level of maximal transgene expression they support, pharmacodynamic and kinetic properties of the activating or inactivating small-molecule ligands required, degree of humanization achieved or potentially achievable, and the nature of the transcription factor, i.e., whether it is monomeric, or homo- or hetero-oligomeric. Other differences relate to the level of characterization and consequently, useful information available to the research community.

Perhaps even more important than temporal regulation is spatial restriction of transgene expression. Although efforts have been undertaken to produce vectors that have specificity

for certain target tissues, standard viral and nonviral vectors have limited ability or no ability to deliver transgenes exclusively to tissues, organs, or regions in need of therapy. Several approaches have been pursued to restrict expression of therapeutic genes or replication of viruses such as oncolytic viruses to an intended site of action.

Historically, the foremost strategy has been employment of tissue-specific or tissue-restricted promoters for controlling transgene expression [1,2]. Although simple in principle, this approach to transcriptional targeting is associated with several difficulties relating to less than perfect tissue specificity, fixed level of activity of a given promoter, and a need for using different promoters for different targets. Another strategy takes advantage of disease-associated biological or biochemical differences. Hypoxia-inducible promoters have been used to limit transgene expression to ischemic tissues including ischemic portions of solid tumors [3,4]. Promoters that are selectively active in proliferating cells have been exploited for confining transgene activity to tumor tissues [5,6]. A glucose-sensitive promoter has been employed for controlling insulin expression [7]. E1A- and E1B-deleted oncolytic viruses were investigated for their ability to selectively replicate in certain tumor tissues. Perhaps, the best known example of such a

virus is ONYX-015, an E1B-deleted oncolytic adenovirus that has undergone advanced clinical studies [8]. While the latter approaches are expected to be more generally applicable than the tissue-specific promoters discussed before, they may suffer from some of the same disadvantages, i.e., uncertainties relating to specificity of gene regulation as well as to uniformity of gene expression throughout diseased tissues or organs.

Another strategy that is expected to be essentially free of the limitations discussed before relies on the use of promoters, which are activated in essentially all tissues by directed physical force. A major portion of this chapter will be devoted to a discussion of this strategy. Promoters of this type include heat shock protein (hsp) gene promoters and radiation-induced promoters. Transgenes controlled by such promoters can be activated and their expression restricted to desired target regions by directed radiation or ultrasound, respectively. It is noted that the kinetics of activation and subsequent deactivation of the latter inducible promoters are defined by endogenous signaling mechanisms and therefore cannot be readily adapted to yield a desirable temporal profile of expression of a therapeutic transgene or virus replication. More complex systems were built and tested that combine a radiation- or ultrasound-activated promoter and a gene switch comprising a small-molecule-dependent transactivator. Such systems allow for deliberate control of both location and duration of transgene expression.

29.2 SMALL-MOLECULE-DEPENDENT GENE SWITCHES TO ACHIEVE CONTROL OVER DURATION OF TRANSGENE EXPRESSION

29.2.1 GENE SWITCHES COMPRISING TETRACYCLINE REPRESSOR-DERIVED TRANSACTIVATORS

Tetracycline-responsive gene switches were shown to effectively control transgene expression in cultured cells as well as in yeast, *Dictyostelium*, *Drosophila*, *Candida*, amphibia, rodents, and nonhuman primates. The *Escherichia coli* Tn10 tetracycline resistance operator consists of tetracycline repressor protein (TetR) and a specific DNA-binding site, the tetracycline operator (TetO) [9]. TetO is also referred to as tetracycline-response element (TRE) [10]. TetR forms dimers that bind to TRE. Tetracycline and derivatives including doxycycline interact with TetR and induce a conformational change that causes dissociation from TRE. A first tetracycline-dependent eukaryotic gene switch employed a fusion protein consisting of TetR and an activation domain from herpes simplex virus (HSV) protein VP16. This fusion protein was termed tTA. *In vitro*, tTA enhanced the activity of an artificial promoter consisting of a minimal cytomegalovirus (CMV) promoter and seven TRE sequences four orders of magnitude better in the absence than in the presence of tetracycline. This gene switch is referred to as the Tet-Off system (Figure 29.1A). The Tet-Off system was also shown to function in transgenic mice containing a tTA-encoding gene and a luciferase or β -galactosidase reporter gene [11]. To decrease the likelihood

that tTA interacted with cellular factors, the VP16 activation domain was reduced subsequently to three minimal repeats of 12 amino acids each [12].

Silencing of a transgene controlled by the Tet-Off system requires continuous administration of tetracycline or tetracycline derivative. This feature of the system may preclude its clinical application, especially when vectors are employed that result in an extended residence time of a therapeutic gene. A mutant of TetR was identified whose TRE-binding ability was induced rather than inhibited by tetracycline. This mutant was used to design the so-called Tet-On gene switch that incorporated an antibiotic-activated transactivator, referred to as rtTA (Figure 29.1B) [13]. As would have been expected, activation of the Tet-On switch was considerably more rapid than that of the Tet-Off switch. However, rtTA was less sensitive to doxycycline than tTA. This raised a concern that full transgene activation may not be achievable in tissues in which elevated concentrations of antibiotic cannot be attained. In addition, the Tet-On system exhibited instability that, presumably, was due to a residual affinity of rtTA for TRE. Several avenues were pursued to produce an improved version of the Tet-On system. A new transactivator, rtTA^{2S}-M2, was engineered through random mutagenesis and codon optimization. rtTA^{2S}-M2 had an improved sensitivity to inducer as well as a reduced residual activity in the absence of inducer [14]. More recently, viral evolution approaches were used for obtaining different variants of rtTA that also were more sensitive to inducer and, in addition, were more active than the original rtTA [15,16].

Residual rtTA activity could also be suppressed by means of a tetracycline-controlled transcriptional silencer (tTS) (Figure 29.1C) [17]. tTS is capable of binding TRE-containing promoters, preventing their activation by rtTA in the absence of doxycycline. When doxycycline is added, tTS is inactivated, rtTA is fully activated, and transcription from TRE-containing promoters is fully enabled. Zhu et al. [18] prepared tTS^{Kid}, a fusion between TetR and the KRAB domain of human kidney protein Kid-1. Gene switches that included both rtTA and tTS^{Kid} were able to stringently control expression of genes for toxic products. Transgenic mice that expressed tTS^{Kid} and rtTA under the control of a lung-specific promoter and interleukin-13 (IL-13) under the control of an artificial promoter containing TRE sequences were established. tTS^{Kid} suppressed residual IL-13 expression in the absence of doxycycline. In the presence of inducer, rtTA effectively stimulated IL-13 expression. To optimize delivery, the genes for rtTA, tTS^{Kid}, and IL-13 were introduced in a single adenoviral or episomally replicating vector. These systems performed well *in vitro* and *in vivo* [19–23]. However, not all experimentation with tTS-containing systems was successful. Lamartina et al. [24] reported that addition of tTS to a Tet-On switch resulted in impaired transgene activation. Barde et al. [25] found that target gene activation in CHO cells transduced with a lentiviral vector expressing rtTA^{2S}-M2 and tTS^{Kid} was progressively lost with time and repeated induction.

Yet another strategy for minimizing residual rtTA activity in the absence of inducer was to regulate rtTA expression by

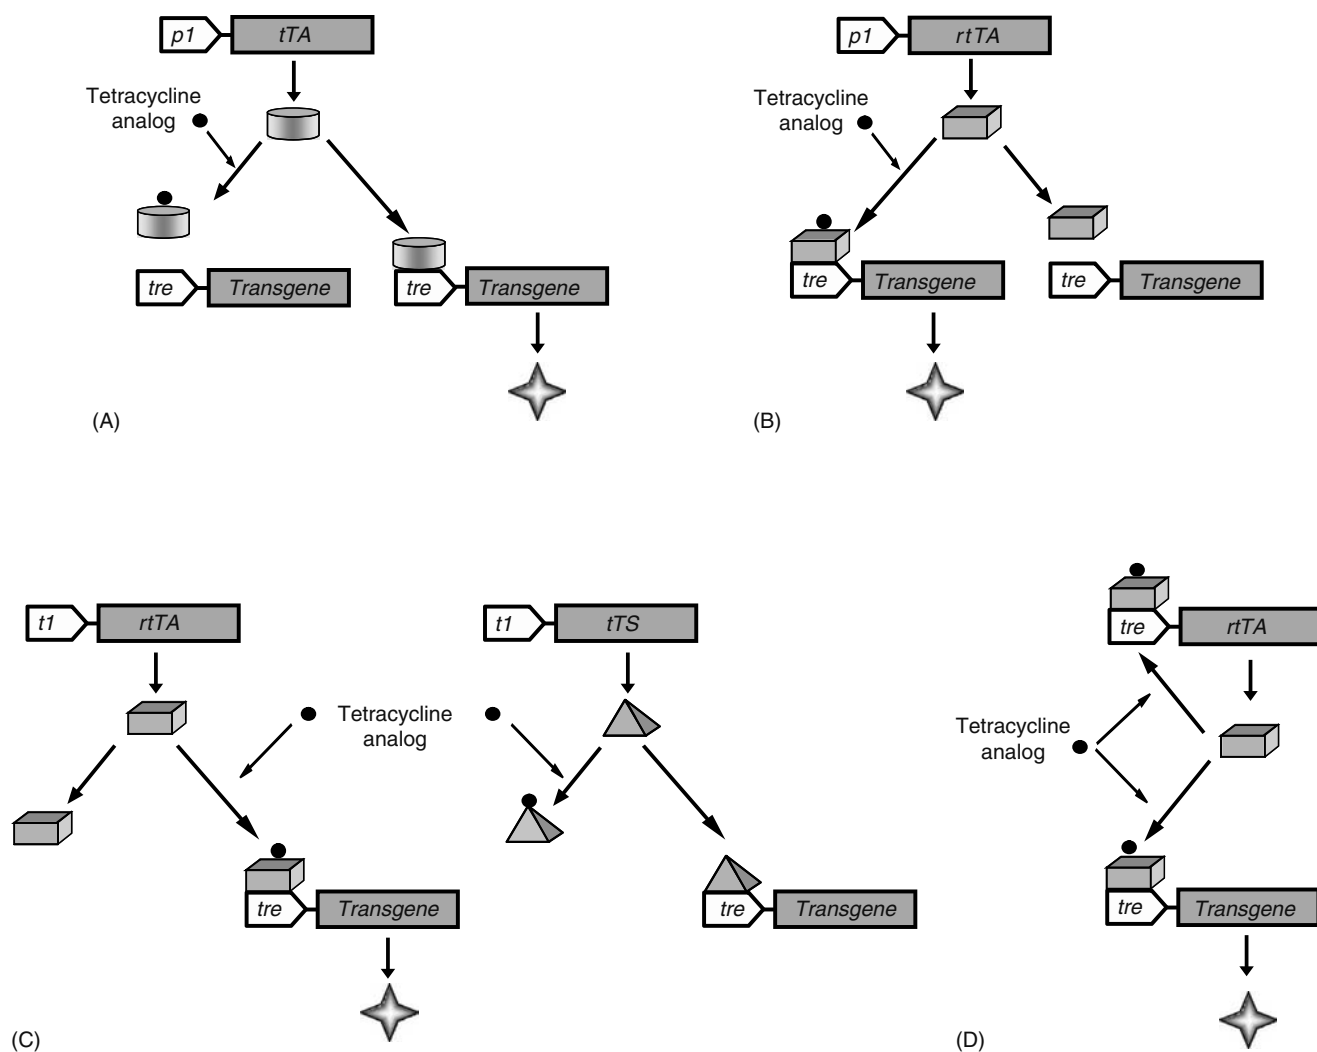

FIGURE 29.1 Tetracycline-responsive gene switches. (A) Tet-Off switch. (B) Tet-On switch. (C) Tet-On switch incorporating a tetracycline-controlled transcriptional silencer. (D) Tet-On switch comprising an autoactivated gene for rtTA. tTA and rtTA refer to tetracycline-inactivated and tetracycline-activated transactivators, respectively. tTS is a tetracycline-inactivated transcriptional silencer. tre, TRE sequence-containing (tetracycline-responsive) promoter; t1, tissue-restricted promoter.

means of an autoactivated promoter (Figure 29.1D) [26]. Such a system was tested in a panel of human primary and established cell lines transduced with lentiviral vectors and was found to exhibit low background activity in the absence of inducer and strong induction in the presence of inducer. Induced gene expression levels surpassed those produced by a CMV promoter [27].

To achieve prostate cell-specific transgene expression, a DiSTRES vector was recently designed by Woraratanadharm et al. [28]. Several gene cassettes were subcloned into the genome of a replication-incompetent adenovirus vector. To develop a prostate-specific and tTA-inducible promoter, a TRE was introduced upstream of a probasin promoter. The resulting *TRE-ARR2PB* promoter was used to control the expression of a Lac repressor (*lacI*) gene. A second component consisted of a probasin promoter linked to a *tTA* gene that was cloned immediately opposite of the *TRE-ARR2PB-lacI*

cassette such that the TRE had bidirectional activity. A third component contained a green fluorescence protein (*gfp*) gene under the control of a tetracycline-responsive promoter. In addition, a gene cassette containing a newly developed Lac repressor-responsive promoter was cloned into the left-end of the genome and controlled expression of a *tTS* gene. In a prostate cell, both *tTA* and *lacI* genes would be active, because they are under the control of prostate-specific TRE-ARR2PB promoters. In the absence of tetracycline or a derivative, tTA would then transactivate the *gfp* gene. The tTA protein would also bind to the TREs within its own *TRE-ARR2PB* promoter, thereby establishing a feedforward loop of tTA amplification. Lac repressor would bind to the Lac repressor-responsive promoter of the *tTS* gene, thereby suppressing *tTS* gene transcription. Neither tTA nor Lac repressor would be expressed in nonprostate cells. In the absence of Lac repressor, the *tTS* gene is actively transcribed, resulting in transcriptional silencing of

all tetracycline-regulated genes, including the gene of interest (here the *gfp* gene). Note that tetracycline or its derivatives are not required for cell-specific performance of this system. Green fluorescent protein (GFP) expression from DiSTRES adenovector was more than 30-fold higher than from Ad/CMV-*GFP* in LNCaP cells.

Weber et al. [29] constructed a synthetic mammalian gene network that processes different input signals to control tightly the expression of a specific target gene. Three components of the switch were controlled by constitutive promoters: the first component of the circuitry was a VP16 transactivation domain fused to an AVITAG biotinylation signal; the second component was *E. coli* biotin ligase BirA, and the third component was streptavidin fused to tetracycline repressor (TetR-SA). A fourth component consisted of a TRE-containing promoter that controlled a human placental-secreted alkaline phosphatase target gene. In the presence of biotin and in the absence of tetracycline, VP16 was biotinylated by BirA and interacted with TetR-SA that was bound to the TRE-containing promoter, resulting in target gene expression. Upon removal of biotin, biotinylated VP16 was eliminated by degradation and target gene expression ceased. In the absence of biotin, VP16 was not biotinylated and the target gene promoter remained silent. Addition of tetracycline induced dissociation of TetR-SA from the TRE-containing promoter, disabling the target gene expression.

In summary, the newer tetracycline-controlled gene switches are capable of tightly regulating transgene expression *in vitro* and *in vivo*. Fully activated transgene expression compares well with that achievable by other small-molecule-dependent gene switches [30,31]. However, some concerns remain. TetR is of bacterial origin. Hence, there is a possibility of immune responses to TetR-derived regulators. In fact, rTA transactivators were shown to be immunogenic in monkeys, an effect that appeared to be related to short-lived expression of transgenes under their control [32,33]. Furthermore, therapy with a transgene under the control of a tetracycline-responsive gene switch may result in the development of resistance to tetracycline or other antibiotically active derivatives. Finally, there appear to exist cellular factors such as interferon α -stimulated gene factors and GATA factors that have an affinity for standard tetracycline-responsive promoters. Evidence was obtained that binding of these factors affects the activity of tetracycline-responsive systems [34,35].

29.2.2 OTHER GENE SWITCHES EMPLOYING BACTERIAL-DERIVED TRANSACTIVATORS

Gene switches that responded to streptogramins, such as pristinamycin, or macrolide antibiotics, such as erythromycin, were described [36–41]. Like the tetracycline-responsive systems, these gene switches employed transactivator proteins of bacterial origin. It is noted that pristinamycin and erythromycin are approved for human use. Cronin et al. [42] reengineered the *lacI* gene to avoid silencing and to ensure widespread expression in mouse tissues. The repressor was found capable of controlling effectively a tyrosinase transgene

in a transgenic mouse model. The transgene was active in the presence but not in the absence of inducer isopropyl- β -D-thiogalactopyranoside (administered at a nontoxic dose). Transgene expression resulted in readily visible increases in fur and eye pigmentation. Ryan and Scrable [43] reported another application of this system. The regulatory mechanisms of the *p-cym* operon of *Pseudomonas putida* were exploited for the development of several mammalian gene switches incorporating the CymR repressor that is responsive to small-molecule inducer cumate [44]. A concern common to these systems is that they involve expression of bacterial protein sequences. Therefore, the possibility of adverse immune reactions exists that may render these systems unsuitable for controlling long-term expression of transgenes.

29.2.3 GENE SWITCHES EMPLOYING STEROID RECEPTOR-DERIVED TRANSACTIVATORS

29.2.3.1 Ecdysone Receptor-Based Gene Switches

Insect ecdysone receptor (EcR) forms a heterodimeric transactivator with ultraspiracle protein (USP). USP is the insect ortholog of vertebrate retinoid X receptor (RXR) [45]. Binding of ecdysteroids (insect steroids) to EcR is increased in the presence of USP. Binding stabilizes EcR/USP complex and enhances the affinity of the complex for ecdysteroid response elements (EcRE) present in promoters of ecdysteroid response genes [46]. A mammalian homolog of EcR does not appear to exist. Ecdysteroids are not detected in vertebrates. Like mammalian steroids, ecdysteroids readily distribute to all important tissues and are quickly metabolized and cleared.

No et al. [47] described a gene switch consisting of chimeric receptor VpEcR and a target gene promoter. VpEcR is a fusion protein comprising *Drosophila melanogaster* EcR (*DmEcR*) and an HSV VP16 transactivation region. In human 293 cells, VpEcR effectively forms a complex with endogenous RXR in the presence of an ecdysteroid such as ponasterone A. VpEcR/RXR complex binds to EcRE-containing promoters and activates downstream genes. Highly induced reporter gene activity was observed in 293 cells expressing VpEcR in the presence of muristerone A. An early improvement consisted of replacing the EcRE sequences in the target gene promoter with synthetic E/GRE sequences and of mutagenizing VpEcR to enable it to bind the latter synthetic sequences. E/GRE is a hybrid between a glucocorticoid response element and a response element for a type II receptor (e.g., EcR, RXR). This improvement was aimed at preventing possible interference by endogenous receptors such as farnesoid X receptors. The improved gene switch consisting of VgEcR (mutated VpEcR) and a target gene under the control of an E/GRE-containing promoter exhibited lower basal activity and higher inducibility than a tetracycline-regulated switch in 293 cells [47].

Despite the fact that RXR is expressed in many mammalian cell types, human 293 cells were found to be uniquely capable of supporting efficient formation of EcR/RXR complex. In other cells, extra RXR needed to be supplied from

Deliberate Regulation of Therapeutic Transgenes

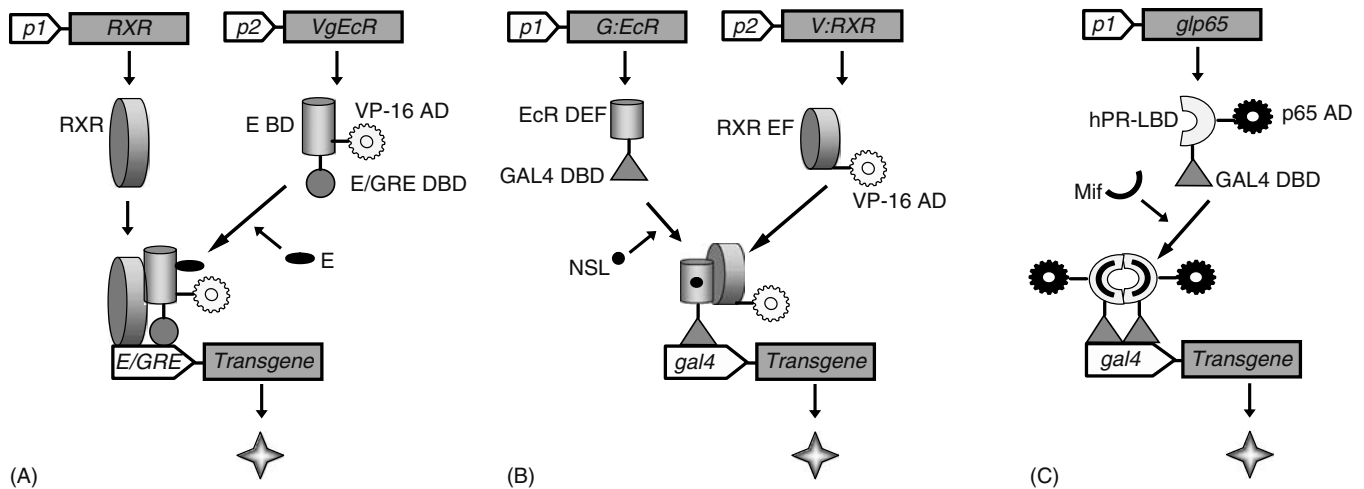

FIGURE 29.2 Gene switches employing steroid receptor–derived transactivators. (A) System based on coexpression of retinoid X receptor (RXR) and an ecdysone receptor (EcR)-derived transactivator (VgEcR) consisting of an E/GRE DNA-binding domain (E/GRE DBD), ecdysteroid-binding domain (E BD) and VP16 transcriptional activation domain (VP-16 AD). (B) EcR/RXR-based gene switch in two-hybrid format. G:EcR comprises a yeast GAL4 DNA-binding domain (GAL4 DBD) and EcR D, E and F domains (EcR DEF), and V:RXR includes a VP16 transcriptional activation domain and RXR E and F domains (RXR EF). (C) Progesterone receptor–based gene switch. The *glp65* gene encodes a mifepristone-activated transactivator comprising a yeast GAL4 DNA-binding domain, a human progesterone receptor ligand-binding domain (hPR-LBD) and a human P65 transcriptional activation domain (p65 AD). E, Ecdysteroid; NSL, nonsteroidal ligand; Mif, mifepristone.

exogenous genes (Figure 29.2A) [45,46,48]. To achieve coordinate expression of VgEcR and RXR, Wyborski et al. [49] used a CMV promoter-driven bicistronic expression cassette. Galimi et al. [50] transduced mouse hematopoietic progenitor cells with two lentiviral vectors, the first expressing the VgEcR–RXR cassette and the second harboring a reporter gene encoding GFP. Four months after transplantation into mice, exposure to an ecdysteroid increased the number of peripheral blood cells expressing the *gfp* reporter gene. This result showed that the gene switch could be employed in a gene therapy setting.

Further engineering resulted in versions of EcR-based gene switches that did not require cointroduction of an RXR gene. A modified *Bombyx mori* EcR transactivated effectively in the presence of ecdysone agonist tebufenozide [51]. Hoppe et al. [52] constructed DBEcR, a chimeric *Drosophila/Bombyx* ecdysone receptor that combined activation and DNA-binding domains of VgEcR with hinge region and ligand-binding domain of *B. mori* EcR. DBEcR was a potent transactivator in the presence of ecdysteroid ponasterone A in mammalian cells or of nonsteroidal ecdysone agonist GS-E ([*N*-(3-methoxy-2-ethylbenzoyl)-*N'*-(3,5-dimethylbenzoyl)-*N''*-tert-butylhydrazine]) both *in vitro* and *in vivo*. DBEcR-based gene switches have the advantages of being encoded by a relatively short nucleic acid, as only a single transactivator subunit needs to be supplied, and of not causing large increases in RXR concentration, which may have adverse biological effects.

More recently, EcR-based gene switches were also developed in a two-hybrid format (Figure 29.2B). Palli et al. [53] prepared a G:CfE (DEF) fusion receptor comprising the D, E, and F domains of *Choristoneura fumiferana* EcR (CfEcR)

and a yeast GAL4 DNA-binding domain. Two-hybrid partner was V:MMR (EF) comprising E and F domains of mouse RXR and a VP16 activation domain. The heterodimeric, chimeric receptor transactivated a reporter gene controlled by a *gal4* promoter almost 9000-fold better in the presence than in the absence of ligand. Nonsteroidal ligands were more effective than ecdysteroids. This system, now known as RheoSwitch, performed well in stable cell lines and a bladder cancer xenograft model [54]. Use of the ligand binding domain of a new mutant of CfEcR (GEvy) enhanced the sensitivity of the system such that maximal activation occurred at nanomolar concentrations of nonsteroidal ligands [55]. Substitution of mouse RXR sequences with corresponding sequences from *Locusta migratoria* RXR (*Lm*RXR) also increased ligand sensitivity. Two-hybrid transactivator G:CfE (DEF)–V:MMR (EF) stimulated a reporter gene in 3T3 cells at lower GS-E concentrations than G:CfE (DEF)–V:HSR (EF) [56]. A further improved RXR chimera was prepared that contained helices 1–8 from *Hs*RXR and 9–12 from *Lm*RXR and tested in combination with G:CfE (DEF). Nanomolar concentrations of GS-E sufficed to induce reporter activity in 3T3 cells. This two-hybrid gene switch also performed well in mouse muscle subsequent to *in vivo* electroporation. The development of multiplexed gene switches is also notable, which switches exploited differences in affinities of different EcR forms for steroidal and nonsteroidal ligands [57].

In summary, EcR-based gene switches are now available that exhibit high ligand sensitivity. Different systems preferentially respond to either steroidal or nonsteroidal ligands. The systems are characterized generally by low basal and high induced activities. One possible drawback of employment of

these systems in mammalian organisms relates to the fact that they necessarily include nonmammalian protein sequences. The possibility of immune responses that limit their usefulness cannot be excluded. Although EcR-based systems should not influence or be influenced by endogenous steroid regulation, a recent report by Oehme et al. [58] raises some concern. The authors observed that FasL- and TRAIL-induced apoptosis in colon carcinoma cells was inhibited by ecdysteroid muristerone A.

29.2.3.2 Progesterone Receptor-Based Gene Switches

Mifepristone is a synthetic steroid that acts as a competitive antagonist of progesterone receptor. The drug substance that was formerly known as RU486 is approved for human use. Mifepristone may be administered orally or, in animal studies, intraperitoneally (i.p.). To avoid repetitive administration, implanted mifepristone timed release pellets may be utilized [59].

A mutant human progesterone receptor lacking 42 carboxy-terminal amino acids failed to bind progesterone but interacted with mifepristone and enhanced transcription of reporter genes [60]. A chimeric transactivator was constructed by replacement of the original DNA-binding domain with a GAL4 DNA-binding domain and addition of a VP16 transcriptional activation domain at the amino terminus [61]. The chimeric receptor transactivated reporter genes controlled by a promoter containing 17-mer GAL4 upstream activating sequences in the presence of very low concentrations (0.1–1 nM) of mifepristone both *in vitro* and *ex vivo*. A more effective transactivator was obtained, in which the progesterone receptor ligand-binding domain was extended and the VP16 activation domain was added at the carboxy terminus [62]. To partially humanize the transactivator, the VP16 activation domain was replaced with an activation domain from the P65 subunit of human NF- κ B [63]. As already discussed in the context of Tet-On systems, placing transactivator expression under feedforward regulation by means of a promoter containing GAL4 response elements reduced basal activity [64]. Finally, shortening the GAL4 DNA-binding domain resulted in transactivator GS4 that has a reduced ability to homodimerize and, consequently, to transactivate in the absence of a ligand [65]. See Figure 29.2C for a depiction of a progesterone receptor-based gene switch.

Wang et al. [66] produced transgenic mice containing a gene for a mifepristone-activated, chimeric transactivator under the control of a “liver-specific” promoter and a human growth hormone (hGH) reporter gene driven by a *gal4* promoter. A single dose of mifepristone induced hGH expression, resulting in transiently elevated serum levels. Minimal induction was observed in the absence of mifepristone. Expression of hGH was reversible and could be re-induced by administration of a second dose of ligand. Similarly, transgenic mice were described that were capable of expressing inhibin under mifepristone control [59]. Mifepristone-dependent expression *in vivo* was also observed subsequent to the delivery of

transactivator and target gene by means of adenovirus vectors [63,67,68]. Mifepristone-dependent transgene expression in the brain resulted from delivery of gene switch and target gene by means of an HSV vector [69].

Generally, mifepristone-activated gene switches are characterized by low basal activity and high degree of inducibility. However, Xu et al. [31] reported that induced levels of target gene expression tend to be lower than those produced by tetracycline-responsive or dimerizer-activated gene switches. Possible concerns relate to the fact that the currently available mifepristone-dependent gene switches contain yeast GAL4 protein sequences. Hence, the mifepristone-activated transactivators may be immunogenic, limiting the usefulness of the gene switches in human genetic therapy. Furthermore, although mifepristone-dependent gene switches can be triggered by subclinical concentrations of ligand, whether these low concentrations are, in fact, without effect on the ovarian cycle appears not to be known.

29.2.3.3 Estrogen Receptor-Based, Fully Humanized Gene Switch

Roscilli et al. [70] engineered a gene switch based on chimeric transactivator HEA-3. This transactivator is comprised of the DNA-binding domain of human hepatocyte nuclear factor-1 α (HNF1 α), the G521R mutant of the ligand-binding domain of human estrogen receptor and activation domains from the P65 subunit of human NF- κ B. Transcription factor HNF1 α is expressed in the liver but not in the muscle. The G521R domain binds antiestrogen 4-hydroxytamoxifen but not estradiol. The expression of a reporter gene in cells expressing HEA-3 was three orders of magnitude greater in the presence than in the absence of 4-hydroxytamoxifen. Induction of about 100-fold was measured in mouse muscle into which transactivator and reporter genes had been electroinjected. Expression in muscle of a HEA-3-controlled erythropoietin (*epo*) gene could be maintained for about 300 days in mice dosed daily with tamoxifen, a validated drug substance that is converted to 4-hydroxytamoxifen *in vivo*.

The tamoxifen-activated gene switch was capable of effectively controlling target gene expression *in vitro* and *in vivo*. The system is fully humanized. Hence, limiting immune reactions in human therapy are not expected. Potential concerns include that activation of the system requires elevated doses of tamoxifen. Tamoxifen has been known to induce thromboembolic phenomena, a low increased risk of endometrial cancer and hot flashes (discussed in Ref. [71]). Furthermore, the DNA-binding domain of HEA-3 originates from a human transcription factor. It cannot be excluded that HEA-3 may modulate endogenous gene expression, particularly when delivered by means of standard, untargeted vectors.

29.2.4 DIMERIZER-ACTIVATED GENE SWITCHES

These gene switches take advantage of known biological properties of drug substances such as rapamycin and FK506. To begin with rapamycin, this macrolide is approved for

human use. It causes inhibition of T cell proliferation and immunosuppression. Of interest in the context of gene regulation is that the molecule distributes systemically, including in the brain. Rapamycin is known to interact with abundant immunophilin FKBP12. FKBP12–rapamycin complex associates with mTOR/FRAP and inhibits its enzymatic activity. FKBP rapamycin-associated protein (FRAP) is a phosphoinositide-3-kinase homolog that is involved in the control of cell growth and division (reviewed in Ref. [71]). The concept underlying the rapamycin-based gene switches is that essential components of a transcription factor, i.e., DNA-binding site and activation domain(s), are distributed between two fusion proteins comprising FKBP12 and sequences required for docking of rapamycin–FKBP12 complex, respectively. In the presence of rapamycin, the two fusion proteins are joined. This dimerized factor, but not the individual fusion proteins, is capable of functioning as a transcription factor.

A first rapamycin-based gene switch was described by Rivera et al. (Figure 29.3) [72]. The first fusion protein contained DNA-binding fusion ZFHD1 and three tandem copies of FKBP12. ZFHD1 includes human zinc finger and homeodomain DNA-binding domains that bind tightly to composite DNA response elements with the consensus sequence

TAATTANGGGNG [73]. The second fusion protein included FKBP12–rapamycin-associated protein (FRB), a 100-residue domain of FRAP that is sufficient for binding rapamycin–FKBP12 complex, and an activation domain from P65. The gene to be regulated was under the control of a minimal *il-2* promoter supplemented with 12 ZFHD1 binding sites. This system was tested in stably transfected cells and mice [72,74]. Strict rapamycin-dependent regulation as well as high levels of induced expression were reported. Maximal induced target gene activity was found to be limited by the nature of the transactivation domain used. The current version of the system that is considerably more active than the original version employs a combination of activation domains from P65 and human heat shock factor 1 [75].

Stringent rapamycin-dependent gene expression was observed following delivery of transactivator and target genes by means of onco-retroviral and lentiviral vectors [75,76], adenoviral vectors [77–79], HSV amplicon vectors [80], and adeno-associated viral (AAV) vectors [77,81–83]. Long-term expression following AAV-mediated delivery was investigated extensively. Johnston et al. [84] introduced an *epo* gene under the control of a rapamycin-dependent gene switch into muscle of β -thalassemic mice. Substantial increases in hematocrit values were measured upon periodic activation of

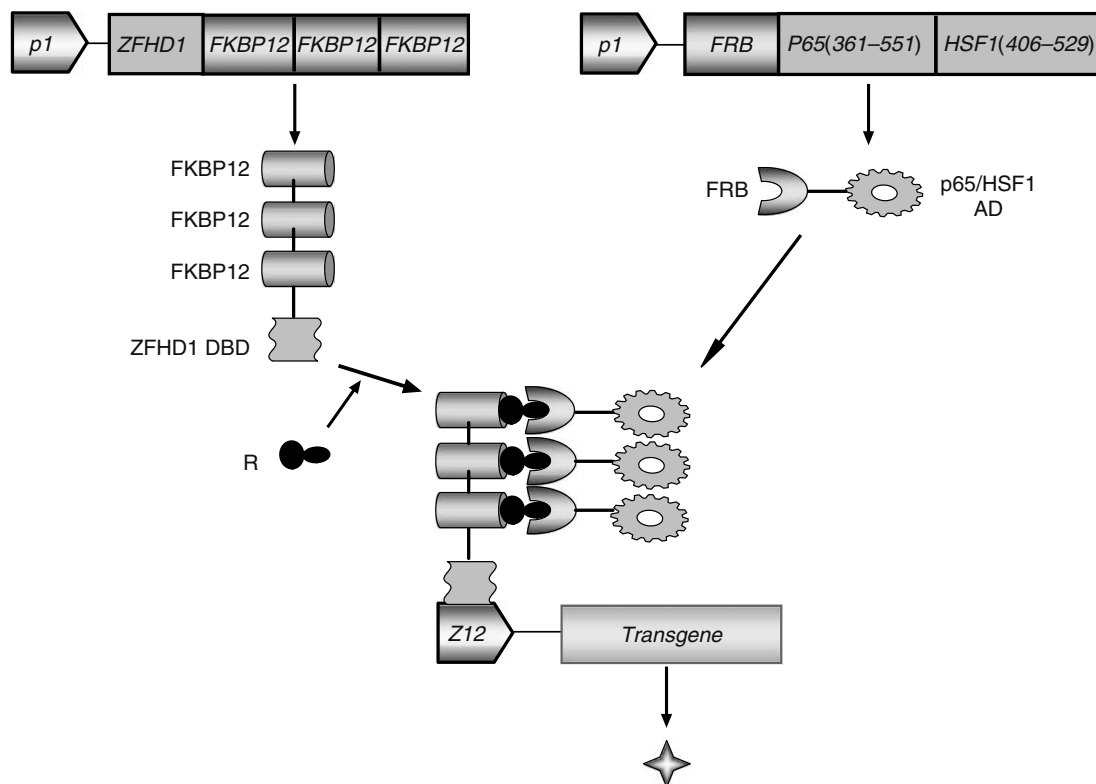

FIGURE 29.3 Rapamycin-activated gene switch. A first fusion protein encodes a ZFHD1 DNA-binding domain (ZFHD1 DBD) and three copies of FKBP12 arranged in tandem. The second fusion protein comprises the 100-residue FRB domain and a composite transcriptional activation domain made from activation domains from human P65 protein and human heat shock transcription factor HSF1 (P65/HSF1 AD). Note that numbers refer to amino acid positions in P65 and HSF1, respectively. *p1*: promoter that drives expression of fusion proteins; *Z12*: promoter containing 12 recognition sequences for ZFHD1; *R*: rapamycin.

the rapamycin-controlled *epo* gene. Importantly, the severe toxicity (polycythemia) known to be caused by uncontrolled overexpression of expression of erythropoietin (EPO) from constitutively expressed transgenes was not observed. Notably, the *epo* gene could still be activated reversibly half a year after delivery. Rivera et al. [85] introduced AAV vectors containing a rapamycin-dependent gene switch and an *epo* target gene into leg muscle of Rhesus monkeys. Remarkably, EPO expression could be induced reversibly over a period of more than five years. Induced levels of EPO were sufficient to produce significantly increased hematocrit values. Leberherz et al. [86] published results of a similar study, in which long-term inducible expression in the eyes of Rhesus monkeys was obtained.

Several studies compared optimized rapamycin-activated systems with Tet-On or Tet-Off and steroid receptor-based systems [30,31]. The consensus emerged that transgene expression was controlled more stringently by rapamycin-activated gene switches than any of the other systems. This conclusion is not surprising if one considers that rapamycin-activated gene switches are based on two proteins containing necessary components of a transcription factor, each of which has an affinity for rapamycin but not the other protein. Perhaps, the most remarkable demonstration of the degree of regulation achievable was provided by Pollock et al. [75]. These authors were able to establish a cell line, in which a rapamycin-activated gene switch controlled expression of the highly toxic diphtheria toxin A chain protein. Rapamycin-activated and Tet-On/Tet-Off systems were reported to support higher levels of target gene expression than steroid receptor-based systems.

The main concern with rapamycin-based systems relates to the immunosuppressive properties of rapamycin. However, several derivatives of rapamycin, so-called rapalogs, were identified that have greatly reduced immunosuppressive activity but still can trigger rapamycin-activated gene switches, provided that the FRB domain present in one of the two transactivator halves contains a compensatory Thr-to-Leu substitution at position 2098 [83,87]. Two such rapalogs, AP22565 and AP21967, were shown to be competent activators *in vitro* and in mice [79,83]. Rivera et al. [85] tested activation of an *epo* gene controlled by a rapamycin-activated gene switch by other rapalogs in muscle of Rhesus monkeys. AP22594 (28-epi-rapamycin), a rapalog that is about 100 times less immunosuppressive than rapamycin, was a similarly potent activator of EPO expression as the prototype drug.

Clemons et al. [88] designed an FK506-activated gene switch. This gene switch relies on interactions of FK506 and FKBP12, and of FK506–FKBP12 complex and calcium-dependent protein phosphatase calcineurin that results in immunosuppression. FK506 is a well-characterized molecule that has been used clinically. The authors succeeded in constructing a fusion protein comprising sequences from both calcineurin subunits that was capable of binding FK506–FKBP12 complex. They also were able to prepare nonimmunosuppressive derivatives of FK506 that interacted with mutant forms of the FKBP12 fusion protein. These developments enabled the construction of a novel gene switch that is activated by nonimmunosuppressive derivatives of FK506.

29.3 SPATIAL RESTRICTION OF TRANSGENE EXPRESSION: PROMOTERS RESPONDING TO EXOGENOUS STIMULI

29.3.1 RADIATION-INDUCED PROMOTERS

Irradiation of cells is known to result in changes in gene expression. A group of genes, so-called “immediate early genes,” react rapidly to ionizing radiation (IR). Protein synthesis is not required for this induction. Immediate early genes include genes for transcription factors such as c-FOS, c-JUN, AP-1, NF- κ B, and EGR-1 (reviewed in Ref. [89]). Early growth response-1 (EGR-1) binds to consensus sequence GCGGGGCG and regulates genes for tumor necrosis factor α (TNF- α), IL-1, platelet-derived growth factor α , and basic fibroblast growth factor. Activation of the *egr-1* promoter by IR is transient: it occurs within 15 min of irradiation and the promoter remains active for about 3 h. The primary mechanism of activation involves P38 kinase and JUNK/SAPK pathways that mediate phosphorylation of ternary complex factor ELK-1 and binding of serum response factor/ELK-1 complex to sequence elements comprising the core sequence CC(A/T)₆GG in the *egr-1* promoter. Alternatively, ELK-1 phosphorylation may be achieved by a mechanism that involves activated protein kinase C.

The use of focused IR for spatially restricting transgene expression was advocated by Weichselbaum et al. [90]. Their studies largely focused on tumor therapy by TNF- α and on controlling expression of TNF- α by means of an *egr-1* promoter and directed IR [91]. TNF- α was an attractive choice for an effector both because of its demonstrated antitumor activity and its known systemic toxicity. Regarding systemic toxicity, studies by Marr et al. [92,93] had shown significant toxicity of TNF- α expressed from a constitutively active gene delivered using an adenoviral vector. Concerning antitumor activity, TNF- α was known for its cytotoxicity, antiangiogenic effects, and enhancement of antitumor immunity. Considering the current limitations to gene delivery, the fact that TNF- α is a secreted molecule could be expected to contribute significantly to therapy efficacy.

Hallahan et al. [94] experimented with a nude mouse model onto which a radio-resistant human SQ-20B tumor was grafted. A pure IR therapy was compared with a combination IR/TNF- α therapy. Combination therapy involved intratumoral administration of an adenovector containing an *egr-1* promoter-controlled *tnf- α* gene (Ad.Egr-TNF). Animals were subjected to fractionated IR (50Gy). Regression of tumors was observed in the course of a 60-day period. Regression was more pronounced for the combination therapy than the pure IR therapy. Immunochemical analysis of tumor samples revealed that irradiation produced an eightfold increase of TNF- α expression. It is noteworthy that serum concentration of TNF- α remained far below the known toxic level. As far as the mechanism of regression is concerned, Hallahan et al. observed that the combination therapy produced significant tumor cell apoptosis and necrosis in the tumor bed. Work by others indicated that the therapy resulted in selective damage to the tumor vasculature [95,96]. An antiangiogenic effect of TNF- α was also described [97].

Two phase I clinical trials investigated combination therapy with IR and TNF- α . These trials were completed and were reviewed in Mezhir et al. [98]. Generally, the trials showed improved tumor responses compared to historical controls. TNF- α was provided by means of a recombinant adenovirus referred to as TNFerade. TNFerade consisted of a second generation adenovirus vector containing E1, E3, and E4 deletions that harbored a *tnf- α* gene functionally linked to an *egr-1* promoter. In one of these phase I studies, patients having different types of solid tumors were treated by intratumoral injections of TNFerade over a period of 6 weeks (4×10^7 to 4×10^{11} particle units) and IR (30–70 Gy) [99]. Twenty-one of the 30 evaluable patients showed objective tumor responses. The study also included five patients with synchronous lesions. Both lesions were subjected to IR, but only one received TNFerade. In four of the five patients, the combination treatment showed an improved response compared to IR alone. In the other study, patients with soft tissue sarcomas of the extremities were injected intratumorally with TNFerade over a 5-week period (4×10^9 to 4×10^{11} particle units) and received IR (36–50.4 Gy) [100]. Tumor responses, including two complete responses, were recorded in 11 of the 13 evaluable patients. No dose-limiting toxicity of TNFerade was observed. Several phase II trials are under way.

Other combinations of radiation-induced promoters and transgenes were also tested. Kawashita et al. [101] examined effects of a suicide therapy in a hepatocellular carcinoma model. The therapy involved delivery of an HSV thymidine kinase (*tk*) gene under the control of an *egr-1* promoter. Tsurushima et al. [102] recently tested a plasmid harboring the radiation sensitive *egr-1* promoter linked to a gene for tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) for the treatment of malignant gliomas. *In vivo* electroporation of U251 gliomas growing subcutaneously in nude mice followed by IR led to significant decreases in tumor volumes. Worthington et al. [103] prepared a construct comprising an inducible nitric oxide synthase (*inos*) gene controlled by a *p21/waf1* promoter and utilized this construct to transfect rat tail arterial sections. After a 4 Gy IR dose, a fivefold increase in iNOS level could be measured, whose increase correlated with a dramatically reduced contractile response to phenylephrin. The same group also advocated use of a *p21* promoter for controlling *inos* gene therapy of cancer. The combination of iNOS and IR showed efficacy in models of both p53 wild-type and p53 mutant tumors [104]. The *p21* promoter, transduced by rAAV vectors, was found to be remarkably responsive to very low doses of IR [105]. This high sensitivity of the *p21* promoter to IR may be exploited for the design of safer, radiation-based cancer gene therapies.

The *egr-1* promoter is only weakly inducible by IR [106]. However, significant improvements were shown to be possible. Manipulation of the CArG units of the *egr-1* promoter was found to enhance the response to IR. Improved IR responsiveness was obtained after increasing the number of CArG elements or after specific alteration of the core A/T sequences [107]. Combination of optimal number and sequence of CArG elements resulted in the best IR induction levels attained to

date, both *in vitro* and *in vivo*. Scott et al. [108] designed a two-component gene switch. The first component was a gene for CRE recombinase under the control of a synthetic *egr-1*-like promoter. The second component consisted of a gene for an enhanced GFP (EGFP) linked to a CMV promoter. Promoter and gene were separated by a stop cassette flanked by LOX sites. IR induced expression of CRE recombinase from the first construct. CRE recombinase removed the stop cassette from the second construct, enabling EGFP expression. EGFP expression was found to be induced about 40-fold by IR. It is noted that target gene expression is irreversibly activated by IR in this system, limiting its range of possible applications. A gene switch of this type was recently employed by Greco et al. [109] in a model of IR-induced HSV *tk* suicide tumor therapy.

As reviewed herein, radiation-inducible promoters were used successfully to regulate different transgenes, and therapeutic effects, without limiting toxicity, were obtained. As therapies become more effective, the low inducibility, a significant basal activity of many radiation-induced promoters, is expected to become an obstacle to their therapeutic use. However, it has already been demonstrated that systems with substantially increased inducibility can be engineered. Hence, improved IR-induced systems may be available when the need arises. What remains are potential dangers inherent in IR. IR-inducible gene switches may be utilized primarily in situations in which IR therapy has some demonstrated effectiveness and addition of an IR-induced transgene can be expected to improve upon the therapeutic outcome.

29.3.2 HEAT-INDUCED PROMOTERS

Heat can be administered to a subject in a focused fashion. Heat delivery may be achieved simply by contact with a heated surface or liquid. Microwave devices may be utilized for heating selective body regions. Devices that should be suitable for such applications have been constructed and are being marketed for hyperthermic treatment of tumors. Infrared radiation allows for heating of areas close to the body surface, while ultrasound can heat deep-seated areas. Combining focused ultrasound and magnetic resonance imaging (MRI)-based, real-time temperature mapping resulted in an approach that was shown to be capable of achieving controlled heating of narrowly defined regions within the body [110,111].

Heat shock or stress protein (*hsp*) genes are a small group of conserved genes encoding proteins (HSPs) of different subunit molecular weights. Different HSPs are named HSP90, HSP70, HSP60, etc., the numbers referring to approximate subunit molecular weights in kDa. While HSPs are normally present and play important physiological roles, they accumulate transiently to elevated levels in cells exposed to certain physical and chemical stresses. Elevated levels of stress proteins are known to tolerize cells to the latter stresses. HSPs are typically expressed from multiple genes, of which at least one is induced when cells are exposed to a mild to moderate physical or chemical insult. Heat appears to be the most powerful inducer of these genes. One of the most highly inducible

hsp genes appears to be the human *hsp70B* gene. First described in 1985, the promoter of this gene (hereinafter the *hsp70B* promoter) has a very low basal activity, which increases several thousand fold upon heat induction [112–114].

The only recognizable feature common to heat-inducible *hsp* promoters is the presence of one or more so-called heat shock elements (HSEs). These HSEs typically comprise three or more modules of the sequence NGAAN that are joined in alternating orientations. HSEs are binding sites for heat shock factors (HSFs). The *hsp70B* promoter contains three HSEs located within about 300bp from the transcription start site. All three elements appear to contribute to the heat inducibility of the promoter [113]. Note that “minimal *hsp70B* promoter” refers to a truncated *hsp70B* promoter that includes the latter three HSEs but little additional upstream sequence.

Induced expression of *hsp* genes is mediated by HSFs that interact with HSEs present in their promoters. Although mammalian cells express at least three different types of HSFs, the factor known as HSF1 appears to be the most important. This conclusion is based on the observations that (1) heat-induced HSE DNA-binding activity can be traced back to HSF1 (reviewed in Ref. [115]), (2) heat or chemical stresses do not induce *hsp* genes in HSF1-deficient mice [116], and (3) a constitutively active form of HSF1 is capable of inducing enhanced expression of inducible HSPs [117]. HSF1 is ubiquitously expressed and is normally present in an inactive form. Transient activation of HSF1 occurs when a cell is exposed to heat or another insult. This activation is a complex process that involves homotrimerization of the factor (reviewed in Ref. [118]).

As was discussed above, heat can be delivered in a focused fashion. Consequently, it should be possible to use *hsp* promoters for spatially controlling transgene expression, a concept that has been discussed since the 1990s. *hsp* promoters have several additional attributes that should increase their usefulness. Perhaps, the most important among these additional features is that the promoters can be activated in most cell types. Hence, it should be possible to activate a therapeutic gene throughout an organ comprised of different tissues or a complex tumor, eliminating the concern associated with the use of tissue-restricted promoters that certain cells or tissues within an organ or complex tumor may escape therapy. From the point of view of convenience, only one transgene construct would need to be prepared. This construct could be expected to be functional in all possible target tissues. Furthermore, the level of induced activity of an *hsp* promoter is correlated with the intensity of the activating heat dose. Therefore, it should be possible to express in a target tissue a therapeutic gene product at the level that produces optimal therapeutic results. Moreover, activated *hsp* promoters support higher levels of target gene expression than many tissue-restricted promoters. Finally, heat activation of *hsp* promoters is reversible. The promoters are silenced within a period of at most a few hours from the activating heat treatment. Hence, they provide an element of therapeutic safety. However, as is discussed in more detail below, this feature of *hsp* promoters also limits

their usefulness as they may not be suitable for directing therapies requiring transgene activity for more than the latter short time window.

Several studies demonstrated that the *hsp70B* promoter can be utilized for local control of transgene expression. In one such study, an *egfp* reporter gene linked to a minimal human *hsp70B* promoter was introduced into rat C6 glioblastoma cells and a stable cell line was selected [119]. This line was introduced subcutaneously in nude mice. After sizeable tumors had developed, the tumor cells were heated by means of a heated needle that was inserted in the tumors. Heating was either at 50°C for 3 min or at 43°C for 30 min. Strong induction of EGFP expression occurred in heated tumors but not in unheated tumors. The shorter heat treatment at the higher temperature resulted in a better definition of gene activity within the tumors. Time courses of transgene activation and silencing were defined *in vitro*: Peak EGFP level was attained one day after thermal treatment. Two days later, EGFP concentration had returned to background level.

Huang et al. [120] prepared *hsp70B-egfp*, *hsp70B-tnf- α* , and *hsp70B-il-12* gene cassettes and introduced them in replication-deficient adenovirus vectors. Initial experiments in which 4T1 mouse mammary tumor cells were infected with the different viruses revealed that all three transgenes were highly induced by heat treatment (41–43°C for 20 min). EGFP level, detected by fluorescence-activated cell sorter (FACS), increased 500–1000-fold, and levels of TNF- α and IL-12 6.8×10^5 and 13,600-fold, respectively. EGFP level was maximal 18–24 h after heat treatment. At 72 h, EGFP was no longer detectable. Induction *in vivo* was tested following injection of recombinant adenoviruses into B16F10 melanomas growing subcutaneously in the hindleg of C57BL/6 mice and heat treatment by immersion for 40 min in a 42°C waterbath. Induction factors of 835 and 33 were determined for TNF- α and IL-12, respectively. In the absence of heat treatment, expression of the two cytokines was not detected.

Adenovectors containing an *hsp70B-luciferase* (*Ad-hsp70B-luc*) or an *hsp70B-Fas* ligand gene cassette (*Ad-hsp70B-fasl*) were prepared by Smith et al. [121]. The constructs were first tested *in vitro* in smooth muscle cells. The *hsp70B* promoter-driven luciferase gene was essentially silent in the absence of a heat treatment. Heat treatment resulted in a rapid rise of luciferase activity. Consistent with observations made in the previous study and elsewhere, luciferase activity declined to an undetectable level within about 48 h after heat treatment. To test the *hsp70B-luciferase* cassette *in vivo*, *Ad-hsp70B-luc* was injected intradermally in immunodeficient mice or rats. Localized heating was achieved by means of a portable therapeutic ultrasound device. Luciferase activity was assayed 12 h after heating. No luciferase activity above background was detected in unheated animals, whereas substantial activity was measured in heat-treated animals. Induction factors were 212-fold in mice and 540-fold in rats. *Ad-hsp70B-fasl* was introduced through the rat tail vein. The abdominal region was heated by directed ultrasound. Elevated levels of liver enzyme alanine aminotransferase were detected in locally heat-treated animals, where as only normal levels were found

in not-heated animals. This result was taken to suggest that FasL expression also was stringently controlled *in vivo* by the *hsp70B* promoter.

Guilhon et al. [122] explored the benefits of using online magnetic resonance (MR) thermometry for enhancing the spatial accuracy of tissue heating by focused ultrasound. The authors were able to specifically heat subcutaneous C6 glioblastoma-derived tumors containing an *hsp70B*-driven *egfp* gene, inducing strong expression of the reporter protein. It is noted that to obtain optimal definition of the heated area, heating was intense but of short duration.

The feasibility of using focused ultrasound-induced hyperthermia for precisely inducing expression of a target gene under the control of an *hsp70B* promoter in liver, a deep-seated parenchymal organ, was demonstrated by Plathow et al. [123]. An adenovector containing an *hsp70B-gfp* gene cassette was injected into the tail vein of Copenhagen rats. Twenty four hours later, acoustic power at 1.92 W was directed to the rat livers. As indicated by noninvasive magnetic resonance imaging (MRI)-based temperature mapping, a relatively uniform focal temperature reaching 42.5°C within liver parenchyma was achieved. One day later, animals were euthanized and liver sections were examined. Fluorescence microscopy indicated that the *hsp70B* promoter-controlled gene was specifically expressed in the heated areas. In another study conducted by Sicox et al. [124], an adenovirus harboring an *hsp70B*-luciferase gene cassette was directly administered into both lobes of the prostate of three beagles. Two days later, the left lobe of the prostate was heated by MRI-guided ultrasound. High levels of luciferase expression could be measured that were restricted to the areas that had been heated by ultrasound.

In another study of directed ultrasound heating, an *hsp70B*-luciferase gene cassette was introduced in gastrocnemius muscles of mice by electroinjection [125]. The muscles were heated by focused ultrasound. Heating was feedback-controlled by means of a thermocouple inserted in the muscles. Heat-induced luciferase expression was maximal after 24 h. Two days later, activity had declined to background level. The optimal *in situ* heat dose was surprisingly low (39°C for 30 min). Perhaps, the muscles had been mildly injured by the electroinjection procedure and had not recovered by the time of heat treatment, which was administered only one day later.

The *hsp70B* promoter was used to control therapeutic transgenes in several model studies of cancer therapy. Huang et al. [120] injected adenoviruses containing *hsp70B*-controlled *il-12* or *egfp* genes into B16F10 tumors growing subcutaneously in hindlegs of C57BL/6 mice. Two virus doses were administered 1 week apart. After each virus dose, hindlegs were heated by immersion for 40 min in a 42.5°C waterbath. Tumor growth was delayed significantly in the experimental group (*il-12* gene- and heat-treated) but not in control groups. In a related study, adenovirus vector containing an *hsp70B-il-12* gene cassette was injected into B16F10 melanomas or 4T1 mammary adenocarcinomas growing in C57BL/6 mice [126]. Heating was done as before, i.e., by immersion in a water bath for 40 min at 42.5°C. Twenty four hours later,

substantial levels of IL-12 were detected in the tumors, while systemic toxicity was negligible. IL-12 levels in liver were significantly lower than those detected in animals that had been injected intratumorally with an adenovirus carrying an *il-12* gene controlled by a constitutively active promoter. In a study by Siddiqui et al. [127], intratumoral injection of an adenoviral vector containing an *hsp* promoter-linked murine *il-12* gene followed by heat treatment produced antiangiogenic effects in 4T1 tumors growing in Balb/C mice. A replication-deficient adenoviral vector was recently designed for delivering the feline *il-12* gene under the control of the human *hsp70B* promoter [128]. This vector was tested in a phase I clinical trial in cats with spontaneously arising soft tissue sarcoma. Intratumoral injection of adenovirus followed by heating for 1 h at 41°C resulted in high levels of *il-12* mRNA in the tumors and limited systemic toxicity [129].

Brade et al. [130] constructed a modified *hsp70B* promoter, *HSE.70b*, by addition of three synthetic HSE sequences to a minimal *hsp70B* promoter. The *HSE.70b* promoter could be induced by lower heat doses than the original *hsp70B* promoter. The *HSE.70b* promoter was utilized in a subsequent study for controlling the expression of a gene encoding a modified Gibbon ape leukemia virus envelope protein (GALV FMG) [131]. GALV FMG induces cell-cell fusion in permissive cells [132,133]. An *HSE.70b-galv fmg* gene cassette was introduced into HT-1080 tumor cells and stable line HG5 was isolated. In a model tumor therapy experiment, HG5 and control line CII were injected in hind limb footpads of severe combined immunodeficiency (SCID) mice. After sizeable tumors had formed, hind limbs were heat-treated by immersion in a waterbath for 30 min at 44°C. Animals were monitored and sacrificed at tumor volumes of 150 mm³. Median time to sacrifice of mice containing an HG5 tumor was 52 days for heat-treated animals versus 4.3 days for not-heated animals. Only a minor effect of heat treatment was observed in mice with control tumors.

Braiden et al. [134] delivered in several passages an HSV *tk* gene under the control of the *hsp70B* promoter or a control gene to FM3A tumors (mouse mammary carcinoma) growing subcutaneously in nude mice using HVJ (Sendai virus) liposomes. Animals were heated every other day by immersion in a waterbath for 30 min at 43°C. Gancyclovir (GCV) was administered daily during a 2-week period. Animals whose tumor had been administered the *hsp70B*-HSV *tk* gene cassette and were heat-treated showed tumor regression. Animals whose tumor was not heat-treated or had received a control gene instead of the *hsp70B*-HSV *tk* gene cassette continued to grow. In a further experiment, intraabdominal FM3A tumors were treated with *hsp70B*-HSV *tk* liposomes, GCV, and heat exposures. This treatment resulted in a survival rate of 80% at the end of the observation period. Control mice did not survive. A recent study extended these observations to a model of gastric cancer [135].

The studies reviewed above demonstrated convincingly that the *hsp70B* promoter was capable of stringently controlling expression of transgenes *in vivo*. Regional administration of heat resulted in gene expression that was confined to

tumors, organs, or limbs. Focused ultrasound guided by MRI was capable of restricting heating, and consequently, transgene expression to narrowly defined body regions (of about 1 cm in diameter) [110,122]. Several studies investigated time courses of appearance and subsequent disappearance of gene products expressed from *hsp70B* promoter-controlled genes. Typically, gene products accumulated to maximal levels about 1 day after activating heat treatment. About 2 days later, concentrations had fallen to undetectable levels. Although single-activating heat treatments produced therapeutic effects in some of the tumor therapy experiments summarized above, the expectation is that the therapeutic window represented by the time of activity of an *hsp* promoter subsequent to an activating heat treatment is generally too short for effective therapy. Hence, effective clinical protocols may be envisioned to resemble that used in the Braiden study [134], in which elevated levels of transgene product were maintained through multiple heat treatments administered at regular intervals. Obviously, such protocols would be burdensome for patient, physician, and hospital. A concern particular to the use of *hsp* promoters in the context of cancer therapies has been that activating heat treatments would not only enhance expression of a therapeutic protein but also that of endogenous HSPs. Elevated levels of HSPs, which are known to have cytoprotective and antiapoptotic properties, could neutralize the effects of the therapeutic gene product. However, in the experiments reported to date, heat treatments administered for the activation of *hsp70B* promoter-controlled transgenes did not appear to interfere with therapy efficacy. Surprisingly, *in vitro* experiments reported by the Braiden study [134] even furnished evidence for a substantial synergistic effect of heat on tumor cell killing by TK/GCV. Heat treatment of mouse mammary carcinoma FM3A cells constitutively expressing an HSV *tk* gene reduced the IC₅₀ of GCV by about 15-fold. This effect was ascribed to increased levels of Fas and FasL in the heated cells. Other studies demonstrated that cell killing induced by powerful mediators of apoptosis was potentiated by heat treatment or introduction of a constitutively active form of HSF1 [136,137].

29.4 *hsp70* PROMOTER-BASED GENE SWITCHES FOR DELIBERATE SPATIAL AND TEMPORAL REGULATION OF TRANSGENES

As discussed before, *hsp* promoters remain active for at most a few hours after heat activation. At the level of protein product of a transgene controlled by an *hsp* promoter, synthesis of the protein will continue after the controlling *hsp* promoter has returned to an inactive state. However, continued expression may not last much longer than one day, if that long. This narrow time window of active synthesis of therapeutic gene product will not be compatible with therapies requiring the continued presence of an effective level of a therapeutic protein over a longer period of time. In addition, the short period of activity of *hsp* promoters caps peak levels of gene product that can be attained. Repetitive heat treatments administered

at an appropriate interval could compensate at least partially for these shortcomings. However, as also alluded to before, a clinical protocol involving multiple, carefully timed heat treatments may not be accepted readily by patients and care providers.

A more important problem is involuntary activation of *hsp* promoter-controlled therapeutic genes that could occur subsequent to therapy in target as well as nontarget tissues. When occurring in the wake of cytotoxic, cytostatic, or angiogenic therapies, such involuntary activation of the therapeutic gene could compromise severely patient safety. The problem arises from the fact that current technology is not capable of targeted delivery of transgenes. Transgenes inevitably are disseminated systemically even if initially administered directly to a target tissue such as a tumor [138]. A rise in body temperature caused by disease, strenuous exercise, or certain pharmacological interventions, or by ischemic events [139–146] could cause inadvertent activation of an *hsp* promoter-controlled transgene, resulting in systemic expression of transgene product. Ingestion of heavy metals and other toxicants could also prompt activation (see, e.g., Ref. [147]). While it should be possible to avoid such inadvertent systemic activation during therapy in a hospital setting, this would be difficult or impossible to achieve subsequent to hospital discharge or in the context of outpatient care, i.e., when patients are not or no longer monitored carefully (or do not wish to be restricted in their customary activities).

We hypothesized that both problems associated with uses of *hsp* promoters, i.e., insufficiently long periods of transgene expression and the possibility of inadvertent, systemic expression of transgenes encoding highly potent mediators/ effectors could be avoided by a regulatory circuit that properly combined an *hsp70B* promoter and a small-molecule-dependent transactivator [148]. Figure 29.4 outlines components and operation of such a gene switch. The first component is a gene for a small-molecule-dependent transactivator that is under the control of a dual-responsive promoter or promoter cassette. This promoter cassette or promoter incorporates an *hsp70B* promoter and a transactivator-responsive promoter or combines aspects thereof. The second component is a transactivator-responsive promoter that is functionally linked to a target gene. In a cell-containing gene switch and target gene, neither transactivator nor target gene is expected to be expressed in the absence of small-molecule ligand and without an activating heat treatment. Heat treatment will trigger activation of endogenous HSF1, which transactivates the transactivator gene. Transactivator will be synthesized. However, in the absence of small-molecule ligand, transactivator will remain inactive and the target gene will not be expressed. In the presence of small-molecule ligand alone, the minute amounts of transactivator present in the unheated cell will be insufficient to cause autoactivation of the transactivator gene. When the cell is both exposed to small-molecule ligand and subjected to a transient heat treatment, activated HSF1 will transactivate the transactivator gene. Newly made transactivator will be bound by small-molecule ligand, become transcriptionally competent, and transactivate the

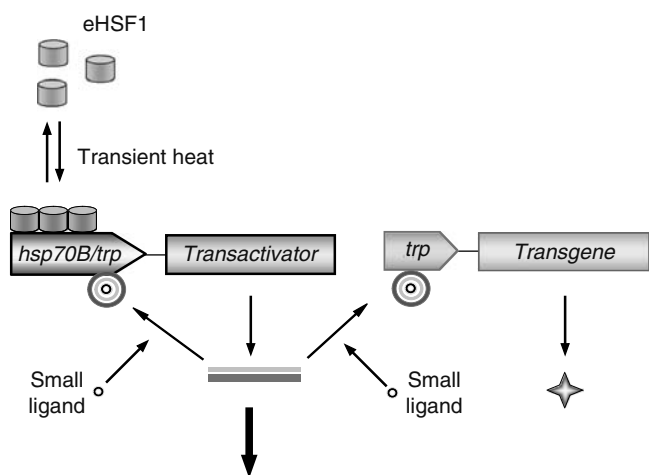

FIGURE 29.4 Heat-activated and small-molecule ligand-dependent gene switch comprising a transactivator gene controlled by a promoter comprising components of an *hsp70B* promoter and a transactivator-responsive promoter (*trp*) or a promoter cassette including an *hsp70B* promoter and a *trp* promoter, and a *trp* promoter to which a transgene of interest is linked. The solid arrow indicates transactivator turnover. eHSF1, endogenous heat shock transcription factor 1.

target gene as well as autoactivate its own gene. Even though HSF1 will revert to its inactive state shortly after heat treatment and the *hsp70B* promoter or promoter-component will become silent, transactivator level is expected to be maintained by the latter feedforward mechanism. Target gene expression should continue for as long as small-molecule ligand is present. Removal of ligand should return the gene switch to its initial inactive state.

The elements of an actual regulatory circuit are depicted in Figure 29.5. Its first component included a gene for GLP65,

FIGURE 29.5 Heat-activated and mifepristone-dependent gene switch comprising transactivator gene *glp65* that is under the control of cassette promoter *hsp70B/gal4*, which responds to activated endogenous heat shock factor 1 (eHSF1) as well as GLP65, and GLP65-responsive promoter *gal4* that controls the linked luciferase transgene. The solid arrow indicates transactivator turnover. Mif, mifepristone.

a partially humanized, mifepristone-activated, chimeric transactivator containing a GAL4 DNA-binding domain [63] (see also Section 29.2.3.2). This gene was controlled by a promoter cassette that combined an *hsp70B* promoter and a *gal4* promoter. The second component was a *gal4* promoter that was linked to a target gene, e.g., a luciferase gene.

This gene switch was tested extensively *in vitro* and *in vivo* [148]. The firefly luciferase gene was utilized as the target gene for most of these experiments. Because of the low stability of mRNA and protein product, luciferase activity served as a reasonable indicator of transcriptional rate. Stability and performance was examined in a human cell line stably containing gene switch and luciferase target gene. The key findings are represented by the data shown in Figure 29.6. The system had very low basal activity in the absence of an activating heat treatment and mifepristone. Addition of mifepristone as well as continued exposure to mifepristone for 6 days did not

FIGURE 29.6 Performance of the mifepristone-activated gene switch shown in Figure 29.5 in a cell line stably transfected with gene switch and luciferase reporter/target gene. Top panel: Reporter gene activity one day after activating heat treatment (HS) at 43°C. Bottom panel: Reporter gene activity 1 day (1d) and 6 days (6d) after heat activation (43°C/2h) in the presence of mifepristone, and reversibility of activation. *Mifepristone was washed away 1 day after heat activation. Mif: mifepristone. See Vilaboa, N. et al., *Mol. Ther.*, 12, 290, 2005 for a more complete data set.

cause a significant increase in luciferase activity. Heat treatment in the absence of mifepristone was without effect. However, in the presence of mifepristone, a 2 h heat treatment at 43°C resulted in a luciferase level that was about 1000 times higher than basal activity. Luciferase expression was proportional to the activating heat dose (cf. activity levels induced by 1 or 2 h heat treatments). Finally, high-level, induced expression of luciferase continued throughout the entire observation period of 6 days. Removal of mifepristone 1 day after activating heat treatment led to rapid decline in luciferase level; background level was attained 3 days later. A similar gene switch and luciferase target gene were electroporated into hindleg muscles of mice [148]. Basal luciferase activity in the muscles was extremely low. A transient heat treatment administered to the hindleg in the presence of systemic mifepristone resulted in a 1000-fold increase in luciferase activity. As in the *in vitro* experiments, the system proved essentially insensitive to heat alone or mifepristone alone. Furthermore, induced activity persisted at a high level during the 6-day observation period during which mifepristone was maintained by daily i.p. injections. Discontinuation of mifepristone administration resulted in deactivation of the gene switch.

These studies demonstrated that a gene switch that combines an *hsp70B* promoter and a small-molecule-dependent transactivator could overcome the shortcomings of *hsp* promoter-based transgene regulation. A single-activating heat treatment produced sustained high-level expression of a transgene. Moreover, transgene expression was dependent on the continuous presence of transactivator ligand. Hence, the danger of inadvertent systemic transgene expression subsequent to therapy can be avoided by using such a system.

29.5 CONCLUDING REMARKS

Until vehicles become available that deliver transgenes with exquisite selectivity to any tissue or organ afflicted by a disease susceptible to gene therapy, achievement of effective transcriptional targeting remains an important goal.

As illustrated in the preceding section, versatile *hsp*-based gene switches can be assembled that are expected to be capable of activation in essentially all cell types. The gene switches allow for deliberate control over spatial as well as temporal aspects of transgene expression. Transgene activity can be restricted to the tissue or organ of interest by means of a focused, transient heat treatment that initiates expression of a small-molecule-dependent transactivator. Transgene expression commensurate with a particular therapeutic window can be achieved by an appropriate protocol of small-molecule administration. In addition, transgene activity may be adjusted to a desired level by modulation of the activating heat dose. Methods for accurate heating of narrowly defined regions within the body were developed as evidenced by the studies reviewed in Section 29.3. Hence, clinical exploration of *hsp*-based gene switches should now be feasible.

The example *hsp*-based gene switch discussed in Section 29.4 incorporated a mifepristone-activated gene switch. In

principle, any small-molecule-controlled gene switch may be utilized, including those described under Section 29.2. The choice of small-molecule-controlled gene switch will impact the properties of the resulting *hsp*-based gene switch. As discussed in Section 29.2, small-molecule-dependent gene switches can differ in respect of both maximal levels and basal, uninduced levels of transgene expression. Additional differences originate from the nature of the small-molecule ligands that activate or repress particular transactivators. The ligands may or may not distribute to all tissues, and they will have different *in vivo* half-lives and toxicities. Furthermore, they may or may not affect endogenous gene expression, and consequently cause unintended physiological reactions. Finally, transactivators may differ in the degree of humanization and, therefore, may pose a greater or lesser danger of untoward immune reactions. Given these differences, the optimal choice of small-molecule-controlled gene switch to be incorporated in an *hsp*-based gene switch can be expected to be influenced by multiple factors, including the potency of the therapeutic gene product in question, the therapeutic indication targeted, and the anticipated therapy protocol. Certainly, future improvements that may be made to different ligand-dependent gene switches will also affect this choice.

Radiation-inducible promoters are encumbered with similar limiting features as *hsp* promoters. They are inactivated within hours of irradiation. As with *hsp* promoters, there exists a danger of inadvertent activation. Radiation-inducible promoters can be expected to be activated by many drugs, including several widely used chemotherapy drugs [98]. Because of the similarity of problems, the principles used for the design of *hsp*-based gene switches should also be applicable to the preparation of IR-inducible promoter-based gene switches. Such gene switches would not only increase the safety of IR-induced therapy but may also allow for the use of therapy protocols that cannot presently be envisaged, e.g., sequential radiation-induced genetic therapy and classical chemotherapy of cancer.

30.1 INTRODUCTION

Human clinical trials for gene- and cell-based therapeutic strategies can be significantly aided by the ability to determine the locations, magnitude, and time variation of transgene expression. Gene therapy vectors have to be held accountable for their actions and recent developments in noninvasively imaging gene expression in living subjects are certain to help in this regard. Following delivery of a therapeutic vector into a

patient, a gene therapist wants to know the answers to some fundamental questions: Did the vector get delivered to the desired target organ, tumor, or cell population or have inappropriate tissues been transfected? Did gene transfer or transcription take place? How much gene product is being generated from the transgene? How much control do I have in the expression of this vector? What happens to expression levels as the patient responds (or fails) to therapy? Current clinical methods have difficulty in answering these questions: They rely upon

serum markers, tissue sampling followed by histochemical analysis or autoradiography, anatomical-based imaging, and physical examination, most of which are inefficient, invasive, or inadequate in this era of targeted gene therapy and molecular medicine. Answering these questions rapidly, easily, and effectively during a patient's clinical course is clearly desirable not only to tailor an individual patient's needs and improve clinical outcomes but also to promote gene therapy for routine clinical use.

Recognizing this need, molecular imaging researchers have advanced the principles of reporter gene technology for use in intact, viable subjects. To the molecular biologists, reporter gene technology is well-trodden territory and they have been familiar with the process of coupling a reporter gene to a therapeutic gene as a means of measuring the efficacy of gene delivery and tracking gene expression. Commonly used reporter genes for *in vitro* or *ex vivo* analyses include: (a) chloramphenicol acetyltransferase, which transfers (radioactive) acetyl groups to chloramphenicol and detection is rendered through thin layer chromatography and autoradiography [1–3]; (b) β -galactosidase (GAL), which hydrolyzes colorless galactosides to yield colored precipitate, is detected via tissue extracts or histochemical techniques [4–6]; (c) β -lactamase, which catalyzes hydrolysis of cephalosporin, is monitored by a change in fluorescence emission of a substrate [7,8]; (d) green fluorescent protein (GFP), which fluoresces upon radiation, is examined with epifluorescence microscopy or utilized in cell sorting techniques [9–11]; (e) Firefly luciferase (FL), which oxidizes D-luciferin to generate bioluminescence, can be visualized

using luminometry or microscopes fitted to specialized cameras [12,13]; and (f) Renilla luciferase, which catalyzes oxidation of coelenterazine, leading to bioluminescence [14]. While some of these technologies cannot make the jump into studies of living subjects (e.g., chloramphenicol acetyltransferase, β -galactosidase) because of technical limitations, the optically based technologies, such as those based on GFP and the luciferases, have been applied to intact, small living subjects using sensitive optical detection systems [15–18].

Furthermore, there has been an exciting surge in the development of reporter gene technologies that are compatible with current clinical imaging modalities such as the radionuclide-based techniques (positron emission tomography [PET] and single-photon emission computed tomography [SPECT]), magnetic resonance imaging (MRI), and magnetic resonance spectroscopy (MRS). To understand these clinical technologies does not require a large leap of faith. In fact, they are conceptually similar to the optical systems described above. All *in vivo* reporter techniques, including the aforementioned optical techniques, depend on the detection of electromagnetic homing signals that arise either from the probe itself or the specific interaction of a reporter protein and its corresponding reporter probe. Just as GFP emits photons in the visible range of electromagnetic spectrum, which can be seen with the naked eye or cameras, radionuclide-based reporter techniques emit photons in the gamma ray-wave range that are detected by specialized scintillation crystals or more recently solid state detectors. Table 30.1 lists the various reporter systems available for *in vivo* imaging. In this chapter,

TABLE 30.1
Summary of Reporter Gene Systems Used in Living Subjects

Method	Imaging	Reporter Gene	Action	Imaging Agent/Substrate	Ref.	
<i>In vitro</i> (selected few)	Chromatography and autoradiography	Chloramphenicol acetyltransferase	Acetylation	Radioactive acetyl group	[2]	
	Light microscopy	β -Galactosidase	Hydrolysis	Metabolized galactosides	[6]

we will discuss the basic principles of the various tools now available, display several examples of the images generated from such tools, and at the end, provide a strategy to help scientists or gene therapists interested in using *in vivo* reporter techniques to choose optimal strategies.

30.2 IMAGING INSTRUMENTATION FOR LIVING SUBJECTS

30.2.1 BASIC PRINCIPLES OF OPTICAL IMAGING (FLUORESCENCE AND BIOLUMINESCENCE)

Although photons emitted in the visible light range of the electromagnetic spectrum face considerable obstacles traveling through layers of tissues, notable advances in light sensor technology have permitted the use of optical reporter genes in intact organisms. There are fundamentally two different types of optically based imaging systems: (a) fluorescence imaging, which uses emitters such as GFP, wavelength-shifted GFP mutants, red fluorescent protein (RFP), fluorescent small molecules, “smart” near-infrared fluorescent (NIRF) probes and (b) bioluminescence imaging, which utilizes systems such as firefly luciferase-D-Luciferin or Renilla luciferase/Gaussia luciferase-coelenterazine [15,19–21]. Each of these systems will be discussed in further detail in Section 30.3.1. Emission of light from fluorescent markers requires external light excitation while bioluminescence systems generate light *de novo* after an injectable substrate is introduced and the appropriate conditions are met (Figure 30.1). In both cases, light emitted from either system can be detected with a thermoelectrically cooled charge-coupled device (CCD) camera since they emit light in the visible light range (400–750 nm) to near-infrared (NIR) range (~800 nm). Cooled to -120°C to -150°C , these cameras can detect weakly luminescent sources within a light-tight chamber. Being exquisitely sensitive to light, these desktop camera systems allow for quantitative analysis of the data. The method of imaging bioluminescence sources in living subjects with a CCD camera is relatively straightforward: the animal is anesthetized, subsequently injected intravenously or intraperitoneally with the substrate, and placed in the light-tight chamber for a few seconds to minutes. A standard light photographic image of the animal is obtained, followed by a bioluminescence image captured by the cooled CCD camera positioned above the subject within the confines of the dark chamber. A computer subsequently superimposes the two images on one another and relative location of luciferase activity is inferred from the composite image. An adjacent color scale quantitates relative or absolute number of photons detected. This scale does not reflect the color (wavelength) of the emitted photons, but only the number of such photons, measured as photons/cm²/s/steradian. Here steradian is a measurement of solid angle. Differences between fluorescence and bioluminescence systems are discussed in a later section of this chapter.

Comparison of optical-based imaging systems with the other imaging modalities, such as the radionuclide-based or

FIGURE 30.1 (See color insert following blank page 206.) Basic principles of optical CCD imaging (fluorescence/bioluminescence). There are fundamentally two different types of optically based imaging systems: fluorescence imaging, which uses emitters such as GFP, wavelength-shifted GFP mutants, RFP, smart probes and near-infrared fluorescent (NIRF) probes, and bioluminescence imaging, which utilize systems such as firefly luciferase/D-Luciferin or Renilla luciferase/coelenterazine. Emission of light from fluorescent markers requires external light excitation while bioluminescent systems generate light *de novo* when the appropriate substrates/cofactors are made available. In both cases, light emitted from either system can be detected with a thermoelectrically cooled CCD camera since they emit light in the visible light range (400–700 nm) to NIR range (~800 nm). Cooled to -120°C to -150°C , these cameras can detect weakly luminescent sources within a light-tight chamber. Being exquisitely sensitive to light, these desktop camera systems allow for quantitative analysis of the data. Image shown above the “fluorescence imaging” schematic is a representative image obtained from a glioma model, which expresses RFP (image used with permission from Anticancer, Inc.). The method of imaging bioluminescent sources in living subjects with a CCD camera is relatively straightforward: The animal is anesthetized, subsequently injected with the substrate, and immediately placed in the light-tight chamber. A light photographic image of the animal is obtained which is followed by a bioluminescence image captured by the cooled CCD camera positioned above the subject within the confines of the dark chamber. The two images are subsequently superimposed on one another by a computer, and relative location of luciferase activity is inferred from the composite image. An adjacent color scale confers relative concentration of luciferase activity. Sample image above the “Bioluminescence imaging” schematic is a typical image obtained with this technology. In this specific example, image was obtained after intravenous injection of coelenterazine into a mouse containing intraperitoneal Renilla luciferase-expressing tumor cells. Significant bioluminescence is detected from the region of the xenograft. (From Bhaumik, S. and Gambhir, S.S., *Proc. Natl. Acad. Sci. USA*, 99, 377, 2002. With permission.)

MRI-based systems, reveals important differences. Advantages of optical-based reporter systems are that they are at least an order of magnitude more sensitive than the radionuclide-based techniques but at limited depths [22]. Furthermore, the direct and indirect costs are generally less than radionuclide-based techniques or MRI. However, there is significantly less spatial information obtained from optical imaging and signal obtained from light-emitting reporter systems is limited by the tissue depth from which it arises. Skin autofluorescence is also a major obstacle to imaging at visible light wavelengths. The Maestro *in-Vivo* Imaging System from Cambridge Research and Instrumentation helps to resolve some of these issues by allowing simultaneous imaging at multiple spectra with a tunable filter that can operate at wavelengths from 500 to 950 nm. This multispectral acquisition, unmixing, and analysis approach dramatically improves sensitivity by detecting and minimizing autofluorescence noise. The system also provides multicolor flexibility and quantitative accuracy for both visible and NIR labels [23].

In the recent past, significant progress has been made to localize fluorescent signals tomographically to obtain distribution of fluorochromes in deep tissues [24]. Currently there are three approaches for achieving optical tomography: continuous wave, time-domain (TD), and frequency-domain. In continuous wave fluorescence tomography, the subject is trans-illuminated by a constant intensity light source and transmitted light is collected at different points on the surface surrounding the subject [25]. The fluorescence molecular tomography (FMT) platform from VisEn Medical uses this approach to quantify fluorescent signals from living animals at different depths and at multiple NIR wavelengths. FMT captures approximately 50,000–100,000 source–detector pair measurements rapidly within a scan time on the order of 2–4 min [26]. These large data sets are then processed by a sophisticated tomographic reconstruction algorithm taking into account the optical properties of the tissue being imaged and of the probe being used [23].

The second approach to accurately determine the localization and concentration of fluorophores is based on the principles of TD imaging. Most biologically relevant fluorophores exhibit characteristic decay times ranging from picoseconds to nanoseconds. In TD optical imaging, photons are classified based on the time at which they emerge from the tissue. The eXplore Optix™ system from ART, Inc. exploits this concept to facilitate detection, localization, and tracking of fluorescent probes noninvasively and in real-time. Typically, the subject is illuminated with a short, subnanosecond duration laser pulse and a fast detector measures the arrival distribution of photons as a function of time at different locations. A light pulse propagating through the tissue is broadened and attenuated due to scattering and absorption [27]. A fluorophore embedded in tissue is excited by this pulse of light and emits a fluorescence pulse with lifetime decay typical of the fluorophore. The generated time-of-flight distribution (generally referred to as temporal-point-spread-function) is a statistical distribution

of all possible photon paths between the point of illumination and the point where the light exits the tissue. This distribution is then used to determine the optical characteristics of the specimen and to discriminate scattering from absorption [28]. Theoretically, fluorescence lifetime is capable of distinguishing between exogenous and endogenous fluorescence, resulting in an increase in the signal-to-noise ratio, hence of the sensitivity. Apart from measuring the fluorescence intensity, tissue transport properties, or local fluorophore microenvironment, the system is also capable of tomographic reconstruction [29]. Some other advantages include the ability to distinguish and quantify two different fluorophores simultaneously based on their overlapping decay kinetics and to distinguish when certain classes of fluorophores are in a given chemical environment based on variations in fluorescence lifetime.

The various optical imaging strategies have been recently compared. Results indicate that the eXplore Optix system can be more sensitive with significantly higher detection depth and spatial resolution compared to the IVIS200 continuous wave imaging system [27]. However, unlike the IVIS200 system, major drawbacks of the TD imaging system are increased acquisition time and the inability to image multiple animals simultaneously.

Another strategy, which utilizes frequency domain photon migration imaging, is also under active investigation [30,31] but no commercial systems are yet available. In this approach, the incident light is modulated at a frequency of 10 MHz–1 GHz (range for physiological tissues being 30–200 MHz). The modulated excitation light then propagates within the tissue and generates a redshifted and intensity-modulated emission wave on reaching a fluorescent target. The emitted light then propagates to the tissue surface and is collected and passed through optical filters to reject the excitation portion of the reemitted light signal. These frequency domain systems may prove to have some advantages including enhanced depth penetration, lower noise, and higher sensitivity compared to the continuous wave method [31].

More effective *in vivo* optical imaging has become possible now because of the development of far-red and NIR probes (700–900 nm) that can overcome the unique obstacles posed by living tissues. The principal absorbers of light in the biological systems, like hemoglobin, water and lipid, are known to have their lowest absorbance at the NIR region. An additional advantage of imaging at NIR region involves low-tissue autofluorescence, which helps to further improve the target/background ratio.

30.2.2 BASIC PRINCIPLES OF POSITRON EMISSION TOMOGRAPHY

With recent breakthroughs in molecular/cell biology and target discovery, it is now possible to design specific markers to image events noninvasively in small animals and humans with PET. Natural biological molecules such as glucose, peptides, proteins, and a variety of other structures can either be

labeled with a radioisotope or slightly modified to accommodate a radioisotope. In the jargon of molecular imagers, these radiolabeled molecules are referred to as molecular probes, reporter probes, markers, or tracers. The term contrast agent should be avoided as it usually refers to a nonspecific imaging agent in distinction to molecular probes. In PET imaging, molecules are labeled with isotopes that emit positrons from their nucleus. This is in contrast to gamma camera or SPECT imaging (discussed in Section 30.2.3), where molecules are “tagged” with radioisotopes that emit gamma rays. When a molecular probe (tracer) is injected into a living subject and then placed into a PET scanner, the image we acquire is a snapshot of the physiologic distribution and concentration of that tracer.

Let us take the example of 2-deoxy-2- ^{18}F fluoro-D-deoxyglucose (FDG) [32–34], a glucose analog labeled with the positron-emitting isotope, ^{18}F . In the synthesis of this tracer, PET radiochemists have devised a method to replace one of the hydrogens with the ^{18}F radioisotope. Following intravenous injection, this particular probe distributes readily from the intravascular compartments to the extravascular and intracellular compartments. FDG becomes sequestered in cellular populations and tissues, which have a predilection for glucose,

i.e., cells, which possess a larger number of glucose transporters or hexokinase II activity. When FDG encounters hexokinase II, it becomes phosphorylated and subsequently trapped within the cell because it cannot diffuse out due to a negative charge. In contrast, FDG clears from cells or tissues that lack the ability to transport or phosphorylate FDG. The positron-emitting moiety of FDG, in this example, ^{18}F , decays by emitting a positron from its nucleus. This positron eventually collides with a nearby electron, resulting in an annihilation event where two 511,000 eV photons in the form of gamma rays are emitted $\sim 180^\circ$ apart. The two emitted photons travel extracorporeally and are detected nearly simultaneously as they interact with the PET camera, a ring array of detectors (composed of scintillation crystals and photomultiplier tubes) surrounding the subject (Figure 30.2). Detection of a single annihilation event results in the activation of detectors opposing one another, which is recorded as a coincident event, thus defining a set of coincident lines [35]. The recording of multiple detector pair combinations yields a large number of these coincident lines. Sophisticated mathematical analyses of the coincident lines, which include filtered back projection and attenuation correction (correction for gamma rays that do not

FIGURE 30.2 Basic principles of PET imaging. Biologically active molecules such as glucose, peptides, and proteins can be radiolabeled with positron emitting radioisotopes. This radiolabeled molecule is referred to as a probe or tracer. The positron emitting isotope decays by emitting a positron from its nucleus. This positron eventually collides with a nearby electron resulting in an annihilation event where two 511,000 eV photons in the form of gamma rays are emitted $\sim 180^\circ$ apart. The two emitted photons travel extracorporeally and are detected nearly simultaneously as they interact with a ring of detectors (composed of scintillation crystals and photomultiplier tubes) surrounding the subject. Detection of a single annihilation event results in the “activation” of detectors opposing one another, which is recorded as a “coincident event.” The recording of multiple detector pair combinations yields a large number of these coincident lines. Sophisticated mathematical analyses of the coincident lines, which include filtered back projection and attenuation correction, yields the location of cell populations or tissues that contain the molecule labeled with the positron emitter. Tomographic images of relative probe concentration can be reconstructed in the conventional sagittal, coronal, and transverse imaging planes or, actually, in any arbitrary plane. The resultant image depicts the distribution and concentration of the radiolabeled tracer. Sensitivity of PET is in the range of 10^{-11} to 10^{-12} m/L and is independent of the location depth of the tracer of interest. It is also important to note that all positron-emitting radioisotopes produce two gamma rays of the same energy, so if two molecular probes, each with a different positron-emitting isotope, are injected simultaneously, there is no way for the PET camera to distinguish between the two molecular probes. Therefore, to perform studies which look at two or more distinct molecular events (e.g., suicide gene therapy and imaging apoptosis, cardiac gene therapy and perfusion ^{13}N ammonia imaging, etc.), one has to inject molecular probes separately, which allows decay of the isotope.

penetrate through due to absorption), yield the location of cell populations or tissues that have accumulated FDG. Tomographic images of relative probe concentration can be reconstructed in the sagittal, coronal, and transverse imaging planes. Quantitative information obtained from the images is, in turn, related to the underlying biochemical process.

Radiolabeling molecules is not just limited to ^{18}F . A collection of positron-emitting isotopes are available for use, which include the more commonly utilized isotopes, ^{15}O , ^{13}N , ^{11}C , and ^{18}F , and the less commonly used ^{14}O , ^{64}Cu , ^{62}Cu , ^{124}I , ^{76}Br , ^{82}Rb , and ^{68}Ga . Most of these isotopes are created in a cyclotron, a device used to accelerate charged particles to create the relatively short-lived positron-emitting isotopes (for example, ^{18}F , the half-life of which is 110 min) [36]. Automated synthesizers can then couple the isotope to a molecule of interest to produce the molecular probe (tracer). Given the relatively short half-life of positron emitters, the process of producing isotopically labeled molecules has to be performed with great efficiency and in relatively close proximity to the hospital, clinic, or animal research facility. In this regard, a modest number of PET radiopharmacies are available worldwide, producing PET tracers on a daily basis.

Clinical PET scanners have been around for several decades and, in the last decade, PET cameras for small animals have been developed for the purpose of developing molecular imaging assays in small rodents prior to their application in humans. The spatial resolution of most clinical PET scanners is $\sim(6\text{--}8)^3\text{ mm}^3$ with the more recent scanners achieving $\sim(2)^3\text{ mm}^3$ capabilities. By comparison, most small animal PET scanners (microPET) have a resolution of $\sim(2)^3\text{ mm}^3$ with newer generation scanners attaining $\sim(1)^3\text{ mm}^3$ [37–41]. When compared to other modalities, the sensitivity of PET is relatively high, on the order of 10^{-11} to 10^{-12} m/L (MRI's intrinsic sensitivity is $\sim 10^{-4}$ to 10^{-5} M) [42]. Furthermore, the location or depth of the tracer of interest does not affect sensitivity. In contrast, the imaging of many optical imaging probes is significantly affected by tissue depth. Under appropriate conditions, the smallest cluster of cells that can be visualized by a clinical PET scanner is 10^6 to 10^9 in number. Thus, radiotracer imaging techniques afford the detailed locations, magnitude, and persistence of probes or tracers for *in vivo* use in animals and humans.

30.2.3 BASIC PRINCIPLES OF THE GAMMA CAMERA AND SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY IMAGING

Imaging with a gamma camera is similar to PET, but the radiolabel emits gamma rays instead of positrons. A variety of radiolabels, each emitting at characteristic photon energies, can be attached to molecules including ^{111}In (171–245 keV), ^{125}I (27–35 keV), ^{131}I (364 keV), and $^{99\text{m}}\text{Tc}$ (140 keV). Once introduced into the body, detection of these radiolabeled probes is performed with a gamma camera, a scintillation detector consisting of collimator, a sodium iodide crystal, and a set of photomultiplier tubes (Figure 30.3).

Upon decay, these radionuclides emit a gamma ray at their characteristic energies in different directions. Some of the gamma rays will scatter or lose energy and others may never interact with the camera. Since the gamma camera is situated only on one side of the subject, only rays directed toward the camera will be captured. Furthermore, only those gamma

FIGURE 30.3 Basic principles of gamma camera/SPECT imaging. Imaging with a gamma camera is similar to PET, but the radiolabel emits gamma rays instead of positrons. A variety of radioisotopes, each emitting at characteristic photon energies, can be attached to a variety of molecules. Examples of isotopes include ^{111}In (171–245 keV), ^{125}I (27–35 keV), ^{131}I (364 keV), and $^{99\text{m}}\text{Tc}$ (140 keV). Once introduced into the body, detection of these radiolabeled probes is performed with a gamma camera, a scintillation detector consisting of collimator, a sodium iodide crystal, and a set of photomultiplier tubes. Upon decay, these radionuclides emit a gamma ray at their characteristic energies in different directions. Some of the gamma rays will scatter or lose energy and others may never interact with the camera. Since the gamma camera is situated only on one side of the subject, only rays directed toward the camera will potentially be “captured.” Furthermore, only those gamma rays, which arise parallel to collimator, will be detected since scattered gamma rays will be absorbed by the collimator. Those rays, which successfully reach the crystal and stopped by it, will be converted into photons of light. In turn, the photomultiplier tubes convert the light into an electrical signal that is proportional to the incidental gamma ray. Gamma rays, which arrive at detector lower than the expected characteristic energy, are thought to be the result of scattering and summarily rejected from the analysis. Since gamma cameras acquire data in a single plane, the resultant images are a two-dimensional representation of a three-dimensional subject (referred to as “planar imaging”). SPECT acquires volumetric data by rotating a gamma camera around the subject and/or using multi-detector systems (shown above). (From Rosenthal, M.S., Cullom, J., Hawkins, W., Moore, S.C., Tsui, B.M., and Yester, M., *J. Nucl. Med.*, 36, 1489, 1995.)

rays that arise parallel to the collimator will be detected since the collimator will absorb scattered gamma rays. Those rays that successfully reach the crystal will be converted into photons of light. In turn, the photomultiplier tubes convert the light into an electrical signal that is proportional to the incidental gamma ray. Gamma rays, which arrive at the detector lower than the expected characteristic energy, are thought to be the result of scattering and summarily rejected from the analysis. Since gamma cameras acquire data in a single plane, the resultant images are a two-dimensional representation of a three-dimensional subject (referred to as planar imaging).

While more affordable and accessible than PET, the limitations of gamma camera imaging are obvious: (1) diminished sensitivity, since many decay events are either rejected or never captured due to collimation, (2) decreased signal-to-noise since overlapping foci of activity are not delineated, and (3) lower spatial resolution. Alleviating some of these problems is SPECT, which acquires volumetric data by rotating the gamma camera around the subject or using multidetector systems [43] (Figure 30.3). As with microPET, small-animal SPECT devices (microSPECT) have been created to study the use of gamma-emitting radiolabeled reporter probes in animal models of cancer and gene therapy. These instruments have resolutions on the order of 1 mm^3 . Thus, advantages of the SPECT systems are that they generally allow for better spatial resolution. Another advantage of SPECT is that two radioisotopes of different energies can be imaged simultaneously, allowing for the concurrent study of two distinctly radiolabeled molecules (e.g., one radiolabeled with $^{99\text{m}}\text{Tc}$ and another radiolabeled with ^{125}I). With PET imaging, such simultaneous imaging is not possible since all positron-emitting events lead to 511 keV gamma rays. A disadvantage for SPECT, however, is that it is an order of magnitude lower in sensitivity than PET. However, small-animal SPECT imaging systems continue to be developed and can achieve very high spatial resolution [44,45].

30.2.4 BASIC PRINCIPLES OF MAGNETIC RESONANCE IMAGING

With regard to the electromagnetic spectrum, MRI works with longer wavelengths (lower energies) than those used by the radionuclide or optical techniques. A comprehensive review of MRI is beyond the scope of this chapter; there are several excellent reviews and books available [46–49]. A very brief, simplistic description follows here: Spinning charged nuclei generate a magnetic field and MRI depends on these charged atomic nuclei, which contain an odd number of protons. Those nuclei that contain an odd number of protons always have an unpaired proton, which gives the atom a net magnetic field or “magnetic dipole moment” (MDM). In contrast, atoms, which have an even number of protons, have a net magnetic field of zero. Thus, the nucleus of hydrogen (^1H), which possesses a single unpaired proton as its nucleus and is present in abundance (in the form of H_2O and $-\text{CH}_2-$) in cells and tissues, is primarily used for MRI.

The majority of available MR scanners are fitted with a superconducting magnet in the shape of a long hollow tube. The magnet creates an external magnetic field (B_0) and within the hollow center of the tube-shaped magnet, the magnetic field is nearly homogeneous and parallel to the long axis of the tube. When a subject is placed within the hollow confines of the magnet, the MDMs of the hydrogen atoms align themselves with the main magnetic field B_0 , much like the way iron filings behave when placed in the vicinity of a magnet.

Once equilibrium has been established in the external magnetic field, B_0 , a magnetic pulse (an electromagnetic wave), otherwise known as radiofrequency (RF) pulse is introduced perpendicular to B_0 . It is called an RF pulse because the frequency (and energy) of the pulse is in the RF range of the electromagnetic spectrum (3–100 MHz). This causes the hydrogen nuclei to transiently orient their MDM parallel to the new magnetic field (perpendicular to B_0). After the RF pulse, they realign (relax) their MDMs to the main magnetic field B_0 , and, in the process give off energy in the form of RF waves that can be detected by receiver coil, which typically surrounds the subject. To reiterate, both RF pulse and magnetic field are used to perturb the underlying subject, with an RF wave being generated in the process to produce an image. Also, the time it takes for the hydrogen nuclei to relax to equilibrium (or a fraction thereof) can be measured. The rate at which a hydrogen nucleus relaxes is dependent upon the nature of its parent molecule such as a freely mobile water proton versus the rigidly attached proton of hydrocarbon backbone of a fatty acid. Water protons, which randomly tumble in aqueous solution, take longer to regain equilibrium with the main magnetic field, B_0 , than those protons associated with much larger, more fixed molecules. The measurements of relaxation rates can be converted into a value, which translates into image pixel value, with each pixel representing a small, representative unit volume of the subject (voxel). On a certain MRI protocol called a T1-weighted sequence, a voxel composed mostly of fatty (hydrocarbons) protons will have a high (bright) signal since the rate of relaxation is rapid. Compare this to the voxel, which contains a large number of water protons: this voxel will have a low (dark) signal on T1-weighted MRI since the rate of relaxation is much longer. Each MR image is of 256×256 or 512×512 pixels, each a representative slice through the subject (Figure 30.4).

Certain exogenous or endogenous atoms or molecules, like gadolinium (paramagnetic) and iron/hemosiderin (superparamagnetic), respectively, can influence the local magnetic field by their powerful magnetic properties, significantly alter the rate of relaxation of the protons, and therefore generate contrast in the image. Paramagnetic substances have unpaired electrons. They become magnetized in the presence of an external magnetic field and contribute to an increase in the effective magnetic field. Examples include the rare-earth element, gadolinium (Gd) (seven unpaired electrons), deoxyhemoglobin (four unpaired electrons), and methemoglobin (five unpaired electrons). Hemosiderin, an end-stage by-product of hemorrhage, has more than 10,000 unpaired electrons and, thus, belongs to superparamagnetic

FIGURE 30.4 Basic principles of MRI. In MRI, subjects are placed in a strong, external magnetic field, B_0 , produced by a hollow, cylindrical magnet. The B_0 field is nearly uniform and points parallel to the long axis of the magnet. Imaging with MRI is dependent upon atomic nuclei with an odd number of protons, such as hydrogen (^1H). Such atoms have their own net magnetic field (known as MDM) and their moments align accordingly when placed in this external magnetic field. Once equilibrium has been achieved between the subject and the magnet, energy can be added to the system in the form of an RF pulse. In most cases, this pulse, which generates its own magnetic field, can change the alignment of the hydrogen atoms such that their moments are now perpendicular to B_0 . Once the RF pulse is “turned off,” the hydrogen atoms realign or “relax” to B_0 and give up energy in the form of RF waves during the relaxation period. Receivers located in the magnet capture this RF wave. One of the calculations made from the captured information is the rate at which the hydrogen atoms relax to equilibrium. Image construction and image contrast are possible with MRI because hydrogen atoms associated with macromolecules like fat and proteins have a significantly different relaxation rate than the hydrogen atoms of bulk water. The measurements of relaxation rates can be converted into a value, which translates into image pixel value, with each pixel representing a small, representative, unit volume of the subject (voxel). On a certain MR imaging protocol called a “T1-weighted” sequence, a voxel composed mostly of fatty (hydrocarbons) protons will have a high (bright) signal since the rate of relaxation is rapid. In contrast, voxels, which contain a large number of water protons, will have a low (dark) signal on T1-weighted MR imaging since the rate of relaxation is much longer.

group of substances. The magnetic susceptibility of superparamagnetic substances is 100 to 1000 times stronger than paramagnetic substances. Both super- and paramagnetic substances help localize reporter gene expression during MRI (see also Figure 30.10). As we will see in Section 30.3.3, the properties of paramagnetic and superparamagnetic compounds are exploited for MR-based reporter systems.

MRI techniques offer phenomenal spatial resolution (voxel resolutions of $\sim 10\mu\text{m}^3$ *in vitro* and $\sim 50\mu\text{m}^3$ in small animals) but are several orders of magnitude less sensitive than optical- and radionuclide-based techniques. Sensitivity of MRI is on the order of 10^{-3} M while PET imaging is 10^{-12} M, and thus, substantially more MRI probe has to be injected into the living subject in order to provide sufficient contrast [50]. However, in MRI, subjects are not exposed to radiation, which poses as one of the biggest advantage of this modality.

Hyperpolarized gases have also been used extensively in MRI as MR contrast agents or for enhancing temporal reso-

lution and to enhance sensitivity mostly in the lungs [51]. A low proton density and a lack of tissue homogeneity degrade the magnetic resonance signal and therefore interfere with image acquisition in the lungs with conventional MRI [52]. Inert noble gases like helium (^3He) upon inhalation can diffuse rapidly to fill airspaces of the lungs and permit visualization and measurement of the ventilated airways and alveolar spaces [53,54]. However, the density of gases under normal conditions is too low to produce a detectable MR signal. This drawback is overcome by artificially increasing the amount of polarization per unit volume, a process called hyperpolarization. This procedure causes the normal random spin distribution of atoms to be altered and a population of atoms with spins in parallel configuration dominates causing a log-order increase in signal and a favorable signal-to-noise ratio. Hyperpolarization can provide nuclear polarizations that are five orders of magnitude higher than those achieved at thermal equilibrium [55]. The most common methods for

hyperpolarization of noble gases are based on laser optical pumping, and include alkali-metal spin-exchange or metastability exchange. Due to its relatively long stability and its inert gas properties, ^3He became the most commonly applied gas for MRI, with applications including high-resolution functional lung imaging to detect diseases related to smoking or asthma, cystic fibrosis, etc. [53,56,57]. Recently hyperpolarized ^{13}C has shown a lot of promise in angiography and other medical imaging approaches [58,59]. Use of bis-1, 1-(hydroxymethyl)-1- ^{13}C -cyclopropane-D8, a water-soluble compound, demonstrated long relaxation times and excellent resolution in angiographic studies [60]. Other applications of hyperpolarized ^{13}C include angiographic studies with ^{13}C -labeled urea, or more recently, real-time imaging of metabolism with ^{13}C -labeled pyruvate as a metabolic marker [61].

30.2.5 COMPUTED TOMOGRAPHY

Computed tomography (CT) deals in the x-ray range of the electromagnetic spectrum. In CT, the subject is placed in the center of a ring of detectors. A rotating focused x-ray source emits radiation, which penetrates the subject and reaches a set of detectors on the other side of the patient. The amount of x-ray reaching the detector depends upon the amount absorbed by the patient and is inversely proportional to the density of tissues encountered as it passes through the patient. The amount of radiation reaching a detector is given a value, and, through a complex set of back calculations, tomographic images in the transverse plane can be constructed.

While this modality is not currently utilized to monitor gene expression, efforts are under way. Rather, CT's main role in human gene therapy will grow significantly as it currently serves as an anatomical adjunct to PET and SPECT imaging. Both CT and PET (or SPECT) data sets can be coregistered, and because of its superior spatial resolution, CT gives PET information more specificity. Clinical CT scanners have recently achieved spatial resolutions <1 mm. Small animal CT scanners (microCT) have attained resolutions of 50 μm [62]. Already showing its prowess in oncology, PET/CT clinical machines as well as small animal machines should help to show gene expression coupled to anatomy. More details about PET/CT can be found elsewhere [63]. The increasing use of microCT and hybrid systems that combine PET and SPECT with x-ray CT in small-animal imaging has prompted the development of novel imaging probes. Lately, several nanoscale carriers like nanoparticles, liposomes, water-soluble polymers, micelles, and dendrimers have been developed for targeted delivery of cancer diagnostic and therapeutic agents and can also behave as CT-contrast agents. Rabin et al. described a polymer-coated bismuth sulfide nanoparticle preparation as an injectable CT imaging agent. According to their initial results, this preparation shows excellent stability at high concentrations, fivefold higher x-ray absorption compared to iodine-based agents, >2 h long circulation times, and much greater safety than iodinated imaging agents [64]. Such agents can have a huge impact on applications involving

angiogenesis imaging, lymph-node imaging, and developing targeted imaging probes.

30.2.6 ULTRASOUND

Ultrasound (US) imaging uses US waves (frequency > 20 kHz) to produce either static or dynamic images of body organs and to measure velocity of blood flow. US probes are essentially acoustic transducers emitting wave pulses that are reflected as echoes bouncing off the interfaces between materials of different acoustic impedances. The echo signal provides information on the interface depth and the nature of the materials at the interface. Although the echo signals received by the probes are converted into single dimensional signals, it is possible to develop 2D or 3D images by combining the signals obtained from different angles around an organ under investigation [65].

Ultrasonography is being extensively used in small-animal research and is proving to be a valuable tool in gene therapy. In gene therapy, US microbubbles can be employed to successfully deliver genes in living subjects. There is evidence that when US is applied to microbubbles, they are disrupted and this can cause small perforations in the target cells (sonoporation), which allows the DNA to enter. US has been shown to enhance gene transfer into cells both *in vitro* and *in vivo* [66–70]. Enhanced gene transfer was observed when pure plasmid DNA was attached to microbubble shells [71]. In 2003, researchers showed that an innovative combination of US and microbubbles helped in delivering DNA in mice skeletal muscles and the efficiency of gene therapy was improved by about 10 times [72]. In a recent study, researchers were able to transfect prostate tumors in mice efficiently by a combination of therapeutic US and contrast agent, Optison, following intratumoral administration [73].

US-enhanced gene therapy is a rapidly evolving field. The procedure is very safe since the exposure levels required to destroy microbubbles lie in the diagnostic range. Moreover, targeting ligands can be attached to the surface of the microbubbles (i.e., targeted microbubbles), which would assist in directing the therapeutic transgenes to specific tissues [74–76]. In a recent study by Willmann et al., vascular endothelial growth factor receptor 2 (VEGFR2)-targeted microbubble allowed noninvasive visualization of VEGFR2 receptors in two different murine tumor models by contrast-enhanced US imaging [77]. Such tools can be extremely useful in delivering therapeutic genes, peptides, or drugs to the neovasculature bed of a growing tumor.

30.3 REPORTER GENES AND REPORTER PROBES

30.3.1 OPTICAL REPORTER SYSTEMS

There are essentially four different types of optical reporter genes currently in use for studies in living animals. These genes either encode (a) a protein, which contains a chromophore (a short, internal peptide segment that contributes to the protein's

fluorescent capabilities following obligatory posttranslational modifications), which fluoresces when externally irradiated (fluorescence imaging), (b) an enzyme, which can convert an exogenously added optically quiescent substrate into a fluorescent complex, or an enzyme, which changes the conformation of a substrate such that it fluoresces a different color (fluorescence imaging), (c) luciferases that generate light when presented with the appropriate substrate (bioluminescence imaging), or (d) fusion proteins, which couple transgene products with fluorescence or bioluminescence optical reporters with a peptide linker (discussed in greater detail in Section 30.3.1). When compared to other imaging modalities, fluorescence and bioluminescence imaging techniques hold tremendous potential for study of small living animals because of its affordability, relative ease of use, high assay sensitivity, and low requirement for specialized support personnel. In contrast to the radionuclide-based techniques described earlier, all optical reporter gene/probe systems are forms of indirect imaging. The measured light emissions generated from these reporter systems may or may not correlate to the amount of therapeutic gene product present. Briefly reviewed below, extensive work in the past several years has been dedicated to mutating existing or cloning new fluorescent or bioluminescence genes, which are more compatible for use in living subjects.

Mammalian tissues pose a number of obstacles for the propagation of light and, thus, are a challenge for the evaluation of fluorescence- or bioluminescence-based reporter genes in living subjects. Fluorescent-based techniques, in particular, face additional challenges since both the light used to excite the reporter probe and the light emitted from the probe are subject to absorption, scatter, and other optical tribulations. More specifically, the excitation light is not only limited by its ability to penetrate nontransparent tissue, but also contributes to background autofluorescence (from hemoglobin and cytochromes) especially when excitation wavelengths are in the blue and green portions of the spectrum, which is generally the case when GFP (and its close relatives such as blue fluorescent proteins) is used as reporter genes [22]. As a result, fluorescence imaging has relatively poorer signal-to-noise when compared to bioluminescent techniques.

Light emitted from either fluorescence- or bioluminescence-based techniques are subject to tissue absorption and scattering. In mammalian tissues, the blameworthy structures responsible for light absorption are predominantly molecules of hemoglobin, which absorb wavelength emissions of 400–600 nm. To a lesser extent, melanin and other pigmented macromolecules also contribute to light absorption, and, thus, experiments using white-furred or hairless subjects are preferred when using optical reporter systems. Light absorption by water molecules is also another important factor, but not until wavelengths approach >900 nm range. Light scatter is another important confounding factor in the detection of low-level photon emissions; the interfaces at the surface membranes of cells and organelles are largely the cause for this occurrence [22].

Yet, despite these impediments, recent advances in the fields of optics and sensor technology make it possible to detect relatively low emissions events with great sensitivity and generate remarkable images [78,79]. Furthermore, optical reporters are being developed to operate with longer wavelengths; that is, away from the blue–green part of the spectrum and towards the red (also called redshifted, between 600 and 900 nm) so as to maximize transmission, minimize absorption, and background autofluorescence. Additionally, the fluorescence efficiency of each of the fluorescent proteins is being optimized through site-directed mutagenesis. The intrinsic physical and chemical properties of the mutants are altered. Characteristics such as protein stability, extinction coefficients, fluorescence quantum yield, tendency to dimerize or form multimers, requirement for oxygen, efficiency of fluorochrome formation, and susceptibility to photoisomerization and photobleaching can be modulated through mutagenesis, and, thus, the amount and rate of light photons emitted from such structures can be optimized [80].

For example, wild-type *Aequorea* GFP, a 238 amino acid polypeptide (27–30 kD) specifically isolated from the Pacific jellyfish (*Aequorea victoria*), is a highly fluorescent molecule with excitation peaks at 395 (largest peak) and 475 nm [81]. GFP emission occurs at 509 nm, which is in lower green portion of the visible spectrum and is therefore highly susceptible to tissue attenuation. As a result, imaging of GFP expression in living subjects often requires surgical measures like creating skin or skull windows for optimal visualization of GFP in deeper structures such as the pancreas or brain [82]. Such tissue-window-based intravital microscopy methods allow high-resolution imaging of implanted labeled cells, extracellular matrix (ECM) components, and local blood vessels in the living animal over days and weeks [83,84]. Additionally, GFP fluorescence is not immediate and only detectable at about 7 h after injection of recombinant adenovirus carrying GFP (vAd-CMV-GFP). The rate-limiting step in GFP “maturation” appears to be a necessary oxidation step in chromophore formation [85].

Extensive work has been dedicated to creating GFP mutants since wild-type GFP possess a few compromising factors for its use in living subjects. The list of available GFP mutants, each having their own characteristics, is quite lengthy. An excellent review is available [80]. One of the more thoroughly studied mutant S65T, also known as enhanced GFP (EGFP), has some impressive advantages. Ser65, one of the amino acids of the chromophore, is replaced by Thr in this mutant. The wild-type 395 nm excitation peak is suppressed and the 475 nm peak is enhanced five- to sixfold in amplitude (sixfold increase in brightness), the peak is shifted to 489–490 nm [85]. It is fourfold faster during the rate-limiting oxidation step, not subject to photoisomerization and exhibits very slow photobleaching [86]. Examples of the use of EGFP in living subjects are shown in Figure 30.5.

GFP mutants come in all kinds of colors: blue, cyan, yellow, and green. However, the maximum emission peak attained by the GFPs is 529 nm. Cloned red fluorescent protein (dRFP), a 28 kDa protein responsible for red coloration

FIGURE 30.5 (See color insert following blank page 206.) Optical (fluorescence) imaging of transgene expression. The adenoviral (vAd) vector AdCMV5GFPΔE1/ΔE3 [vAd-GFP] (Quantum, Montreal, Canada) constitutively expresses an EGFP, which is driven by a cytomegalo virus (CMV) promoter. The vector was delivered to the brain after an upper midline scalp incision and creation of a parietal skull window. Twenty microliters containing 8×10^{10} plaque-forming units (pfu)/ml vAd-GFP per mouse was injected into the brain. Twenty four hours later, fluorescence imaging of the entire animal (lower magnification) was carried out in a light box illuminated by blue light fiber optics, which provided the external excitation wavelength and imaged by using the cooled color CCD camera. Emitted fluorescence was collected through a long-pass filter GG475 on a three-chip thermoelectrically cooled, color CCD camera. Images of $1,024 \times 724$ pixels are captured directly on a personal computer or continuously through video output on a high-resolution video recorder. Images are subsequently processed for contrast and brightness and analyzed with imaging software. Higher magnification images (not shown here) can be accomplished by using a fluorescence stereomicroscope equipped with a 50 W mercury lamp. In this scenario, selective excitation of GFP is produced through a D425/60 bandpass filter and 470 DCXR dichroic mirror. Emitted fluorescence are captured and processed as described above. Images (A) and (B) demonstrate GFP transgene expression following adenoviral delivery to the brain. Image (C) demonstrates Ad-CMV-GFP delivery to the liver via portal vein cannulation. (Courtesy of Anticancer, Inc. and from Yang, M., Baranov, E., Moossa, A.R., Penman, S., and Hoffman, R.M., *Proc. Natl. Acad. Sci. USA*, 97, 12278, 2000. With permission.)

seen in the coral *Discosoma*, has broken the 529 nm barrier and excitation and emission maxima are at 558 and 583 nm, respectively [87]. The relatively high extinction coefficient and fluorescence quantum yield indicate that the brightness of the mature, well-folded protein is comparable to any other fluorescent protein. Furthermore, a commercially available mutant, DsRed, is resistant to photobleaching and has been further redshifted to 602 nm, which reduces the tissue absorption of the emitted light photon. Unfortunately, there are some significant limitations to the use of dRFP. It is an obligate tetramer and it is quite slow in its maturation; it takes days for it to mature from green to red. Mutations attempted to alleviate this problem resulted in a monomeric form designated as mRFP1 that matures more than 10 times faster than the native DsRed protein [88]. In addition, the excitation and emission peaks of mRFP1, 584 and 607 nm, are approximately 25 nm redshifted from DsRed, which should confer greater tissue penetration and spectral separation from autofluorescence and other fluorescent proteins. A recently discovered far redshifted variant of mRFP1, mPLUM (emission 649 nm), will be very useful in optical imaging experiments in living animals [89].

Apart from fluorescent reporter genes, many fluorescent reporter probes like nanoparticles or “smart probes” are also being investigated actively. Fluorescent organic and inorganic nanoparticles like quantum dots (QDs) that interface with biological systems have recently attracted widespread interest in the fields of biology and medicine. They have the potential as intravascular or cellular probes for both diagnostic (imaging) and therapeutic purposes (gene delivery) in gene therapy. Target-specific gene delivery and early diagnosis in cancer treatment using these probes can play a critical role in medicine [90]. QDs are essentially semiconductor nanocrystals with a core/shell structure of 2–8 nm in diameter with size-dependent fluorescence emission. The unique optical properties of QDs that make it suitable for *in vivo* optical imaging include high absorbency, high quantum yield, narrow emission bands, large Stokes shifts, and high resistance to photobleaching [91]. QDs can also allow multiplex detection of multiple targets in a single experiment. There are some excellent reviews that summarize the synthesis, bioconjugation chemistry, optical features, and applications of QDs for *in vivo* imaging [92–94].

Two recently developed smart fluorescent probes have been developed, which are significantly redshifted to the extent that they work in the NIR portion of the electromagnetic spectrum (excitation wavelength 673 nm; emissions wavelength of 689 nm), making them ideal fluorescent agents for use in intact organisms. Although they are being exploited to measure endogenous protein levels, they are worth mentioning here since they have the potential to be activated by exogenously delivered genes and be used to monitor gene therapy [19]. This new breed of fluorescent probe is dependent upon the close proximity of multiple near-infrared fluorochromes, Cy5.5, bound to a synthetic graft copolymer consisting of a cleavable backbone (partially methoxy poly(ethylene glycol) modified poly-L-lysine) [95]. When placed in close

proximity, a pair of these fluorochromes will quench each other and, therefore, not be detectable. Upon enzymatic cleavage of the backbone with a protease that has lysine–lysine specificity, the fluorochromes are spatially dissociated and will begin to fluoresce.

Because tumor progression and angiogenesis necessarily produce certain proteases, these clever or smart biocompatible autoquenched near-infrared fluorescent probes can be used to detect tumors, which are known to upregulate certain proteases. Cathepsins B and H are tumor proteases, which have lysine–lysine specificity and have been shown to activate this fluorescent probe in tumor xenografts. Other known tumor-enhanced proteases, Cathepsin D and MMP-2, which are dependent on other specific peptide sequences for their action, can also activate this probe if the NIR fluorochromes are attached to the backbone via Cathepsin D-sensitive or MMP-2-sensitive sequences; these enzyme-specific probes have been demonstrated in living subjects [19,96].

Bioluminescent optical systems are increasingly being used in studying living subjects because of their inherently low background (no excitation/irradiation needed that would otherwise cause background autofluorescence). The most commonly used bioluminescence reporter gene is the Firefly luciferase gene (*Fluc*), which encodes for a 550 amino acid, 61 kDa monomeric protein (FL) derived from *Photinus pyralis*, the North American firefly [79]. Photon emission is achieved through oxidation of its native substrate, D-luciferin (D-(–)-2-(6'-hydroxy-2'-benzothiazolyl)-thiazine-4-carboxylic acid) into oxyluciferin in a reaction that requires ATP, Mg²⁺, and O₂. The reaction produces a broad spectral emission that peaks at 560 nm. A number of modifications to the gene since its discovery have facilitated its use in mammalian tissues, which include amino acid substitutions that redshift the emissions peak above 600 nm, optimized mammalian codon language, removal of a peroxisome targeting site for increased expression levels, and cytoplasmic localization [22,97]. Once produced, luciferase does not require post-translational processing for enzymatic activity and it can immediately function as a genetic reporter. However, the enzyme is unstable and loses activity rapidly even at room temperature (*in vitro* half-life of 2 to 3 min at 37°C and *in vivo* half-life of 1 to 4 h) [98]. This property can potentially compromise sensitivity and precision in analytical experiments involving firefly luciferase as a reporter gene. To overcome this problem, a luciferase mutant (*ttl*) containing four point mutations (bearing the mutations E354K, I232A, T214A, and F295L) was generated that showed remarkably greater thermostability (*in vitro* half-life of 15 min) relative to the wild type [99,100]. Examples of an adenoviral-mediated firefly luciferase gene delivery are given in Figures 30.6 and 30.7. Figure 30.6 is an example of cardiac gene therapy and Figure 30.7 is an example of how tissue-specific transgene expression can be achieved using tissue-specific promoters in living subjects.

A second bioluminescence system, which utilizes the Renilla luciferase gene (*Rluc*) that encodes a 36 kDa monomeric protein (RL), has recently been tested in small rodents

[15]. Its peak emission displays a blue–green bioluminescence at 480 nm when Renilla luciferase interacts with its substrate, coelenterazine. In comparison to FL, RL does not need cofactors or ATP to oxidize its substrate, and therefore will be less taxing on the cell in which it is expressed. It also has much more rapid kinetics in terms of light production so that it can potentially be used simultaneously with FL through the injection of both substrates and multiple time-point imaging [15].

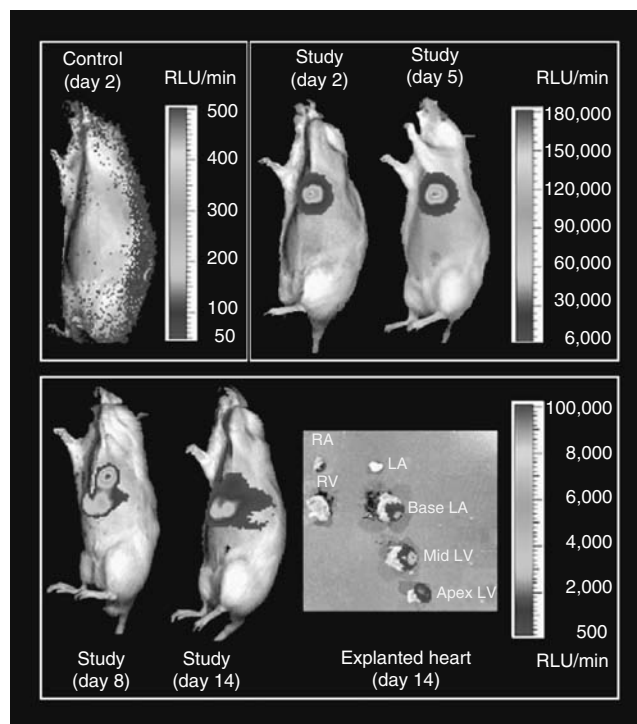

FIGURE 30.6 (See color insert following blank page 206.) Optical (bioluminescence) imaging of cardiac reporter gene expression. Replication-defective adenovirus carrying firefly luciferase (*Fluc*) driven by a constitutive cytomegalovirus (CMV) promoter (Ad-CMV-*Fluc*, 1×10^9 pfu) was injected directly into the myocardium (anterolateral wall) of a rat. Images obtained 2, 5, 8, and 14 days later from a cooled CCD camera demonstrate significant cardiac emissions from FL activity ($P < 0.05$ vs. control). By day 8, luciferase activity is seen in the liver, which is probably from spillover of adenoviral vector into the systemic circulation and subsequent hepatic transfection of the virus via coxsackie-adenovirus receptors on hepatocytes. On day 14, the heart of the same rat was explanted after whole-body imaging was performed and sliced into three sections (bottom right). Firefly luciferase activity is localized at anterolateral wall of left ventricle along the site of virus injection. Control rats, which received an intracardiac injection of Ad-CMV-HSV1-sr39tk (1×10^9 pfu), demonstrate no significant firefly luciferase activity 2 days after the injection (upper left). Please note the bioluminescent scales are different for control rat, study rat days 2 to 5, and study rat days 8 to 14 to account for the wide range of cardiac firefly luciferase activity observed. Scales are a quantitative indicator of light photons detected (relative light units [RLU]/minute [min]). RA indicates right atrium; RV, right ventricle; and LV, left ventricle. (Reproduced from Wu, J.C., Inubushi, M., Sundaresan, G., Schelbert, H.R., and Gambhir, S.S., *Circulation*, 105, 1631, 2002. With permission.)

FIGURE 30.7 (See color insert following blank page 206.) Optical (bioluminescence) imaging of targeted transgene expression using a tissue-specific promoter. One way to target gene therapy is through the use of tissue-specific promoters. However, most tissue-specific promoters yield low levels of transcription. In this example, certain key regulatory elements of the promoter and enhancer of prostate-specific antigen (PSA) have been multimerized to yield a construct, PSE-BC, which is 20-fold more active than the native PSA promoter/enhancer. Following incorporation into an adenovirus vector (AdPSE-BC-luc) and subsequent intratumoral injection into a human prostate cancer xenograft model (LAPC series), firefly luciferase expression can be seen in the main tumor xenograft (left flank) as well as other extratumoral sites, such as the back and chest, in this male SCID mice 21 days after vector delivery. Detailed histologic analysis of the xenograft and extratumoral sites demonstrates that firefly luciferase expression is restricted to the prostate tumor and prostate metastases, respectively. The metastases, in this case, are located in the spine and lung. By comparison, CCD imaging and histologic analysis of xenografts injected with AdCMV-luc show markedly diminished expression of firefly luciferase in the xenograft and increased nonspecific expression in the liver at 21 days postinjection (figure not shown). Results from this study indicate that tissue-specific transgene expression is possible and that CCD imaging can be used to track firefly luciferase-marked tumor cells. Scale indicates the number of photons detected (RLU/min). (Reproduced from Adams, J.Y., Johnson, M., Sato, M. et al., *Nat. Med.*, 8, 891, 2002. With permission.)

Recently, RLuc was mutated at eight sites to develop an optimized protein (RLUC8) which, compared with the parental enzyme, is 200-fold more resistant to inactivation in murine serum and exhibits a fourfold improvement in light output. Based on mutation analysis, a double mutant showed half the resistance to inactivation in serum of the native enzyme while yielding a fivefold improvement in light output, and hence more suitable as a reporter gene [101]. RLUC8 has been mutated further to obtain Renilla luciferase variants with

bathochromic (red) shifts of up to 66 nm (547 nm peak) that also had greater stability and higher light emission than native enzyme [102]. Such redshifted forms will be immensely helpful for imaging gene expression from deep tissues.

A third example of a bioluminescent reporter gene is the *Gaussia* luciferase enzyme from the marine copepod *Gaussia princeps*. *Gaussia* luciferase (*GLuc*; 185 aa, 19.9 kDa) is the smallest luciferase known and is naturally secreted. This luciferase emits light at a peak of 480 nm with a broad emission spectrum extending to 600 nm when it reacts with its substrate, coelenterazine. The humanized form of the protein when expressed in mammalian cells from an HSV-amplicon vector showed about 100-fold higher bioluminescent signal intensity compared to other well-studied luciferases like *Rluc* or *Fluc* under most conditions. Like other coelenterazine luciferases, *Gluc* does not require ATP for activity, but unlike other luciferases, it is a secretory protein and therefore can report from the cells themselves as well as their immediate environment [21]. The secretory nature of the protein however poses a problem while trying to correlate signal intensity with the number of transduced cells. Another major disadvantage involves rapid loss of signal through diffusion away from transduced cells. Regardless, because of its small size, *Gluc* will likely have many potential uses as reporter genes in gene therapy using vectors in which payload size is limited.

Recently, activatable luciferase molecules have been developed for imaging apoptosis. In principle, the luciferase activity is silenced by flanking the protein moiety at both termini with in-frame caspase-3 substrate sequences and the estrogen receptor regulatory domain [103]. The attenuated activity of the fusion protein can be unleashed on induction of caspase-3 in cells undergoing apoptosis and thus can be imaged with bioluminescence imaging. A different strategy was employed to build a new caspase-3 sensor fusion protein (MTF) using three different reporter genes to allow multimodality imaging of apoptosis. This fusion protein contains a fluorescent reporter-mRFP1, a bioluminescence reporter-FL, and a PET reporter-HSV1-sr39truncated thymidine kinase (protein) (TK) fused by the caspase-3-recognizable polypeptide linker [Asp-Glu-Val-Asp(DEVD)]. Upon cleavage by activated caspase-3 in apoptotic cells, the fusion protein with attenuated activity for each component showed significant increases in the activities of all the reporter genes both in mammalian cells and in mouse tumor models (Ray et al., unpublished data).

Comparing the technical and practical aspects between fluorescent and bioluminescence systems reveals substantial differences, which are briefly mentioned here. Fluorescence imaging benefits greatly from relatively high photon yield from its proteins and dyes and can be imaged with conventional photographic equipment rather than the more expensive cooled CCD cameras. By comparison, the photon yield of bioluminescence systems is significantly lower, and imaging of living subjects always requires a cooled CCD camera. Fluorescence imaging can potentially be used to image simultaneous signals of different colors, whereas multiplexing different and simultaneous signals in bioluminescence imaging

is difficult, owing to the differential enzyme kinetics and time to peak photon flux between varying luciferases.

On the other hand, bioluminescence imaging has certain advantages over the fluorescence systems. For example, autofluorescence, a source of background signal in the image, is significantly less in bioluminescence for reasons discussed earlier. Also, bioluminescence reporters can be utilized as soon as they are synthesized. In contrast, the fluorescent proteins usually have a requisite period, some substantially longer than others, of posttranslational processing and maturation prior to their function as a fluorescent reporter [80]. In some cases, where temporal resolution is an important issue in the monitoring of gene therapy, the use of fluorescence techniques may be limiting in this regard. Bioluminescence proteins also take some finite time to mature, but anecdotal evidence suggests that it is not as long as the fluorescent proteins; future studies are sure to address this issue.

Imaging with bioluminescence techniques permits rapid, repetitive, or prolonged imaging periods so long as the required substrates and cofactors are available. The physical phenomena of photobleaching, a property seen in many fluorescent proteins where the fluorochrome is permanently extinguished after light excitation or ultraviolet light exposure, makes imaging difficult if prolonged excitation periods or rapid repetitive imaging is needed; repeat imaging can only take place once fresh fluorescent protein has been generated. Among the different fluorescent probes, QDs are much more resistant to photobleaching. These inorganic nanoparticles possess a well-encapsulated semiconductor core, which protects the QDs from the photochemical reactions that cause photobleaching. Therefore, QDs can be employed in continuous tracking studies over a long period of time [104]. However, photobleaching is not a significant problem in bioluminescence imaging. Having stated the above, no formal comparison has yet been made between fluorescence and bioluminescence using the same animal model, fusion reporter/individual reporters, and the same CCD camera. Future studies addressing these issues should help better define the more ideal reporter.

30.3.2 RADIONUCLIDE-IMAGING REPORTER SYSTEMS

Currently, PET or gamma/SPECT reporter genes encode a receptor, enzyme or ion pump, which bind a radiolabeled ligand, interact with a radiolabeled substrate, or facilitate intracellular translocation of ionic radioisotopes, respectively. The reporter gene product is designed to sequester the probe intracellularly and/or on the surface of cells expressing these genes. Ideally, those cells lacking the transgene will be unable to trap the reporter probe. The amount of probe or tracer used is typically in the nanogram range and does not lead to any pharmacological effect [105]. In contrast, bioluminescence strategies, NIRF and MRI require mass amounts of probe (usually micrograms to milligrams) and, as a result, may produce a pharmacologic effect and have a greater potential for toxicity.

Radionuclide imaging has significant advantages in that it permits quantitative and repetitive imaging in the same subject over time [106–109]. Perhaps the main drawback of radionuclide-based techniques is that unsequestered probe usually circulates in the enterohepatic system or is excreted in the kidneys. As a result, probe can collect in the gut, kidneys, urinary bladder, or gall bladder, making it difficult to specifically evaluate these organs. Discussed below are two fundamentally different approaches to radionuclide-based reporter imaging: direct and indirect imaging.

30.3.2.1 Direct Radionuclide Imaging: HSV1-TK, Mutant HSV1-TK, Sodium Iodide Symporter, and Cytosine Deaminase

One of the major advantages of using the radionuclide techniques is that it allows the delivered therapeutic gene to be imaged directly (i.e., direct imaging). In direct imaging, there is no need to couple the expression of a therapeutic gene with an additional reporter gene since reporter probes already exist for the therapeutic gene. The HSV1-tk gene when used under certain conditions is an exemplary model of direct imaging.

Mammalian TKs phosphorylate thymidine for its normal incorporation into DNA during replication. The HSV1-tk, gene on the other hand, is normally employed as a suicide gene for the therapy of cancer. The gene product, with its broad substrate specificity, is able to phosphorylate acycloguanosine, guanosine, and thymidine derivatives and subsequently trap these substrates intracellularly. Therefore, when delivered with a prodrug such as acyclovir, gancyclovir, and penciclovir, the HSV1-tk acts as a suicide gene. The enzyme converts the prodrug to phosphorylated nucleoside analogs, which when trapped inside the cell at high concentrations leads to cell death due to premature chain termination. Transfected cell populations particularly affected by this type of therapy are those which have a high mitotic index. When radiolabeled acycloguanosines (e.g., 9-[(3-¹⁸F) fluoro-1-hydroxy-2-propoxy)methyl]guanine ([¹⁸F]FHPG); 9-(4-¹⁸F) fluoro-3-hydroxymethylbutyl)guanine ([¹⁸F]FHBG)), guanosines (e.g., fluoroganciclovir ([¹⁸F]FPGV); fluoropenciclovir ([¹⁸F]FPCV)), and thymidine derivatives (2'-[¹²⁴I] fluoro-2'-deoxy-1-β-D-arabinofuranosyl-5-iodouracil ([¹²⁴I]FIAU)), 2'-[¹⁸F]fluoro-5-ethyl-1-beta-D-arabinofuranosyluracil ([¹⁸F]-FEAU) are used in nonpharmacologic (trace) doses, they can serve as PET reporter probes. Similarly, [¹³¹I]FIAU and [^{123/125}I]FIAU can be used as gamma camera or SPECT reporter probes. The pyrimidine analog FEAU is a strong antiherpetic agent with much lower toxicity against host cells. Compared to other pyrimidine analogs, FEAU exhibited a much higher affinity for viral TKs than for host cell enzymes, has primarily renal clearance, leading to a low background signal in the abdomen. This led to the growing interest in radiolabeled FEAU as a PET tracer for the HSV1-tk reporter gene [110–112]. Details of the synthesis and kinetics of these and other similar agents have been reviewed [113–119].

Endogenous TK, HSV1-tk and a mutated form of HSV1-tk, HSV1-sr39tk, each demonstrate different substrate specificity, which can be exploited for therapeutic and imaging purposes. For example, endogenous TK demonstrates narrow substrate specificity and cannot efficiently phosphorylate radiolabeled prodrugs. Although endogenous TK can phosphorylate the prodrugs/probes to a minor degree, nontransfected cells cannot accumulate significant amounts of the radiolabeled prodrugs. Instead, these radiolabeled prodrugs specifically localize to cells, tissues, or tumors that express the HSV1-tk gene.

Comparison of the HSV1-tk probes demonstrate that [^{18}F]FEAU displays favorable pharmacokinetics (greater sensitivity, better contrast, less background noise) and, thus, the best imaging potential. Cell uptake studies showed that [^3H]FEAU has a higher specificity compared to [^{13}C]FIAU. This is consistent with another study with C6 cells where [^{18}F]FEAU showed the highest specificity ratio of 84.5 compared to 10.3 for [^{18}F]FIAU and 40.8 for [^{18}F]FHBG [110]. Studies with the fluorine-18-labeled tracer in mice with HT29 xenografts showed rapid clearance from the blood within 2 h and a fivefold higher uptake in HSV1-tk expressing tumor compared to the wild-type tumor. Majority of the activity was retained in the tumor while all other organs demonstrated low accumulation at 2 h except the bladder owing to urinary excretion. Uptake in wild-type tumors in the left thigh was as low as the background activity at 2 h [112].

Among the other tracers, [^{124}I]FIAU may also be a good choice in some cases because the half-life of ^{124}I is 4.2 days, allowing for longer systemic clearance. On the other hand, this longer half-life may also prove problematic in cases when frequent repeat imaging is needed since a minimum 10 to 12 days between imaging sessions is needed to allow clearance of prior probe administration. Further testing has shown that [^{18}F]FHPG and [^{18}F]FHBG are inferior agents for HSV1-TK. This variability seen amongst HSV1-TK reporter probes is in part due to differences in biologic half-life, stability, substrate competition, degree of nonspecific binding, specific retention, rates of cellular transport, method of transfer (viral-mediated vs. stable transfection), and routes of clearance [120].

Mutated versions of the suicide gene, HSV1-tk, have been created to enhance its killing potential by increasing its ability to phosphorylate prodrugs [121]. From a library of site-directed mutants, it has been determined that the product of mutant HSV1-sr39tk suicide gene is more adept at phosphorylating ganciclovir and less efficient in phosphorylating endogenous thymidine when compared to wild-type HSV1-TK. In light of this, mutant kinase has been exploited as a reporter gene since radiolabeled reporter probes already exist and are identical to those used for the wild-type HSV1-TK. As expected, HSV1-sr39TK efficiently phosphorylates [^{18}F]FGCV, [^{18}F]FPCV, [^{18}F]FHPG, and [^{18}F]FHBG, with [^{18}F]FHBG as the most effective substrate for the mutant TK. The ability to trap the reporter probe is improved by at least a factor of 2 to 3 in mutant TK-expressing tumor xenografts when compared with wild-type TK. Significantly improved uptake of the reporter

probe is seen in the liver following systemic delivery of a recombinant adenoviral vector carrying the mutated transgene, resulting in enhanced sensitivity for imaging this transgene *in vivo* when compared to wild-type HSV1-tk [122]. An example of the use of HSV1-sr39tk as a potential reporter gene for cardiac gene therapy is provided (Figure 30.8). As an aside, an example of an optical reporter for use in cardiac gene therapy (using a nearly identical adenoviral vector and the firefly luciferase reporter gene) is provided for side-by-side comparison to better demonstrate the spatial advantages of microPET imaging (Figure 30.8).

Ponomarev et al. recently described a novel, human derived, nonimmunogenic reporter gene, the human mitochondrial thymidine kinase 2 (hTK2) [123]. A truncated version of the protein, ΔhTK2 , was capable of phosphorylating and trapping PET probes FIAU and FEAU both *in vitro* and in animals with high specificity. Because of its human origin, such a reporter gene has the potential of being applied in preclinical and clinical trials to follow molecular events noninvasively.

Other viral TKs have also been explored as reporter genes. The varicella-zoster virus TK gene (VZV-tk) was explored as a potential PET imaging gene recently. The protein product of VZV-tk gene is capable of phosphorylating bicyclic deoxynucleoside analogs (BCNAs) and trapping them in cells. Thus BCNAs labeled with a positron-emitting radioisotope in combination with the VZV-tk gene can result in a new PET reporter gene/probe system [124].

Another therapeutic transgene, which lends itself to direct imaging in living subjects, is the sodium/iodide symporter (NIS) gene (Figure 30.9). NIS is an intrinsic membrane protein, which is responsible for translocating and concentrating iodide within thyroid follicular cells. In this normal, physiologic situation, iodide is eventually used to make the thyroid hormones [125]. Recent cloning of the symporter has permitted the investigation of its role as a suicide gene [126]. Because the symporter can concentrate high intracellular levels of iodide (including radioiodide, ^{131}I), targeted cells expressing the symporter can be killed in this form of targeted radiotherapy by the accumulation of radioiodide. It is estimated that a dose of up to 50,000 cGy of ionizing radiation can be achieved in targeted cancer cells [127–130]. The lethal effects of the NIS have been cleverly demonstrated *in vitro* in a variety of cell lines including melanoma, colon cancer, and ovarian carcinoma, and in a murine model of a transfected melanoma xenograft following intraperitoneal injection of ^{131}I [131]. Also, tissue-specific expression of NIS transgene is possible by fusing a prostate-specific antigen (PSA) promoter fragment with the NIS gene, the result being tissue-specific expression of NIS transgene and subsequent accelerated death of an androgen-dependent prostatic carcinoma xenograft after injection with a therapeutic dose of radioiodine [132]. In another elegant study, researchers used a novel oncolytic vesicular stomatitis virus expressing the NIS gene to treat radiosensitive multiple myeloma with ^{131}I . In this study, NIS also acted as a reporter gene and helped in monitoring the intratumoral spread of the infection noninvasively by serial gamma camera imaging of ^{123}I -iodide biodistribution [133].

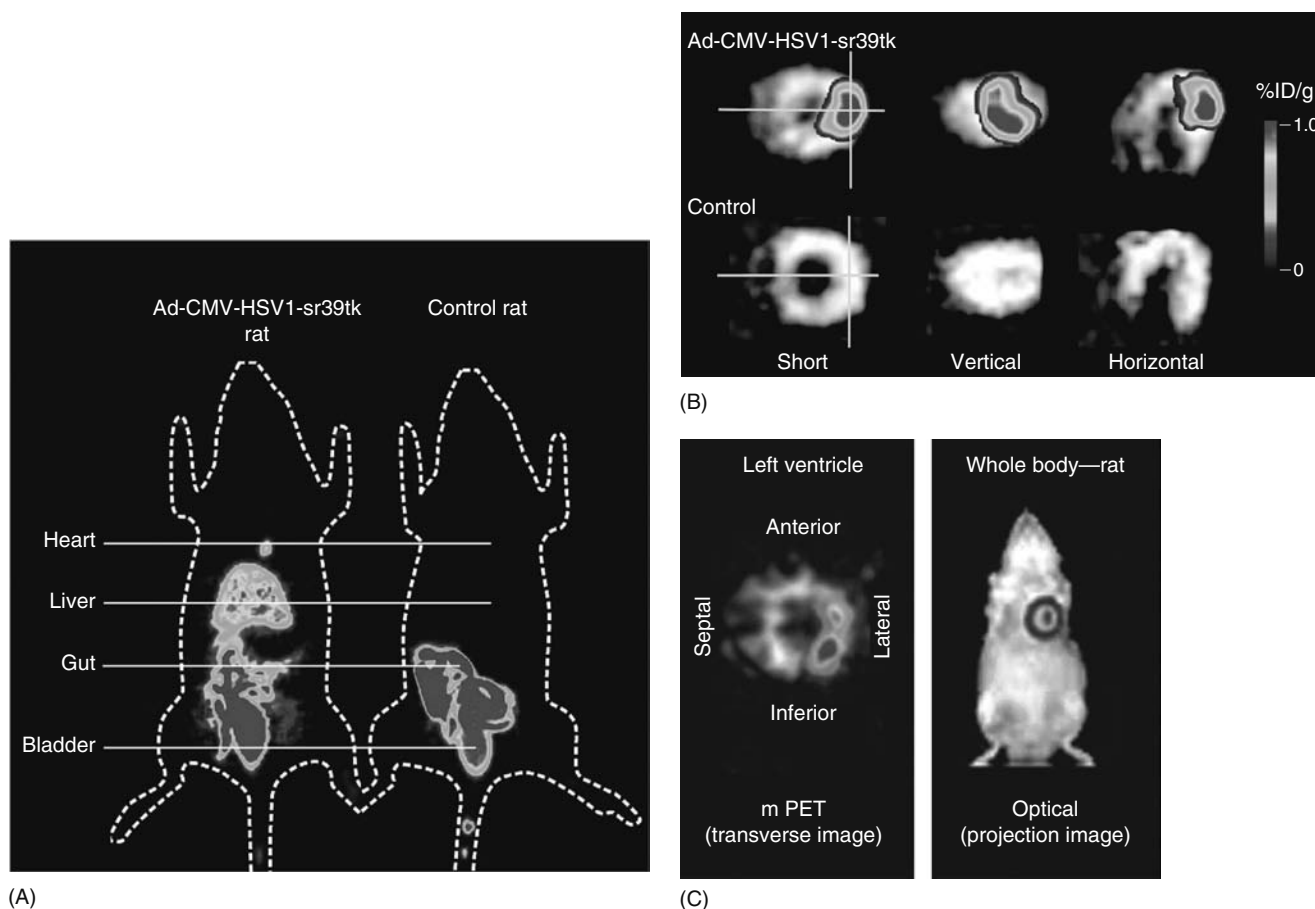

FIGURE 30.8 (See color insert following blank page 206.) MicroPET and optical (bioluminescence) imaging of cardiac reporter gene delivery. (A) Imaging cardiac gene expression using adenoviral-mediated mutant thymidine kinase (HSV1-sr39tk) as PET reporter gene and [¹⁸F]FHBG as PET reporter probe. Trapping of tracer occurs only in cells expressing the reporter gene. At day 4, whole-body microPET image of a rat shows focal cardiac [¹⁸F]FHBG activity at the site of intramyocardial Ad-CMV-HSV1-sr39tk injection. Liver [¹⁸F]FHBG activity is also seen because of systemic adenoviral leakage with transduction of hepatocytes. Control rat injected with Ad-CMV-*Fluc* shows no [¹⁸F]FHBG activity in either the cardiac or hepatic regions. Radiolabeled probe is always “visible” with radionuclide imaging regardless of whether it has localized to its target or not. As a result, radionuclide-based images will exhibit a certain degree of nonspecific tracer localization since “unbound” reporter probe is metabolized through either the enterohepatic or urinary system or both. In this example, nonspecific reporter probe activity gut and bladder activities are seen for both study and control rats because of route of [¹⁸F]FHBG clearance. (B) Tomographic views of cardiac microPET images. The [¹³N]NH₃ images of perfusion are superimposed on [¹⁸F]FHBG images (color scale), demonstrating HSV1-sr39tk reporter gene expression. [¹⁸F]FHBG activity is seen in the anterolateral wall for experimental rat compared with background signal in control rat. Perpendicular lines represent the axis for vertical and horizontal cuts. Color scale is expressed as % ID/g. (C) Comparison of typical images obtained with PET (left) and optical imaging (right). The optical method is more sensitive (at limited depths), easier to perform, and demonstrates minimal background noise. With PET, we can see that the transgene was delivered to the anterolateral aspect of the left ventricle. Such spatial resolution is not afforded by *in vivo* optical imaging at this time. (Reproduced from Wu, J.C., Inubushi, M., Sundaresan, G., Schelbert, H.R., and Gambhir, S.S., *Circulation*, 105, 1631, 2002; Wu, J.C., Inubushi, M., Sundaresan, G., Schelbert, H.R., and Gambhir, S.S., *Circulation*, 106, 180, 2002. With permission.)

Imaging of the NIS transgene is relatively straightforward since the therapeutic agent, ¹³¹I, can also be used as an imaging agent with a gamma camera or SPECT. Similarly, ¹²³I or ¹²⁵I, both of which are commercially available, can also be used as reporter probes. A significant advantage of this reporter system is that the reporter probe is relatively simple to produce and commercially available. Specialized radiochemistry, such as that required for HSV1-tk reporter probes, is not needed here. Another significant advantage of this system is that this reporter system can readily be imaged with PET using ¹²⁴I as the positron-emitting reporter probe, which is already available [134–136]; the very same living subject carrying the NIS

transgene can be imaged with either SPECT or PET depending upon the choice of reporter probe. In a recent study, the combined ¹²⁴I -PET/CT technology was employed to follow NIS gene expression in living animals with great accuracy [137]. The main confounding issue with using this reporter system, on the other hand, is radioiodine will not only localize to target cells, but it will also accumulate in normal tissues such as the thyroid, salivary glands, breast, and stomach, all of which express physiologic levels of endogenous NIS. Also, the use of radioiodide requires specialized environmental safety precautions as iodine is easily aerosolized and can pose a hazard to researchers or health care workers.

FIGURE 30.9 Gamma camera imaging of the sodium iodide symporter transgene. Recently cloned rat and human sodium iodide symporter genes (rNIS and hNIS, respectively) are increasingly showing their potential as a novel suicide gene therapy for a variety of cancer models. Once transduced to a cancer cell line, tumor or target organ via recombinant viral transfection or liposomal-mediated techniques, the expressed membrane proteins facilitate the active intracellular transport of iodide (I^-) into targeted cells. Exogenously administered radiotracers ^{123}I , ^{125}I , or ^{99m}Tc -pertechnetate results in intracellular accumulation of these tracers in cells that are transduced with this symporter. The distribution of these tracers can be imaged with a gamma camera or SPECT, and therefore be used as a means of localizing cells that have been transduced with NIS. Similarly, targeted brachytherapy can be performed by the administration of ^{131}I . (A) A retroviral vector carrying the rNIS gene was used to transduce A375 human melanoma cell line. Transduced (NIS) and nontransduced (NV) tumor xenografts were subcutaneously implanted into the left and right flank of the photographed mouse, respectively. (B) By 30 days, the tumor had reached approximately 10 mm in diameter. An intraperitoneal dose of ^{131}I was administered and a gamma camera image was obtained after a 1 h incubation period. rNIS-transduced xenograft (left flank) demonstrates radioiodide uptake while nontransduced tumor (right flank) does not. The thyroid, stomach and, to a lesser extent, the salivary glands endogenously express sodium iodide symporters and, thus, normal, physiologic radioiodide uptake is seen in these organs. (Reproduced from Mandell, R.B., Mandell, L.Z., and Link, C.J., Jr., *Cancer Res.*, 59, 661, 1999. With permission.)

The CD transgene, another suicide gene, encodes an enzyme, which converts 5-FC to the toxic 5-FU. Efforts to image this transgene, which have been performed with radiolabeled fluorocytosine as a probe, have largely been hampered by suboptimal pharmacokinetics: poor tracer uptake and poor retention of the toxic metabolite [138]. Extended periods of up to 48 h are required to see differential accumulation of tracer between transfected and control cells. While targeted delivery of CD remains a viable method of suicide gene therapy [139], alternative substrates for CD, which are rapidly transported, deaminated, and trapped intracellularly, will have to be developed in order to use this transgene as a reporter gene.

30.3.2.2 Indirect Radionuclide Imaging: D2R, Mutant D2R, and Somatostatin-2 Receptor

In cases where a reporter probe does not already exist for a delivered transgene, a number of strategies exist for indirect transgene imaging. Indirect imaging involves the simultaneous coexpression of the therapeutic gene and reporter gene with both driven by the same or identical promoter. Because reporter gene expression can directly correlate with transgene expression, such approaches have the potential to give us

valuable information on the quantity and localization of transgene expression [140]. It should be noted, however, that it is not given that they directly correlate; one can hope that they do but each approach/application has to be tested. Further details regarding such indirect approaches are provided in a later section.

In radionuclide imaging, one way to perform indirect imaging is to couple the therapeutic gene to a reporter gene, which encodes a receptor that can bind, and, therefore, trap radiolabeled ligands. Following transfection, targeted cells may express the therapeutic gene product and receptor in proportional amounts. Subsequently, the ectopically expressed receptor will either localize to the cell membrane or remain intracellular. Following exposure to radiolabeled ligand probe, cells expressing the receptor will specifically bind the probe resulting in a complex, which can be detected by PET/SPECT/gamma camera imaging. The intensity of activity on the PET image is directly proportional to the number of these receptor–ligand complexes, and, therefore, correlated to the amount of therapeutic gene expressed. Ideally, those cells not producing the receptor will be devoid of tracer signal.

An example of a receptor-based reporter gene is the dopamine type 2 receptor reporter gene (D2R) [108]. D2R is normally an endogenous, cell-surface receptor predominantly

expressed in the striatum. When activated, it causes a G-protein-coupled reduction of cyclic adenosine monophosphate (cAMP) via its inhibition of adenylate cyclase. When D2R is used as a reporter gene, a radiolabeled D2R antagonist, spiperone [3-(2' [¹⁸F]fluoroethyl)spiperone ([¹⁸F]FESP)], serves as the receptor's ligand and accumulates intracellularly and on the cell surface of D2R-expressing tissue. Radiolabeled spiperone, originally used to monitor levels of endogenous levels of striatal D2 receptors *in vivo*, binds to D2R with high affinity and is able to cross the blood-brain barrier (BBB). To overcome potential deleterious effects of ectopic D2R activation by circulating endogenous ligands, mutant D2R reporter genes, D2R80A and D2R194A, have been created, which are disengaged from downstream transduction events while maintaining a high binding affinity for the ligand probe [107].

A few advantages of the D2R-based reporter system are worth commenting. [¹⁸F]FESP's ability to cross the BBB and cell membranes favors its use in the central nervous system (CNS) relative to other reporter systems such as the HSV1-tk (mutant or not) reporter system since [¹⁸F]FHBG is not as efficient in crossing this important barrier. Furthermore, [¹⁸F]FESP has a relatively easier time of localizing to target, which is a cell-surface and intracellular receptor. In contrast, [¹⁸F]FHBG has to cross the cell membrane in order to interact with the target enzyme and is, therefore, subject to transport kinetics. Also, D2R, an endogenous protein, is not immunogenic compared to HSV1-TK and therefore probably more appropriate for repeated imaging during longitudinal studies. Interestingly, despite these relative advantages of the D2R/[¹⁸F]FESP system, equivalent sensitivities are reported between the D2R/[¹⁸F]FESP and mutant HSV1-tk/[¹⁸F]FHBG PET reporter gene imaging systems in the liver (~20% injected dose (ID)/g in the liver when used with adenoviral delivery systems carrying constitutive CMV-based expression of the reporter gene). One must also note that endogenous D2R expression in the striatum will produce background noise and therefore [¹⁸F]FESP imaging will only be useful outside the striatum.

Another receptor-based reporter system takes advantage of the SS membrane receptors (SSTR), which also belong to the family of G-protein-coupled receptors. Under normal conditions, the interaction between SSTR and its ligand, SS is known to have a variety of biologic effects including a role in vasoconstriction, immunomodulation, and an inhibitory effect on endocrine and exocrine secretory functions. More recently, SSTR-activated signal transduction pathways have been implicated in the induction of apoptosis and inhibition of cell growth [141]. SSTRs have also been found in normal and hyperplastic human endothelium where they are believed to exert negative effects on angiogenesis. Five different SS receptor subtypes have been described thus far (SSTR1 through SSTR5) and their respective genes have been cloned [142–144].

Historically, the development of this reporter gene centered on probes which were already in existence and were being used clinically to identify diseased states characterized by upregulated SSTR receptors. Radiolabeled SS analogs, for

example, have been clinically used to identify a number of primary human cancers and their metastases where elevated levels of SS receptors are seen [145]. Neuroendocrine tumors (including carcinoid, islet cell tumors, small-cell lung cancers, pheochromocytomas, gastrinoma, paragangliomas, and medullary thyroid cancers), pituitary gland tumors as well as sarcomas, meningiomas, low-grade astrocytomas, lymphomas, some breast cancers, and metastatic prostate cancers are known to express high levels of SSTR, particularly SSTR2. In fact, the combination of high SSTR receptor density seen in some tumors and the antiproliferative, antiangiogenic, and antisecretory effects of SS analogs form the premise for SS analog therapy for cancer patients [146,147].

The favorable binding kinetics of SS-SSTR are the basis for use of the *sstr2* gene as reporter gene. [¹¹¹In]-DTPA-D-Phe¹-octreotide (Octreoscan) and [^{99m}Tc]-depreotide (Neotect), radiolabeled SS analogs have been in routine clinical use for the past several years for the imaging of SSTR-positive tumors using gamma cameras or SPECT, i.e., SSTR scintigraphy [148,149]. These agents have also been useful in the imaging of non-neoplastic conditions, which are associated with SSTR upregulation such as a variety of autoimmune and granulomatous diseases.

The potential of using *sstr2* as a reporter gene has been realized. Figure 30.10 demonstrates adenoviral delivery via intratumoral injection of human *sstr2* gene into a tumor xenograft of a mouse. The transfected tumor is subsequently detected with a gamma camera following an intravenous injection of [^{99m}Tc]P2045, an SS analog [150]. Recently, a positron-emitting SS analog [^{94m}Tc] Demotate-1 could be used to determine adenovirus-mediated SSTR2 gene transfer by microPET imaging, a modality that can improve the sensitivity of the SSTR2 reporter gene system [151]. For *sstr2* to serve as a true reporter gene, however, it will have to be uncoupled from signal transduction since it may have undesirable effects in targeted and surrounding cells in its current state.

On a side note, *sstr2* is being tried as a double-edged suicide transgene for cancer therapy. Not only does SSTR primarily mediate antimetabolic effects as described earlier, but it can also be utilized for its ability to internalize and retain SS analogs. Efforts are being made to deliver cytotoxic agents to targeted cells by using the receptor as a courier of toxic SS analogs, such as [⁹⁰Y]-DOTA-D-Phe¹-Tyr³-octreotide ([⁹⁰Y]-SMT 487).⁹⁰Y exerts its lethal effects by local irradiation via emitted β-particle. When SSTR-null tumor xenografts were injected with recombinant adenovirus encoding the SSTR2 receptor, they become susceptible to systemically administered [⁹⁰Y]-SMT 487 [152]. This version of targeted radiotherapy is able to significantly reduce quadrupling times of the xenograft. When the *sstr2* transgene is used in this manner it can be directly imaged using Octreoscan.

Indirect imaging can also be accomplished by coupling the therapeutic gene to a reporter gene that encodes an enzyme, which converts freely dispersible radiolabeled substrate probes into sequestered products [153]. For example,

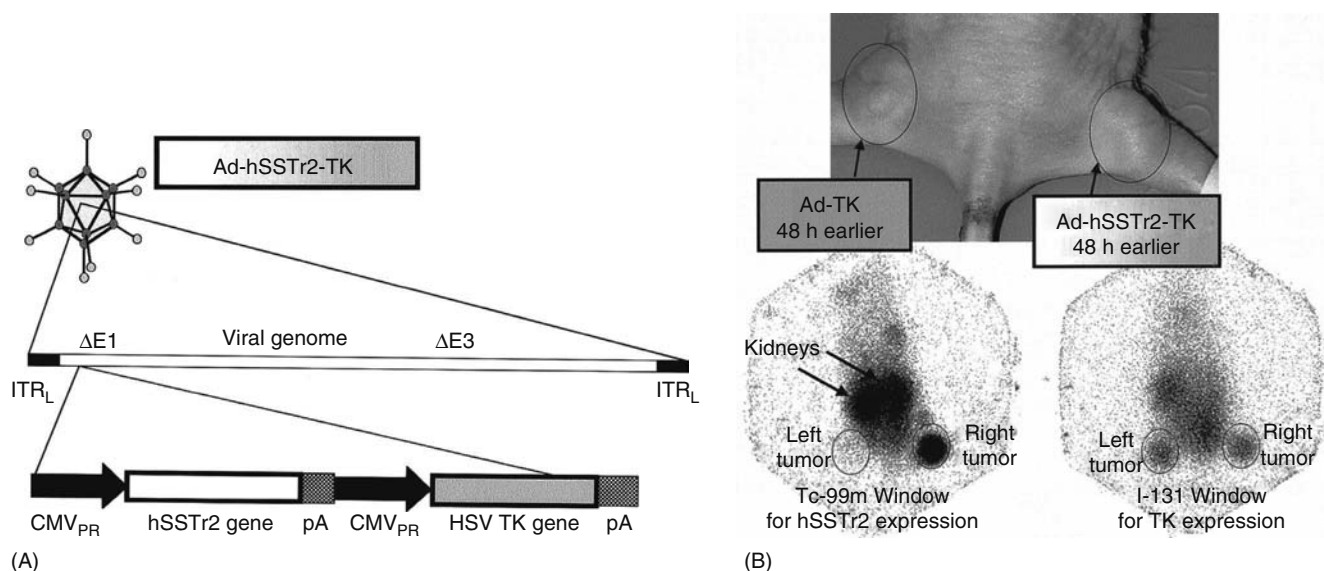

FIGURE 30.10 Gamma camera imaging of a dual promoter construct. (A) To measure target (therapeutic) gene expression, several strategies are employed to “link” the therapeutic gene with a reporter gene on a single vector. In one strategy, indirect measurements of a target gene expression can be made by a downstream reporter gene with both genes driven by separate and identical promoters (i.e., the “dual-promoter” construct). Replication-incompetent adenovirus encoding human type 2 somatostatin receptor (hsstr2) and the herpes simplex TK enzyme (Ad-CMV-hsstr2-CMV-tk) is an example of this construct. Both transgenes are driven by the CMV promoter element. (B) Human nonsmall cell lung cancer tumor xenografts were subcutaneously implanted in the right and left flank of a mouse. The left tumor was injected with Ad-CMV-tk and the right tumor was injected with Ad-CMV-hsstr2-CMV-tk. Forty-eight hours later, the mouse was simultaneously injected (IV) with both ^{99m}Tc -P2045, which is an SS receptor peptide ligand, to detect expression of hsstr2 and radioiodinated ^{131}I -2'-deoxy-2'-fluoro- β -D-arabinofuranosyl-5-iodouracil (FIAU) to detect TK expression. Imaging was performed with an Anger gamma camera 5 h after injection of the radiotracers. The gamma camera can be “tuned” to select for gamma rays that fall within a defined range. It is this property of the gamma camera which can discriminate between the activity of different radioisotopes such as ^{99m}Tc (140 keV) and ^{131}I (364 keV). Thus, two images can be obtained from the same animal by changing the window settings in the gamma camera: one for ^{99m}Tc (for hsstr2 expression, lower left image) and the other for ^{131}I (for TK expression, lower right image). The right flank xenograft, which was injected with the dual promoter construct (Ad-CMV-hsstr2-CMV-tk), demonstrates uptake of both radiotracers, while the left flank xenograft (injected with Ad-CMV-tk) demonstrates [^{131}I]FIAU uptake only. These findings support the feasibility of the dual promoter approach for tracking transgene delivery. (Reproduced from Zinn, K.R., Chaudhuri, T.R., Krasnykh, V.N. et al., *Radiology*, 223, 417, 2002. With permission.)

previously described HSV1-tk or HSV1-sr39tk can be used as reporter gene by using [^{124}I]FIAU or [^{18}F]FHBG at tracer levels (subpharmacologic, nontherapeutic dose). In this manner, the HSV1-tk or mutant counterpart can be utilized strictly as a reporter gene.

30.3.3 MRI REPORTER GENES

Imaging transgene expression using MRI depends on reporter genes that encode receptors or enzymes, which specifically interact with probes which are attached or chemically modified to accommodate paramagnetic or superparamagnetic substances. Once localized to their targets, these probes alter the local magnetic field, which changes the relaxivity of nearby protons, and, concomitantly, effects a change in the RF signal detected by the receiver. A number of MRI reporter systems have been proven in animal studies: Engineered transferrin receptor (ETR)-dependent reporter systems, the iron-binding metalloproteins (e.g., the tyrosinase enzyme and the ferritin protein), and the *lacZ*-EgadMe system.

Iron, a superparamagnetic ion, can cause significant changes of the local magnetic field, which can be detected by MRI if supraphysiologic concentrations can be achieved. Transferrin (Tf), an iron-binding protein, and its cell-surface receptor (Tf-R), ubiquitously present on most cell types, mediate normal cellular iron metabolism and regulation. Normal intracellular stores of iron are dependent upon internalization kinetics of this receptor–ligand complex. Removal of the mRNA destabilization motifs in the 3' untranslated region and the iron-regulatory region of the Tf-R gene resulted in an ETR that can be constitutively overexpressed and liberated from feedback regulatory control [154,155]. As expected, ETR-transfected cells accumulate approximately 500% more probe (holo-Tf) than control cells [156]. To further augment the difference between transfected and control cells, the reporter probe itself has been modified to possess even greater magnetic susceptibility characteristics. It involves the synthesis of a 3 nm monocrySTALLINE iron oxide nanoparticle (MION) that is surrounded by a layer of low molecular-weight dextran to

which holotransferrin is covalently bound (Tf-MION). On the average, each MION particle contains approximately 2000 superparamagnetic Fe atoms (compared to the 2 Fe atoms present in a single molecule of the paramagnetic chelate, holotransferrin). As expected, T₂-weighted gradient echo MR imaging (1.5 T; imaging time 3–7 min per sequence; voxel resolution 300 × 300 × 700 μm) reveal significantly lower signal intensity in ETR⁺ tumor xenografts than control following intravenous administration of Tf-MION [154]. Recently, a second superparamagnetic reporter probe, a dextran cross-linked iron-oxide (CLIO) superparamagnetic particle conjugated to transferrin (Tf-CLIO) has also been effective in identifying ETR⁺ tissues with MRI [157]. Such superparamagnetic iron-oxide (SPIO) nanoparticles have shown much promise as cell-labeling agents giving a negative contrast in MR images wherever the labeled cells are present. The small size of the particles assists in easy transport across cell membranes, and low toxicity of the particles allows for labeling with huge iron loads (25 pg/cell) [158,159]. Stem cells (e.g., embryonic or neural stem cells) can be easily labeled by incubating them *in vitro* with SPIO particles and visualized *in vivo* using MRI [160,161]. However, a fundamental drawback of these particles is that they cannot be distinguished from a void in the MR image. Moreover these negative contrast agents also suffer from partial volume effects. Recent developments in the field allow cells labeled with SPIO to be imaged with positive contrast [159]. Spectrally selective RF pulses are employed to excite and refocus the off-resonance water surrounding the labeled cells, thereby allowing only the tissues and fluid around the cells to be detected in the MR image. Phantom studies showed a significant linear correlation between the number of cells and the signal observed ($r = 0.87, p < 0.005$). This will help in quick assessment of the location of injected cells and also for quantifying the volume of labeled cells in cell-based therapeutic approaches.

Another example of an MR reporter gene is the tyrosinase enzyme. Tyrosinase catalyzes the hydroxylation of tyrosine-yielding dioxyphenylalanine (DOPA) and its subsequent oxidation to DOPAquinone. DOPAquinone is subsequently converted to melanin, which in turn shows a high affinity for iron. Thus over-expression of tyrosinase enzyme results in cellular accumulation of iron, which accounts for the iron-induced T₁ hyperintensities in MR images. Such significant increase in signal intensities is well documented in cells [162,163]. However, toxicity issues can limit the application of this system. It has been found that melanin and melanin precursors produce highly reactive oxygen species, and thus exhibit significant toxic effects [164].

Ferritin, another metalloprotein, serves as the body's iron depot and its main function is to store iron inside its protein shell in a biochemically safe crystal configuration. Native ferritin is, however, a weak contrast agent. In an effort to improve its relaxivity, the native iron oxyhydroxide core was removed and the protein shell was reconstituted with a superparamagnetic core. These so-called magnetoferritin molecules have proven to be effective T₂ contrast agents both

in vitro and *in vivo* at 1.5 T [165,166]. In an effort to use ferritin as a reporter gene, an adenovirus vector encoding the protein was injected into the mouse brain. After injection, the transfected cells showed a marked hypointensity on T₂-weighted MR images [167].

A different MR imaging method shown to be compatible with living subjects relies on an enzymatic amplification strategy to monitor gene expression. As mentioned before, gadolinium (Gd) is a rare-earth element with the largest number of unpaired electrons. With seven unpaired electrons, Gd is a strong paramagnetic substance, collectively affecting the spins of water protons immediately surrounding it. The increased signal (for T₁-weighted sequences) seen in Gd-enhanced MR imaging is afforded by the increased relaxation rate of intimately associated water protons surrounding a Gd atom. Gd's ability to affect the relaxation rate of protons varies inversely with the distance between the paramagnetic ion and water protons.

Based on these principles, a reporter probe, (1-(2-(β-galactopyranosyloxy)propyl)-4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane)gadolinium(III) (EgadMe), has been cleverly formed by encasing Gd in a water-proof package, an artificial barrier or cage, which is designed to keep water molecules away so as not to be affected by the Gd's magnetic properties (Figure 30.11A) [168]. In this configuration, water has no access to the paramagnetic ion and therefore this probe is silent on MR imaging. As it turns out, part of the physical barrier is composed of a sugar- a galactopyranose cap, which has been attached to the cage by a β-galactosidase-cleavable linker. If *lacZ* is used as a reporter gene, subsequent enzyme cleavage releases the cap and allows water access to the Gd ion, thus activating this novel MR contrast agent. β-galactosidase activity, following introduction of linearized plasmid cDNA encoding *lacZ* into a specific subset of cells in a *Xenopus laevis* embryo, has been imaged after an intracellular injection of EgadMe (Figure 30.11B and C).

In its current state, EgadMe has difficulty crossing cell membranes and as a result has to be directly injected intracellularly to maximize detection *in vivo*. Furthermore, relatively slow kinetics of cleavage for this agent is perhaps suboptimal for imaging gene expression [168]. Regardless, these relatively recent developments will be refined and indicate great potential for MRI of transgene expression.

30.3.4 MAGNETIC RESONANCE SPECTROSCOPY REPORTER GENES

Certain metabolites produced physiologically from endogenous enzymes or uniquely from exogenous enzymes have unique chemical signatures that can be detected using MRS also called nuclear magnetic resonance (NMR) spectroscopy. These enzymes can be overexpressed in target tissues and can be used as MRS reporter genes to successfully track gene expression in transgenic models, transfected tumor xenografts, or viral-mediated gene transfer experiments. At this time, MRS does not produce true, spatial pictures, and,

FIGURE 30.11 MRI of β -galactosidase-activated MRI reporter probe (EgadMe). One can obtain image contrast in MRI by using paramagnetic substances, which change the local magnetic field and, thereby, increase the relaxation rate of nearby water protons. Gd is an example of a paramagnetic substance and relatively high local concentration of this agent translates into enhanced brightness as seen on T1-weighted images. (A) A reporter probe, EgadMe, has been formed by “encasing” Gd in a molecular casing, an artificial barrier, which is designed to keep water molecules away so as not to be affected by the Gd’s magnetic effects. In this configuration, water has no access to the paramagnetic ion and therefore this probe is “silent” on MR imaging. Part of the physical barrier is composed of a sugar, a galactopyranose cap, which has been attached to the cage by a β -galactosidase-cleavable linker. If *lacZ* is used as a reporter gene, subsequent enzyme cleavage releases the cap and allows water access to the Gd ion, thus, “activating” this novel MR contrast agent. (B) EgadMe permits MRI detection of *lacZ* gene expression. Linearized plasmid cDNA encoding *lacZ* is injected into one of the cells of the two-cell stage *Xenopus laevis* embryo. EgadMe is injected into both cells of the two-cell stage. Subsequent enzyme expression is on one side of the animal since the two cells represent the future right and left sides of the animal. MR imaging of the embryos has been obtained at approximately the 100,000-cell stage using a 11.7T magnet. As expected, β -galactosidase activity is seen in one half of the animal as depicted as areas of high signal intensity within the endoderm (e) and head (h). (C) Light microscopic images of same embryo fixed and stained with X-gal. Areas of X-gal staining follow regions of high signal intensity on MR image. (Reproduced from Louie, A.Y., Huber, M.M., Ahrens, E.T. et al., *Nat. Biotechnol.*, 18, 321, 2000. With permission.)

instead, shows spectral tracings of the various metabolites it is able to identify. It is a sensitive, quantitative, and relatively fast technique when compared to MRI [42].

One particular MRS-sensitive metabolic reaction produces ATP, a process catalyzed by CK:

where PCr is phosphocreatine and Cr is creatine. More specifically, ^{31}P -MRS identifies amounts of PCr, ATP, ADP, and free phosphorus in the reaction. This molecule can be detected readily in the heart, muscle, and brain since they are produced in great quantities in these organs. The liver, on the other hand, has very low levels and thus can serve as a background for situations where CK is overexpressed. A transgenic mouse model that overexpresses this enzyme in the liver has shown that it can generate MRS-detectable levels of PCr [169]. This technique is however invasive in nature as a tissue window has to be created to minimize background noise from the overlying muscle and other surrounding structures rich in CK. Future developments in ^{31}P 3D spectroscopy may eventually prove helpful.

A related study employs an invertebrate analog of CK as its reporter gene. *Drosophila melanogaster* AK has been cloned and, when introduced into mammalian muscle, produces phosphoarginine (PArg) in the following reaction [170]:

PArg provides a unique phosphorus signal, which is amplified when the transgene for AK is delivered to mammalian tissues (Figure 30.12). One important consideration in the

FIGURE 30.12 MRS of transgene expression. ^{31}P -MRS has the ability to detect phosphorus NMR signals. A recombinant adenovirus (rAdCMVAK) can be constructed to deliver AK, an enzyme unique to invertebrates, into muscle. Once introduced into mammalian muscle, the enzyme catalyzes the production of PArg, which has a unique spectral signature (both in magnitude and location on the spectrum) and which can be detected by MRS. The figure represents *in vivo* basal ^{31}P spectra from the hind limbs of a 6-month-old mouse. ^{31}P -MRS spectra from the rAdCMVAK-injected limb (upper spectrum) reveal a ^{31}P resonance at the chemical shift for PArg that is not present in the contralateral control limb (lower spectrum). (Reproduced from Walter, G., Barton, E.R., and Sweeney, H.L., *Proc. Natl. Acad. Sci. USA*, 97, 5151, 2000. With permission.)

use of *Drosophila* AK is it can act as an ATP buffer in mammalian tissues and thus the consequences of this need to be explored prior to its widespread use as an *in vivo* gene reporter gene.

Another MRS-friendly system is the CD reporter system [171]. Using ^{19}F MRS, the conversion of the relatively benign 5-FC to the cytotoxic agent (5-FU) driven by this enzyme can be detected. Tumor xenografts transfected to express yeast CD have been shown to produce 5-FU with MRS.

30.4 STRATEGIES FOR TRACKING VEHICLES AND TRANSDUCED CELLS

The list is quite long for the array of vehicles being developed, both viral and nonviral, for the delivery of gene vectors. The details of such carriers are, of course, provided elsewhere throughout this book. There are two fundamentally different ways to track the biodistribution of delivered agents. One method is to track the sites of successful gene transfer/expression (various methods described in this chapter) and the other method relies on directly labeling vehicles, DNA, or cells with radionuclides, fluorescent dyes, or MR-compatible contrast agents. The last method may give better spatiotemporal information with respect to distribution of the vehicles or DNA material used for therapy, but does not give any information with regard to the success of gene transfer. The latter method has been reviewed recently and includes the direct labeling of herpes virus with ^{111}In , adenoviral knob with $^{99\text{m}}\text{Tc}$, liposomes with ^{111}In , double-stranded DNA by peptide-based chelates ($^{99\text{m}}\text{Tc}$]PBC), genetically modified mesothelioma cells with technetium ($^{99\text{m}}\text{Tc}$]PA1-STK), myoblasts with technetium, and DNA delivery systems with MRI-detectable DNA-binding chelates [172–179].

For those involved in the development of novel viral or nonviral delivery vehicles, targeting and efficiency of gene transfer are primary concerns, and, thus, examples of the former method are given here. The success of exogenous gene expression is dependent on its ability to at least survive the following series of stringent events: the DNA–vehicle complex has to bind specific cell-surface receptors, undergo receptor-mediated endocytosis, survive endosomal lysis, be released from endosomal captivity, endure the cytoplasmic environment, be destined for targeted entry of the nucleus, and ultimately released from carrier molecules to facilitate gene expression [180]. Whether it is pseudotyped lentiviruses, modified PEI complexes, liposomes, etc., one major role reporter genes are expected to provide is the monitoring of localization, biodistribution, and gene transfer efficiency of these delivery vehicles in living subjects. Noninvasive localization of retroviral [181], adenoviral [182], herpes viral vector [183] mediated HSV1-tk gene transfer has been performed. Figure 30.13 is an example of replication-conditional, oncolytic herpes simplex virus–mediated gene delivery. Constitutively expressed optical or PET reporter genes have been helpful in studying the distribution of nonviral vehicles such

FIGURE 30.13 (See color insert following blank page 206.) Tracking HSV infection with [^{131}I]FIAU using autoradiography. Tracking wild-type HSV-1 infection with radionuclide-based techniques can be accomplished using the virus' native TK gene and a reporter probe such as radiolabeled [^{131}I]FIAU. To help corroborate imaging findings with histochemistry findings, a replication conditional, oncolytic recombinant HSV-1 virus vector, hrR3, containing a *lacZ* insertional mutation within the *RR* gene locus, has been prepared. Following injection of the vector into rat gliosarcoma xenografts, tumors were processed for tissue-sectioning, autoradiography, and β -galactosidase-stained histology. Image coregistration of tumor histology, HSV-1-tk related radioactivity (assessed by [^{131}I]FIAU autoradiography), and *lacZ* gene expression (assessed by β -galactosidase staining) demonstrated a characteristic pattern of gene expression around the injection sites. A narrow band of *lacZ* gene expression immediately adjacent to necrotic tumor areas is observed, and this zone is surrounded by a rim of HSV-1-tk-related radioactivity, primarily in viable-appearing tumor tissue. PET images (not shown) of injected tumors in the intact animal have also been performed using [^{124}I]FIAU as a reporter probe; the areas of PET-labeled probe uptake correlate well with the β -galactosidase-stained photomicrographs. (Reproduced from Jacobs, A., Tjuvajev, J.G., Dubrovin, M. et al., *Cancer Res.*, 61, 2983, 2001. With permission.)

as PEI polyplexes, which have been covalently modified with Tf to facilitate targeting (Figure 30.14) and cationic lipid-DNA complexes (Figure 30.15).

30.5 NONINVASIVE IMAGING OF CELL TRAFFICKING

Stem cell-based therapeutic approaches hold great promise in the treatment of degenerative diseases, cardiovascular diseases, and certain genetically inherited deficiencies. For example, transplantation of embryonic stem cells into an ailing heart is gradually emerging as a promising therapeutic option for coronary heart disease. Similarly, neural stem cell-based approaches have been successfully employed in several CNS pathologies like Parkinson's disease, traumatic lesions of the spinal cord, ischemic and hemorrhagic brain lesions, and multiple sclerosis [184]. On a different note, elimination of tumor cells by T-cell transfusion, a process termed as adoptive immunotherapy, is being rigorously pursued as a promising treatment option for cancer. All these cell-based therapeutic approaches can hugely benefit from ways to repeatedly monitor the locations of engrafted cells to determine their viability, performance, and expansion noninvasively [185]. This can be achieved by either transfecting these cells stably with a suitable reporter gene or by labeling the cells by a suitable contrast agent prior to systemic administration. For long-term tracking, the reporter gene approach is more desirable. Reporter genes integrated in to the cell genome would be extremely useful in assessing survival status of the implanted cells because the reporter will be expressed as long as the cells are alive and will be

passed to daughter cells upon cell division. However, long-term expression of the reporter gene can be subjected to silencing by epigenetic mechanisms such as promoter methylation or histone deacetylation. Krishnan et al. showed that luciferase expression in a rat embryonic cardiomyoblast cell line H9C2 stably transfected with firefly luciferase reporter gene decreased with every passage, such that at passage 8 it was only 0.01% of that of passage 1 [186]. When cells were treated with an antimethylating agent, 5-Aza, they showed a higher luciferase signal in living animals compared to the untreated counterparts even 8 days postimplantation. Such loss of reporter gene expression poses a difficult challenge for molecular imaging of reporter gene-labeled cells.

30.5.1 NONINVASIVE IMAGING OF STEM CELL BASED THERAPY

Since stem cells are emerging as promising tools to replace damaged organs and to rejuvenate diseased organs in many human disorders, ways to track these cells once they enter the body have become a very important field of study. Different imaging modalities and contrast agents have been employed to monitor cell transplantation, transduction, and migration, and for evaluation of cell trafficking, correction mechanisms, and efficacy of new therapeutic strategies in different animal models of human diseases [184]. Such imaging approaches may not only improve our understanding of therapeutic mechanisms in preclinical studies but may also facilitate rapid translation of cell-based therapies into clinical practice.

Stem cells can be labeled directly by contrast agents such as 2-[F-18]-fluoro-2-deoxy-D-glucose ([F-18]FDG) for PET, [In-111]oxine for SPECT, and SPIO particles for MRI. This

FIGURE 30.14 (See color insert following blank page 206.) Tracking Tf targeted polyethylenimine (PEI)-mediated gene delivery using optical bioluminescence imaging. Delivery of the bioluminescence reporter gene, firefly luciferase (*Fluc*), by CMV-*Fluc* DNA/PEI polyplexes and subsequent *Fluc* expression can be imaged in living mice using a cooled CCD camera. Additionally, the biodistribution of modified PEI polycation complexes, altered with molecules such as Tf or polyethylene glycol (PEG), can be studied in this manner. Tf targeting has been shown to improve the transfection efficiency in certain tumor cell lines and PEG modification has been shown to improve circulation times of DNA/PEI complexes and prevent their nonspecific uptake by the reticuloendothelial system. All CCD images are of living mice carrying N2A xenograft 24 or 48 h after intravenous injection of various DNA/PEI polyplexes. Site of tumor is indicated (T). (A) PEI (positive control) treated animals show relatively high *Fluc* expression (using 1× D-Luciferin) in the lungs as compared with the tumor. The activity on the left-hind limb is from the N2A cell tumor (T). Nonspecific tail activity occurs at the DNA/PEI polyplex injection site. All *Fluc* expression decreases at 48 h. (B) Tf-PEI-PEG-A, Tf-PEI-PEG-B, and Tf-PEI treated mice show *Fluc* expression (using 2× D-luciferin) in the tumor (T) and tail regions, but no detectable signal in the lungs. For each formulation, expression in the tumor varied over 24 to 48 h. All images are quantitated as indicated by the two scales (RLU/min). (Reproduced from Hildebrandt, I.J., Iyer, M., Wagner, E., and Gambhir, S.S., *Gene Ther.*, in press. With permission.)

method does not involve extensive manipulation of the cells and, therefore, is often preferred for clinical applications. However, there are a couple of limitations: labels are diluted upon cell division, making these cells invisible and labels may efflux from cells or may be degraded over time. Furthermore, even cells that are nonviable can lead to signal till the dead cells are removed by the macrophages.

As described earlier, reporter genes can be used to label stem cells. Imaging of genetically labeled cells was performed using rat cardiomyoblasts, which were infected *ex vivo* with adenovirus carrying the HSV1-sr39tk and luciferase reporter genes (detectable number of cells was 5×10^5 cells by optical imaging and 3×10^6 cells by PET) [187]. Cell-specific *in vivo* optical and micro-PET imaging was feasible for up to 2 weeks after direct injection of cells into the myocardium of nude rats. Similarly mouse embryonic stem cells labeled with a trifusion reporter gene (*fluc-mrfp-ttk*)

helped in monitoring the kinetics of ES cell survival, proliferation, and migration following cardiac delivery (Figure 30.16) [188].

The ideal imaging modality should be the one that can provide integrated information related to the entire process of cell engraftment, survival, and functional outcome with high sensitivity and better resolution. Both radionuclide technology and MRI have the advantage of clinical applicability, with MRI having some advantages in terms of spatial resolution. While studies using conventional MRI scanners could detect up to 105 iron-oxide labeled hematopoietic bone marrow-derived and mesenchymal stem cells, use of high-field magnets (11.7T) enhanced the sensitivity many fold and showed the ability to track single cells containing a single iron particle [189,190]. Compared to MRI, direct labeling of cells with radionuclides can provide high sensitivity due to low background. After intraventricular injection,

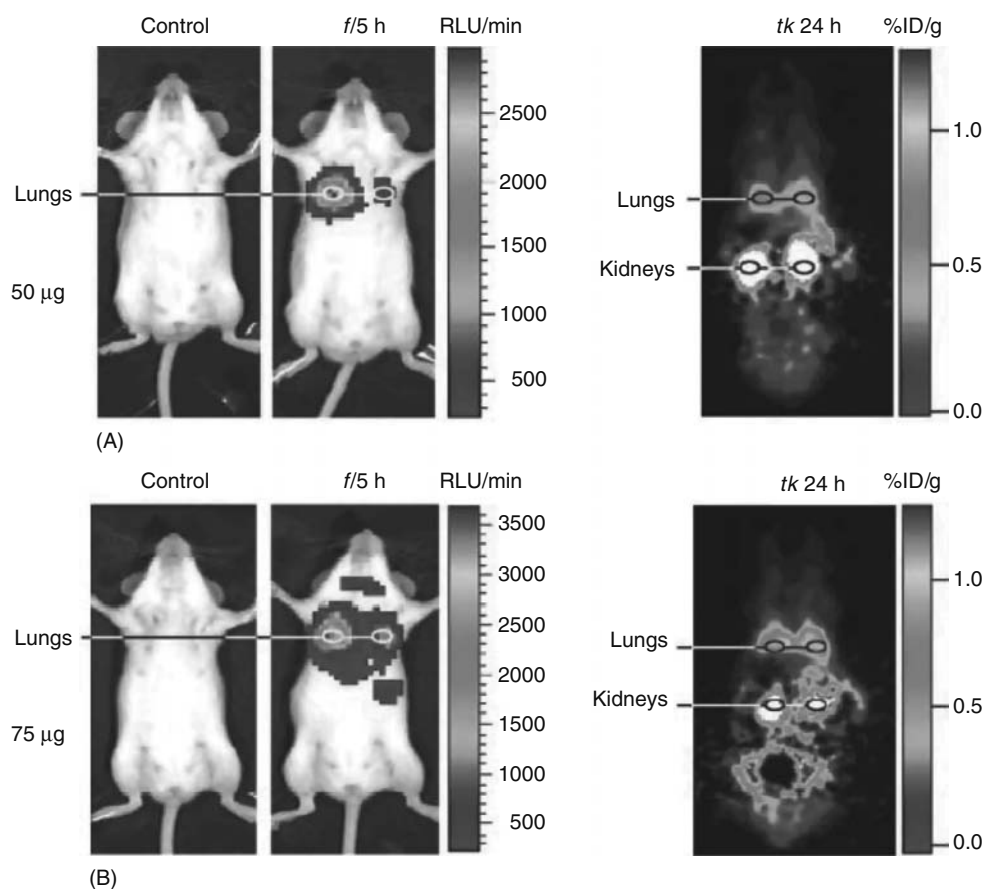

FIGURE 30.15 (See color insert following blank page 206.) Tracking cationic lipid-mediated reporter gene delivery using optical (bioluminescence) and PET imaging. Cationic lipids associate with negatively charged DNA to form complexes that bind to cell surfaces by way of electrostatic interaction, thereby allowing a nonviral means of gene transfer. Distribution of systemic administration of DNA–lipid complexes in mice is demonstrated by delivering prepared DNA–lipid complexes that carry optical and PET reporter genes. CMV-*fl* plasmid DNA (CMV promoter driving expression of firefly luciferase [*fl*] gene) was mixed with cationic lipid, 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) and cholesterol, to form *fl* DNA–lipid complexes. Similar procedure was used to prepare HSV1-sr39tk DNA–lipid complex (tk DNA–lipid complex). (A, B) show images following administration of 50 and 75 µg of each *fl* and tk DNA–lipid complexes via tail vein injection into CD-1 mice, respectively. Bioluminescent images (left images) were obtained 5 h after injection of the vector and 5 min after intraperitoneal injection of D-Luciferin. MicroPET images (right images) were obtained 24 h after vector delivery and 1 h after [¹⁸F]FHBG injection. Control mice (left) optical images obtained prior to administration of D-luciferin. Optical and PET images demonstrate that lungs are primary organs for transgene expression. Increased dose of DNA–lipid complex results in greater pulmonary transgene expression. Activity seen in the kidneys in the microPET images is the result of excreted, unsequestered reporter probe, [¹⁸F]FHBG. (Reproduced from Iyer, M., Berenji, M., Templeton, N.S., and Gambhir, S.S., *Mol. Ther.*, 6, 555, 2002. With permission.)

a small number of indium (In)-111–labeled endothelial and hematopoietic progenitor cells were found to accumulate in infarcted rat myocardium by SPECT [191]. In conclusion, molecular and cellular imaging retains a fundamental role not only in preclinical studies, but also in clinical practice, since accurate delivery or homing of cells to target tissues is crucial for the clinical success of such cell-based therapeutic applications [184].

30.5.2 NONINVASIVE IMAGING OF T-CELL TRAFFICKING

Immunotherapy with tumor-targeted lymphocytes is an active area of basic and clinical research. For better therapeutic outcome, it will be highly beneficial if the kinetics, specificity, and longevity of tumor-targeted lymphocytes

could be repetitively monitored in cancer patients receiving cellular immunotherapy. Dubey et al. infected T-cells from mice carrying Moloney murine sarcoma virus/Moloney murine leukemia virus (M-MSV/M-MuLV) tumors with a retrovirus encoding for both GFP and HSV1-sr39tk [192]. The modified lymphocyte population once injected into animals bearing M-MSV/M-MuLV tumors could be followed repetitively by PET and showed specific accumulation at the target M-MSV/M-MuLV tumors (Figure 30.17). In a similar experiment, Epstein–Barr virus (EBV)-specific T cells programmed to encode HSV1-TK enzyme selectively accumulated radiolabeled FIAU after adoptive transfer in animals and the HSV1-TK + T cells could be tracked noninvasively in SCID mice bearing human tumor by PET [193]. These T cells selectively accumulated in EBV + target tumors but

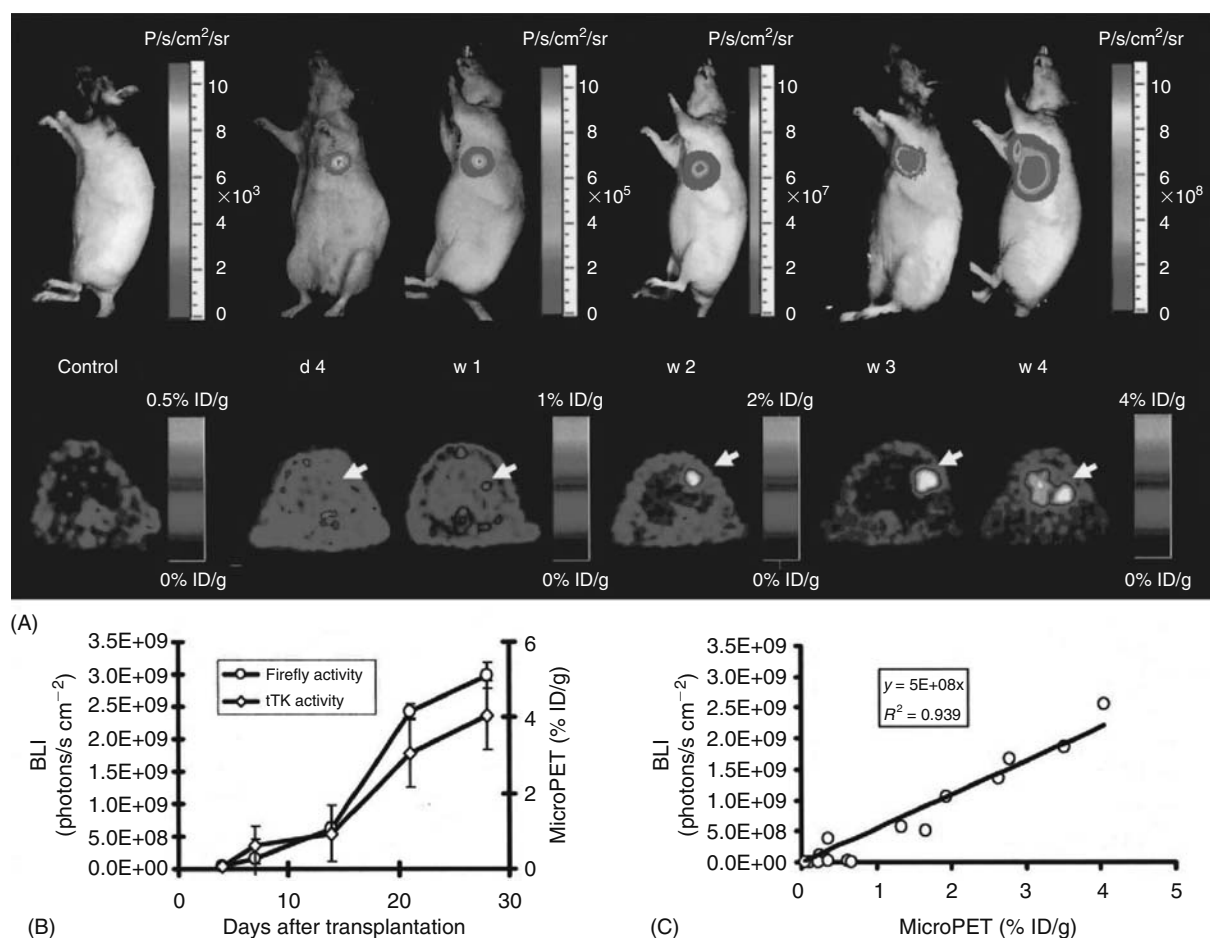

FIGURE 30.16 (See color insert following blank page 206.) Molecular imaging of transplanted ES cells with bioluminescence and PET imaging. (A) Embryonic stem cells stably transduced with a triple fusion reporter gene *mrfp-fluc-ttk* were transplanted in the heart of athymic rats. Animals were subsequently imaged for 4 weeks to assess cell survival. A representative study animal is shown in the figure. Significant bioluminescence (top) and PET (bottom) signals were observed at day 4, week 1, week 2, week 3, and week 4 following transplantation. In contrast, control animals had background activities only. (B) Quantification of imaging signals showed a drastic increase of fluc and ttk activities from week 2 to week 4. Extracardiac signals were observed during subsequent weeks. (C) Quantification of cell signals showed a robust *in vivo* correlation between bioluminescence and PET imaging ($r^2 = 0.92$). BLI indicates bioluminescence. (Reproduced from Cao, F., Lin, S., Xie, X. et al., *Circulation*, 113, 1005, 2006. With permission.)

not in control tumors. Moreover, the radiolabeled transduced T cells retained their capacity to eliminate targeted tumors selectively.

Tracking of cells with MR provides detailed anatomical information and is therefore more informative for the evaluation of the localization of therapeutic cells after injection. However, it has been relatively difficult to label cells with contrast agents at high enough concentrations to monitor cell trafficking by MR [194]. In a recent report, ovalbumin-specific splenocytes (OT-1) were labeled with anionic $\gamma\text{-Fe}_2\text{O}_3$ SPIO nanoparticles and adoptively transferred into mice with ovalbumin-expressing tumors [195]. OT-1 cells could be tracked *in vivo* with high resolution using a 7 T MRI and showed significant negative enhancement of the spleen at 24 h, and of the tumor at 48 and 72 h after labeled cell injection.

Bioluminescence imaging has been employed to study T-cell trafficking. Luciferase-expressing human papillomavirus

type 16 (HPV-16) E7-specific CD8(+) T cells were followed noninvasively over time. The injected E7-specific T cells not only showed preferential migration to the E7-expressing target tumor but also proliferated at the tumor site [196]. In a different approach, optical imaging was employed to study the kinetics of distribution and homing of luciferase-expressing cytokine-induced killer (CIK) cells, following intravenous administration into tumor-bearing mice [197]. The study showed that CIK cells exhibit early localization to the lungs, followed by the liver and spleen and subsequently the tumor.

The different imaging approaches can be safely adopted to noninvasively monitor tumor targeting of antigen-specific cell-based cancer therapies. These studies will be helpful in determining various parameters like routes of administration, cellular, and systemic factors affecting T-cell survival, residence time, and activation to maximize the therapeutic outcome.

FIGURE 30.17 (See color insert following blank page 206.) Noninvasive imaging of T-cell trafficking following adoptive transfer. Tumors were implanted subcutaneously on the shoulders of the mouse in the figure: A Moloney murine sarcoma virus–Moloney murine leukemia virus (M-MSV/MMuLV) tumor on its left shoulder and a control P815 tumor on its right shoulder. T-cells from an animal carrying an M-MSV/M-MuLV tumor were transfected with a retrovirus expressing both the HSV1sr39Tk and GFP reporter proteins. Transfected cells were first sorted by FACS and then injected intraperitoneally into the mouse bearing the M-MSV/M-MuLV and P815 tumor, and the animals were imaged by microPET following [^{18}F]FHBG injection. Homing of the cells to the M-MSV/M-MuLV tumor, but not the P815 tumor, was apparent within day 13 of injection. (Reproduced from Dubey, P., Su, H., Adonai, N. et al., *Proc. Natl. Acad. Sci. USA*, 100, 1232, 2003. With permission.)

30.5.3 NONINVASIVE IMAGING OF T-CELL ACTIVATION

In addition to elucidating the trafficking pathways of immune cells *in vivo*, means to visualize their differentiation, and antigen-dependent activation status will be immensely beneficial for a better understanding of how the immune system interacts with cancer. In an effort to image T-cell activation, Ponomarev et al. created a human T-cell line expressing an HSV1-TK–GFP fusion protein under the control of the T-cell receptor (TCR)-dependent nuclear factor of activated T cells (NFAT)-responsive promoter [198]. Mice bearing subcutaneously implanted cells were treated with anti-CD28 and anti-CD3 antibody to initiate TCR mediated T-cell activation. This in turn triggered expression from the NFAT promoter, which was subsequently measured by PET analysis of [^{124}I]FIAU accumulation by the HSV1-tk gene.

With the advent of new probes and new ways to label T-cells, repetitive and noninvasive monitoring of both tumor-specific lymphocytes homing and antigen-dependent activation of these cells at their targets will be highly feasible.

30.6 MONITORING GENE THERAPY LEVELS

Precise localization and quantitative assessment of the magnitude and temporal variation of transgene expression is a necessary component of any gene therapy trial. Direct imaging with a transgene-specific imaging probe is ideal but not feasible or practical in most cases. To develop a specific probe for each individual transgene is not always technically possible;

furthermore, it is necessarily labor- and cost-intensive. Using indirect imaging methods by linking a portable reporter gene to a therapeutic gene allows for more flexibility as a variety of transgenes can be individually monitored by cloning in a reporter gene into appropriate sites of the vector. Coexpression of the therapeutic gene product and reporter gene product in a coordinated and regulated manner enables a correlative and quantitative relationship between the two genes. Thus, levels of therapeutic gene expression can be inferred by the amount measured from reporter genes, provided that the expression of both genes remains coupled. Several such approaches, ranging from the more straightforward, like the dual vector approach, to the more sophisticated, such as the bidirectional transcriptional approach, are currently being developed and briefly discussed below [153].

30.6.1 COVECTOR ADMINISTRATION

One relatively simple method to monitor gene therapy *in vivo* is to coadminister two different vectors, which are identical except for the transgene they are carrying: one vector would encode the therapeutic gene and the other would encode the reporter gene and both genes would be driven by the same promoter. This approach has been validated using the two PET reporter genes, HSV-sr39tk and D2R, each cloned into distinct adenoviral vectors and both driven by the same CMV promoter [140]. While individual cell differences in expression levels may be seen, macroscopic measurements made at the tissue culture or organ level (adenoviral-mediated hepatic transfer) correlate quite well ($r^2 \geq 0.93$). The technique may prove useful in specific experimental situations.

30.6.2 SINGLE VECTOR APPROACHES

The use of an internal ribosomal entry site (IRES) signifies the bicistronic approach to coupling genes [199–201]. In a bicistronic expression cassette, an IRES sequence is interpositioned between the therapeutic and reporter genes, usually the first and second cistron, respectively. Both genes are under the control of the same promoter and transcription of this construct results in a single mRNA molecule. Initiation of translation of the first cistron is by way of the usual cap-dependent manner, but translation of the second cistron is facilitated by the IRES sequence in a cap-independent mechanism, which allows translation by a second ribosome. This approach has been verified in a few studies. For example, an IRES derived from an encephalomyocarditis virus has been used to construct a bicistronic vector from which both D2R and HSV1-sr39tk reporter genes are coexpressed from a common CMV promoter (pCMV-D2R-IRES-HSV1-sr39tk) [106]. The levels of D2R and HSV1-sr39tk activity demonstrate a high degree of correlation ($r^2 = 0.97$) using [^{18}F]FESP and [^{18}F]FHBG as imaging probes, respectively. Another vector, which encodes Renilla luciferase (*Rluc*) in a bicistronic configuration, pCMV-*Rluc*-IRES-sr39tk, or pCMV-sr39tk-IRES-*Rluc*, also shows excellent correlation

[106]. Similar relationships have also been seen with the use of an HSV1-tk gene that has been IRES-linked to the *lacZ* gene [202]; imaging with iodinated FIAU (SPECT reporter probe for HSV1-tk) correlates well with β -galactosidase activity seen by light microscopy. These studies corroborate the use of radionuclide and optical reporter genes as means of quantitatively determining relative levels of target gene expression.

One interesting finding in this approach, however, is that expression levels from the gene upstream to IRES sequence is consistently more robust than the levels seen from the gene downstream to the IRES [106]. This may have to do with cell-specific differential translation from the IRES sequence, but nonetheless emphasizes the need for a highly sensitive reporter system as levels of the reporter gene product will be significantly diminished compared to the upstream gene. Further understanding and exploitation of regulatory modules recently found within the IRES may help circumvent this problem in

the future [203]. Alternatively, two different genes expressed from two distinct, but identical, promoters within a single vector can be done to avoid the attenuation problem and tissue variation issues experienced with the IRES-based approach. This is a variation of the bicistronic approach and is otherwise known as the dual-promoter approach [150]. Strong correlation between two reporter genes, *hsstr2* and HSV1-tk, each driven by an independent but identical CMV promoter, has been exhibited (Figure 30.10).

In some situations, gene therapists will want to externally control the levels of transgene expression and, additionally, will need to verify the extent of control with imaging techniques. One particularly novel indirect imaging method makes this entire scenario possible by the use of a single inducible bidirectional tetracycline-responsive element (TRE) and two flanking minimal CMV promoters (Figure 30.18A). The fusion transactivator protein *rtetR*-VP16, which is constitutively expressed and can potentially

FIGURE 30.18 (See color insert following blank page 206.) Indirect PET imaging using a bi-directional transcriptional approach. (A) Target (therapeutic) gene expression can be measured indirectly by imaging reporter gene expression if expression of the two genes is linked. Both genes can be simultaneously expressed from two minimal CMV promoters that are regulated by a single bidirectional TRE. The *rtetR*-VP16 fusion protein is produced constitutively from a CMV promoter. When the *rtetR*-VP16 fusion protein binds doxycycline, this complex binds to the TRE regulatory sequence and substantially enhances expression from the two minimal CMV promoters. The target gene A in one coding region and a reporter gene (for example, a reporter kinase such as HSV1-sr39tk) in the alternative coding region are transcribed simultaneously into two mRNA molecules. Translation of the two mRNA molecules yields two distinct proteins in amounts that are directly correlated with each other.

(continued)

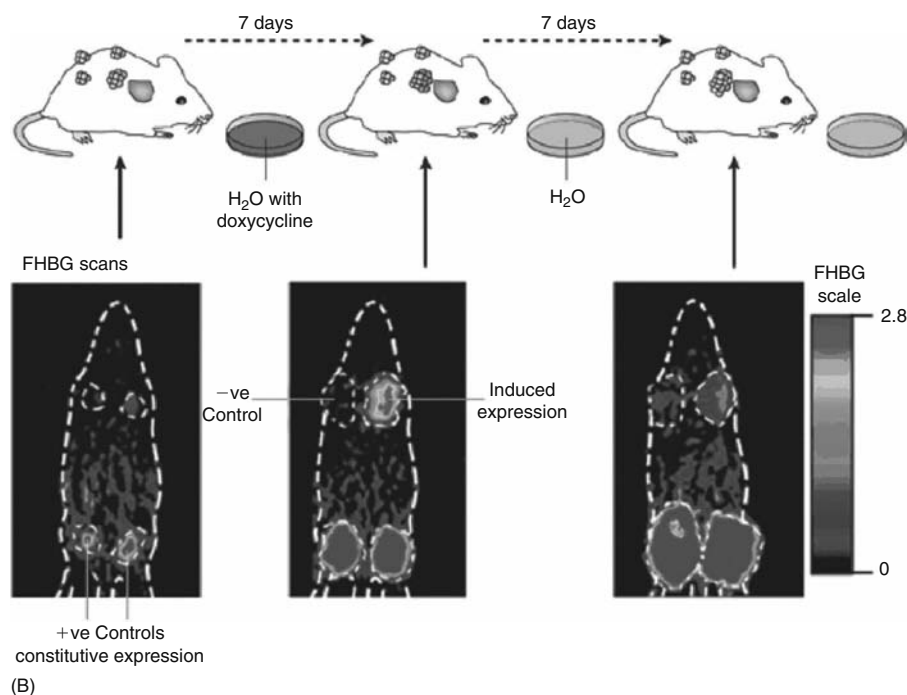

FIGURE 30.18 (continued) (B) Quantitative imaging of the locations and magnitude of PET reporter gene expression by trapping of a PET tracer inside the cell (for example, by phosphorylation of [^{18}F]FHBG by the HSV1-sr39TK reporter protein) provides an indirect measure of target gene expression. Sequential microPET imaging studies of a nude mouse carrying four tumors. Four tumor cell lines, two positive controls (constitutive reporter gene expression), one negative control, and one inducible line (reporter gene expression) induced by doxycycline, were injected subcutaneously into four separate sites in a single mouse. When tumors reached a size of at least 5 mm, the mouse was imaged with 9-(4- [^{18}F] fluoro-3-hydroxymethylbutyl)guanine ([^{18}F]FHBG). Doxycycline was then added to the water supply for 7 days. The mouse was then scanned again with [^{18}F]FHBG. Doxycycline was removed from the water supply for the next 7 days, and the mouse was again scanned with [^{18}F]FHBG. The locations of the four tumors and the mouse outline are shown by the dotted regions of interest. All images are 1–2 mm coronal sections through the four tumors. The % ID/g (% injected dose per gram tissue) scale for [^{18}F]FHBG is shown on the right. The negative control tumors show no gene expression and the positive control tumors show increased expression over the time course. The tumor on the top right, with inducible gene expression, initially does not accumulate [^{18}F]FHBG, then at 7 days after addition of doxycycline, induction of reporter gene expression traps [^{18}F]FHBG. Seven days after withdrawal of doxycycline, there is decreased induction and minimal trapping of [^{18}F]FHBG. The [^{18}F]FHBG image signal correlates well with target gene expression (not shown). (Reproduced from Gambhir, S.S., *Nat. Rev. Cancer*, 2, 683, 2002. With permission.)

be incorporated into the same bidirectional vector, binds to TRE only in the presence of tetracycline or one of its analogs. By varying levels of an exogenously added inducer such as doxycycline, a gene therapist can control transcription and magnitude of expression that can be verified by the accompanying reporter gene. Proof of principle has been shown in rat xenograft models using the reporter genes D2R and HSV1-sr39tk (Figure 30.18B) [204].

The fusion gene–protein approach is yet another powerful means of indirect monitoring of gene therapy. Constructs in this protocol contain two or more genes linked together within the same reading frame so that a single protein is translated. The resultant hybrid or fusion protein will have therapeutic and reporter properties and the expression of the fused gene can be closely monitored since the expression of the therapeutic component is stoichiometrically coupled to the reporter component of the protein. HSV1-tk-*gfp*, HSV1-tk-*Fluc*, HSV1-sr39tk-*Rluc*, *CD*-HSV1-tk are a few successful examples [22,205–208]. Various triple fusion proteins encoded by

fusion genes composed of a bioluminescent, a fluorescent, and a therapeutic/reporter gene are also reported for imaging gene expression from a single cell to living animals. For example, HSV1-sr39tk-*mrfp1-Rluc*, $\Delta 45$ HSV1-tk-*gfp-Fluc*, and the most recent *mTFLuc-mrfp1*-HSV1-tk (*mTFLuc* stands for mutated *Thermostabile Fluc*) [98,209,210]. The fusion gene is engineered such that the proteins are linked via a short peptide spacer. However, while appealing in concept, it is quite challenging in practice to produce generalizable proteins since fusion proteins are often inactive or less active than their individual counterparts; furthermore, fusion proteins also may not localize to appropriate compartments since appropriate signaling mechanisms are either masked or unavailable [153]. Using this technique for every therapeutic gene developed would prove to be a daunting task since each newly generated fusion protein has its own peculiarities. Future technological improvements in the physical linkage of two proteins may help minimize discrepant behavior and allow more flexibility for this technique.

30.7 CLINICAL APPLICATIONS

While human gene therapy trials have been in effect for several years, the imaging of transgene expression in humans has only started. Transgenes, which can serve as both therapeutic gene and reporter gene (i.e., direct imaging), will most likely have an easier transition toward clinical application when compared to indirect imaging methods. More specifically, the kinetics, biodistribution, stability, dosimetry (needed for radionuclide approaches), and safety of the transgene and reporter probe have to be determined in direct imaging reporter protocols. In comparison, an additional verification and characterization of the reporter gene product has to be performed in indirect imaging systems.

Utilizing a direct imaging method, as is the case with the HSV1-tk suicide/reporter gene and one of its reporter probes, [^{18}F]FHBG, where the requisite pharmacokinetics, biosafety, and other related testing have been established in human volunteers [117]. The study indicated that while [^{18}F]FHBG demonstrates acceptable characteristics and should prove to be an acceptable probe for HSV1-tk imaging, [^{18}F]FHBG does not readily cross the BBB. Methods used to disrupt the BBB during [^{18}F]FHBG administration may aid in this regard if needed. Furthermore, imaging HSV1-tk reporter gene expression near the gall bladder, kidneys, and bladder with [^{18}F]FHBG may prove to be difficult since nonsequestered [^{18}F]FHBG passes through these organs, contributing to the background signal seen in these structures. In a recent clinical trial in patients with hepatocarcinoma undergoing adenoviral-HSV1-tk gene therapy, transgene expression could be successfully followed by [^{18}F]FHBG and PET (Figure 30.19) [211–213]. Interestingly, transgene expression in the tumor was largely dependent on the injected dose of the adenovirus and was detectable in all patients who received $\geq 10^{12}$ viral particles. However, 9 days postinjection, no expression could be observed. Most importantly, no specific expression of the transgene could be detected in distant organs or in the surrounding cirrhotic tissue in any of the cases studied.

In another study, which also employed a suicide/reporter gene system, a small group of patients suffering from recurrent glioblastomas were treated with suicide gene therapy (HSV1-tk) [214]. The construct was delivered with a cationic liposomal vector and among the five patients treated with this therapy, one showed accumulation of the reporter probe [^{124}I]FIAU in a portion of the tumor. Following a 2 week course of ganciclovir, FDG PET and methionine (MET) PET scans at the end of treatment indicated that necrosis occurred in the region where [^{124}I]FIAU uptake was previously shown, suggesting successful suicide gene transfer to a portion of the tumor. Those patients who could not accumulate detectable levels of [^{124}I]FIAU in their infused tumors were found to have a low mitotic index in their tumors.

With this small yet novel study, we are able to learn significant amounts about human gene therapy using *in vivo* imaging methods. For example, the investigators were able to identify and localize successful gene transfer in one patient

FIGURE 30.19 [^{18}F]FHBG-PET whole-body imaging in patients with Ad-CMV-HSV1-tk adenovirus shows that the expression of the transgene is circumscribed to the injection site and also that higher vector titers do not necessarily produce higher transgene expression. Whole-body images show that specific accumulation of the tracer (and hence HSV1-tk expression) is restricted to the vector injection site in the liver tumoral nodule (arrows). At later times, the tracer accumulates in the bladder (B) and the intestines (I) due to physiological elimination. In addition, this figure shows that higher vector titers do not necessarily produce higher transgene expression in the tumor as evidenced by [^{18}F]FHBG accumulation. Coronal [^{18}F]FHBG-PET images obtained from patients treated with 10^{12} vp (panel a) and with 2×10^{12} vp (panel b) starting 1.5 h and 6.5 h after injection of the tracer. For the patient treated with the lower adenoviral vector dose, specific [^{18}F]FHBG accumulation in the treated lesion can readily be ascertained in the early images while it can only be seen 6.5 h p.i. for the patient treated with the higher dose. (From Penuelas, I., Haberkorn, U., Yaghoubi, S., and Gambhir, S.S., *Eur. J. Nucl. Med. Mol. Imaging*, 32(Suppl. 2), S384, 2005. With permission.)

68 h after tumor infusion. Also, in the patient where [^{124}I]FIAU uptake was seen, only a fraction of the tumor was sequestering [^{124}I]FIAU. This suggests that the rest of the tumor was either not transduced or that the transduction was too weak to be detected. Additional follow-up scans of the patient would help to determine the outcome of the heterogeneously treated tumor and help determine importance of reporter probe uptake. In the patients who did not demonstrate [^{124}I]FIAU uptake, the failure to see [^{124}I]FIAU reporter probe accumulation may be due to sheer lack of transducible cells or failure of gene transfer. Future studies addressing these and other issues are sure to be extremely helpful in understanding the effectiveness of gene therapy.

30.8 DECISION ALGORITHM FOR REPORTER GENE TECHNOLOGY

The road to clinical gene therapy trials is an arduous one but can be helped with the variety of reporter gene technologies described in this chapter. As with any drug testing, there is a prerequisite period of preclinical testing, much of which takes place in animal models. As expected, there will

be a strong inclination toward optical and radionuclide approaches since these approaches are the most accessible and more rigorously tested among the imaging options. Furthermore, it is likely that a single investigator or a single group of investigators working on a specific gene therapy will most likely have to utilize a combination of modalities (e.g., optical- and radionuclide-based technologies) to efficiently test gene therapy vectors and to facilitate their use in higher organisms. As testing progresses in higher species, efforts need to be made toward the radionuclide approaches and substantial investment of time and money may be needed to develop PET reporter probes. Eventually, human trials will employ either PET, gamma/SPECT and, in the future, MR-based methods. The decision and timing to use certain reporter systems over others is a relatively complex one, and we will attempt to simplify the decision making process by providing the set of guidelines we use to make such decisions.

The first decision depends upon whether you are attempting to study the biodistribution/pharmacokinetics of a gene delivery vehicle or whether you are interested in monitoring gene expression. From an earlier discussion (Section 30.4), the distribution of a vehicle can be directly imaged by directly labeling the vehicle with radioisotope-, fluorescent- or MR-compatible markers. Distribution of injected vehicle can also be inferred from a reporter gene coupled to a constitutive promoter. However, this method is less sensitive since the rate of gene transfer is always less than 100%, and, in fact, is a minority in most cases.

For those interested in monitoring transgene expression, a search for reporter probes that may already exist for the transgene is mandatory. For example, for those who use the suicide gene, HSV1-tk, a number of reporter probes already exist and direct imaging protocols can be performed using radionuclide techniques. In the example of HSV1-tk, the decision to use [^{18}F]FEAU over other probes such as [^{18}F]FHBG is based on preliminary favorable evidence toward [^{18}F]FEAU described earlier. However, the selection of the appropriate reporter probe is not trivial, and, as further tests are being performed, it is likely that the other reporter probes may prove to be just as or more efficient than FEAU depending on specific cell type, local pharmacokinetics, mode of delivery of the transgene (viral vs. nonviral), etc. As we learn more about each reporter system, selection of specific transgene-reporter probe combinations will be disease-specific; it is likely that each reporter combination will have certain strengths and weaknesses depending on the disease model and target tissues. The investigators will have to adjust accordingly. Future studies are bound to address these and other related issues.

If no reporter probe for the transgene exists, then indirect imaging methods are needed. This requires the coupling of the therapeutic genes with an optical, radionuclide-based or MR-based reporter genes. As described earlier, a number of indirect methods are available including the dual promoter approach, bidirectional approach, bicistronic approach, etc. The selection of one of these promoter configurations will

largely depend upon the nature of the promoter of the therapeutic gene. If a robust, constitutive promoter drives the therapeutic gene, then the dual promoter, the bicistronic (IRES-mediated) or bidirectional approaches may suffice. However, if a weak or tissue-specific promoter drives the therapeutic gene, then amplification strategies for the reporter gene (and possibly the therapeutic gene) will need to be employed. Amplification strategies for tissue-specific promoters using the VP16 transactivation domain fused to the yeast GAL4 DNA-binding domain has been verified for use with reporter genes [215]. A recently developed Gal4-VP16-activated bidirectional promoter is capable of linking the amplified expression of a therapeutic gene from a weak tissue-specific promoter to that of a reporter gene, thereby facilitating noninvasive imaging of transgene expression in gene therapy applications [216].

A variety of other factors also dictate the selection of reporter gene systems. For example, if a research group is intent on bringing a specific gene therapy to human application, it requires them to use multimodality reporter gene systems, i.e., use fused reporter genes such as HSV1-tk-*Fluc* (keeping in mind that HSV1-tk is not being used as a therapeutic gene in this case when the reporter probe is administered in nonpharmacologic amounts). By coupling a therapeutic gene to a fused reporter gene, it will be possible to move quickly between the preclinical verification phase (optical imaging of FL) and the clinical phase (radionuclide-based imaging of HSV1-tk). Alternatively, if a research group strictly deals with small animals, then the use of optical reporter genes only may suffice. Along this line of reasoning, the use of large animals precludes the use of optical methods, and as a result, radionuclide-based or MR-based technologies become more important.

Imaging disease processes in the CNS also limits the selection of reporter genes. Some of the radionuclide-based technologies, such as HSV1-tk and its mutants, are limited since their reporter probes do not readily cross the BBB. On the other hand, [^{18}F]FESP, the reporter probe for D2R, easily crosses the BBB and can be used to a certain extent in the CNS. Use of the D2R-[^{18}F]FESP system in the CNS is limited in the striatum where endogenous dopamine receptors are present. Optical methods, both fluorescence and bioluminescence, can be utilized if specific spatial localization is not needed. The substrates of the bioluminescence methods, D-luciferin and coelenterazine, can easily cross the BBB thereby facilitating the use of these reporter genes in the CNS.

In the same token, imaging in the lung, connective tissue or cortical bone, may limit the use of superparamagnetic-labeled agents in MR imaging since it will be difficult to differentiate between signal from the contrast agent and the signal of these anatomic structures since they are identical in certain MR sequences.

Other important factors in the selection of reporter genes include the need for good spatial resolution (preference given to radionuclide and MRI-based imaging), repetitive imaging (preference given to radionuclide approaches), and image

quantitation (preference given to radionuclide, optical, and MRS-based methods). Cost, institutional infrastructure, requirement for support personnel, and physical space required can also be significant factors, which favorably inclined toward the optical and gamma camera methods and less toward the PET and MR-based methods. Thus, a large number of factors have to be considered prior to the selection and implementation of reporter genes in living subjects. With careful planning, an optimal imaging strategy can be followed and can be enormously helpful in the study of gene therapy and disease entities.

30.9 SUMMARY AND FUTURE DIRECTIONS

A wide array of tools are becoming available for the evaluation of gene therapy in living subjects. These tools will be extremely helpful toward the advancement of human gene therapy by providing a means of continuous monitoring of locations, magnitude, and temporal variation of gene delivery and expression. Viral and nonviral transfer of genetic material is bound to improve and these developments will be supported by direct and indirect reporter gene technologies. The ability to monitor gene expression through a variety of bicistronic vectors and control gene expression, either through inducible promoters or through tissue-specific amplification techniques, is likely to play an increasing role in gene therapy as we begin to move away from constitutive expression in some cases.

In the next decade, PET/CT and SPECT/CT will probably be the major workhorses for human gene therapy trials. PET-based technologies particularly have an advantage given their greater sensitivity as well as the ability to use biological molecules that nearly mimic their parent molecule after being radiolabeled. Future technical improvements are certain to aid optical and MR-based protocols for human application. Continued alliances between gene therapists, molecular biologists, engineers, chemists, physicists, and pharmacologists will help build the next generation of molecular imaging technologies to expand its capabilities in gene and cell therapy.

31.1 INTRODUCTION

31.1.1 GENE THERAPY

Gene therapy involves a new class of pharmaceuticals that uses a nucleic acid drug to treat a medical condition. By introducing a

corrected copy of a defective gene or disrupting the production of a harmful protein, gene therapy treats a disease at its source. The ideal gene therapy varies depending on the indication, but in every case, it should be nontoxic, nonimmunogenic, safe, and free of detrimental side effects. For DNA vaccines or some

cancer gene therapy approaches, short-term gene expression may be adequate to control dosing and length of expression of the gene product. By contrast, for recessive monogenic diseases, the therapy should give persistent and sufficient levels of expression of the missing gene product for the life of the patient. Dominant negative diseases could also be cured in theory by disrupting production of the disease-causing protein. Cancer is a somatic genetic disease, and gene therapy treatments for cancer may include either long-term production of a secreted protein drug in normal cells or short-term intracellular manufacture of proteins that cause cell death in cancer cells. We argue that many genetic diseases have the potential to be addressed clinically with nonviral, integrating systems.

31.1.2 LIMITATIONS OF VIRAL VECTORS

Viral systems were the first to be developed for gene therapy and since that time have been tested extensively in clinical trials. Viruses are naturally adapted for cellular entry and transgene expression. However, the human body has evolved under selection to implement complicated and extensive antiviral defenses that make genetically engineered virus-derived systems imperfect tools for human gene therapy. Viral vectors are costly to prepare and may be contaminated during preparation. Additionally, there is some risk of inadvertently creating a self-replicating engineered virus. Systemic inflammatory response syndrome and insertional mutagenesis have been responsible for deaths in two clinical trials [1,2]. The number of new gene therapy clinical trials increased until 1999, when the first death occurred, from which point the numbers have been dropping steadily [1,3].

31.1.3 ADVANTAGES OF NONVIRAL GENE THERAPY SYSTEMS

While some investigators attempt to remedy the flaws that have been uncovered in using viral systems for gene therapy by modifying the viral vectors, another viable strategy is to use nonviral gene therapy systems. As drugs, these systems are predicted to be more clinically acceptable than viral vectors have been to date. Nonviral vectors are expected to have a lower cost of preparation, a greater ease of handling, and fewer side effects from toxicity and immunogenicity than viruses. There is little to no risk of creation of a self-replicating agent, either before administration or after the therapy is given to the host. Nonviral vectors are often less complicated than viral vectors to design, many having no size limit, promoter flexibility, and requiring short, if any, DNA sequences for integration. While some viruses have specific tissue preferences and constitutive promoters, nonviral DNA may be delivered to particular organs and can be engineered to express transgenes with tissue-specific promoters.

31.1.4 INTEGRATING VS. NONINTEGRATING NONVIRAL GENE THERAPY

All nonviral gene therapy clinical trials to date have used plasmid DNA without integrating systems. In part due to

silencing or loss of plasmids from degradation or during cell division, these trials have been able to demonstrate only limited clinical benefit. Silencing may occur due to viral promoters, bacterial sequences, or CpG methylation [4]. Optimized plasmids, including minicircles, have been demonstrated that allow for expression of transgene products episomally in some tissues without silencing [5,6]. This is encouraging for settings in which plasmid loss due to cell division is not a major issue, such as delivery to the brain or muscle, or when expression is only desired short term, such as for DNA vaccines or the production of proteins to combat cancer. Nonintegrating systems carry a low risk of insertional mutagenesis, because random integration occurs at a very low rate, and this rate would be similar for any nonviral system [7]. Another advantage of nonintegrating plasmid systems is that there is no size limit for cargo genes [8]. However, repeated administration to nonquiescent tissues may be prohibitively expensive or difficult over the lifetime of the patient, making integrating technologies that permanently modify the genome preferable. Nonintegrating plasmids may be an improvement over recombinant protein therapy for treatment of recessive genetic disorders. However, approaches that merely potentiate a temporary benefit are expected to be replaced by technologies that do not require repeated administration, such as integrating vectors.

31.1.5 THREE PROMISING NONVIRAL INTEGRATING GENE THERAPY SYSTEMS

There are currently three leading methods under development for nonviral integrating gene therapy. The first to be developed were transposon systems, followed by sequence-specific phage integrases, and then zinc finger nucleases (ZFNs) that catalyze homologous recombination. These three methods were developed independently, but share some common features.

All require cellular production of a foreign DNA-modifying protein and the presence of a donor plasmid containing therapeutic gene sequences. The application of each of these systems for gene therapy is entirely dependent on getting the nucleic acids into cells, and all three will benefit greatly from advances in DNA transfection. Cells may be modified *ex vivo* and then reintroduced to the patient, either after selection of individual colonies so that integration sites can be identified and transgene product assessed, or as pools of cells. Electroporation, nucleofection, and lipophilic reagents are all possible transfection methods. The success of *in vivo* transfection is dependent on the tissue type, but general methods include hydrodynamic delivery, electroporation, and cationic lipids. One advantage of *in vivo* approaches may be a lower cost to the patient since *in vivo* protocols could be performed in the same way on many patients. *Ex vivo* approaches carry with them the need for costly amplification and manipulation of patient cells in cell culture under strict, highly regulated conditions. However, some of the *in vivo* methods that have been proposed are invasive, possibly carrying a greater risk to the patient than *ex vivo* methods. The feasibility of

translation into the clinic of most of the transfection methods currently used in research animals *in vivo* is yet to be determined.

There are three major risks associated with nonviral integrating systems for gene therapy. The first is oncogenic transformation, resulting in a cancer. Genomic integration near a proto-oncogene can lend the potency of the transgene promoter to the endogenous coding regions near the insertion, causing dysregulation of protein expression [9]. Toward the same end, insertion into a tumor suppressor gene can disrupt the activity of genes that prevent cancer [10]. Double strand breaks (DSBs) are also well-known causative agents in tumor formation [11]. The second risk, immunogenicity, is expected to be minimal for any nonviral vector because they lack an immunogenic viral capsid. Lastly, toxicity must be kept within limits that are tolerable, ideally less than the therapy that is currently available, if any. The acceptable level of toxicity may depend on the disease indication. For example, the chemotherapies used to treat cancer are notoriously toxic. Safety profiles are important, because they often determine the success or failure of an effective drug. These three risks vary depending on the system and will be discussed further individually.

31.2 TRANSPOSON SYSTEMS

31.2.1 BACKGROUND

Transposons are naturally occurring mobile genetic elements, also known as “jumping genes.” Originally discovered by Barbara McClintock, they are responsible for the multiple corn kernel colors found in patchwork corn ears by disrupting pigment-producing enzymes [12]. Natural transposable elements act as mutagens. By excising, sometimes replicating, and inserting themselves elsewhere in the host genome, transposons are capable of accelerating evolution and expanding genetic possibilities. Transposons are one of the most important forces in shaping the genomes of higher organisms; genomes are littered with the inactive remains of mobile genetic elements called transposon fossils [13]. These transposon fossils can create duplications during meiosis due to repeated sequences, causing errors during homologous recombination. In some cases, transposition-induced mutations may have negative effects. In humans, transposons are to blame for a small fraction of genetic diseases, which are caused by transposons inserting themselves in or near important genes.

There are two major classes of transposons: retrotransposons and DNA transposons. Retrotransposons replicate via a RNA intermediate, which allows the coding sequence to copy and insert itself into the genome multiple times [14]. DNA of retrotransposon origin is abundant in the human genome. In contrast, transposon systems suitable for gene therapy are DNA transposons, which naturally mobilize without replication, by excision and reinsertion of the DNA into the host genome [15]. The largest family of DNA transposons is the *Tc1/mariner* family [16]. Systems from this family that have been applied to gene therapy applications include *Sleeping*

Beauty (SB), *Frog Prince*, and *Himar1* [17–19]. Transposons from other families that have been shown to function in mammalian cells include *hAT*-like *Tol2* and *piggyBac* [20,21].

The *SB* system will be the central focus of this discussion because it is the leading and most widely used transposon system for gene therapy. However, it should be noted that recent work in cell culture has shown that *piggyBac* may outperform *SB* in integration frequency and that *Tol2* does not show overexpression inhibition, an effect of transposase to transposon ratios that limits translation between applications [22].

31.2.2 SB MOBILE GENETIC ELEMENT

Similar inactive transposable element sequences from fish were aligned and compared to create a consensus sequence [23]. The consensus yielded a functioning synthetic transposon, and since it was awakened after a 10 million year long evolutionary “nap,” the element was aptly named *Sleeping Beauty* [23,24]. *SB* is a two-component system consisting of transposon and transposase. The transposon is a DNA molecule, containing two terminal inverted repeat (IR)/direct repeat (DR) elements separated by a stretch of DNA that in nature would code for the transposase, but in engineered systems may contain any gene of choice, commonly a selectable marker and/or therapeutic gene (Figure 31.1). The transposase protein binds to the DR regions to mediate insertion of the transposon into thymidine–adenine dinucleotides (TA) in another DNA sequence [23]. For genomic engineering, the transposase may be coded for on the same plasmid as the transposon (outside of the two inverted terminal repeat [ITR] regions), on a separate plasmid, or by an mRNA [25,26].

Transposition occurs in a three step process: binding, cutting, and pasting. First, four molecules of transposase bind to the transposon at the DR elements to form a protein–DNA complex [27,28]. Second, three cleavages occur, resulting in TA dinucleotide overhangs in the host DNA and GTC overhangs at both ends of the transposon. After excision, host cofactors assist in nonhomologous end joining to ligate the transposon into the host DNA [29–31]. Other host cofactors then complete the reaction by filling in single-stranded DNA gaps to repair the DNA.

31.2.2.1 Improvements to the Transposon

The originally isolated *SB* transposase was named “SB10,” and the transposon was called “pT.” This first system was capable of transposition in 0.3% of immortalized human cells, a frequency 20–40 times the background rate of random integration [23]. Improvements of the IR/DR sequences have resulted in pT2, pT3, and pMSZ transposon vectors, with rates of transposition about two to four times that seen with pT when SB10 is used as the transposase [28,32–34]. A recent improvement to the transposase is the HSB17 enzyme, which represents a 30-fold improvement of transposition frequency in human tissue culture cells when used in conjunction with pMSZ over the original SB10/pT system [35]. However, after

FIGURE 31.1 Mechanism of gene therapy using the *SB* transposon. A transposon donor plasmid, along with a source of *SB* transposase protein, is introduced into the cell by any transfection method. The donor plasmid contains two IR/DR ITR regions oriented in opposite directions from the transgene insert. The remainder of the donor plasmid may contain selectable markers or code for the transposase. Two molecules of transposase bind to each ITR element and the genomic DNA. *SB* transposase cleaves the DNA in three places in a staggered manner, twice at the ends of the ITRs and once across the TA dinucleotide in the genomic DNA. Nonhomologous end-joining factors provided by the host repair the DNA, and single-stranded gaps are filled in. The TA dinucleotide is repeated as a consequence of staggered cleavage. The promoter/enhancer and transgene are permanently inserted, along with the flanking ITR sequences, into the genomic DNA.

hydrodynamic tail vein injection for liver-specific transgene expression, the HSB17 enzyme was slightly less than twofold above SB10 when both were used with pMSZ [35]. This is less than the sevenfold increase in expression observed in liver when the HSB2 enzyme was used with either the pT or pT3 transposon [34].

31.2.2.2 Factors Affecting Transposition

Knowledge of how the transposase functions in mammalian cells may also allow investigators to increase transposition by better understanding the role of the host environment. HMGB1, a DNA-binding protein and pleiotropic cytokine, was found to interact with *SB* transposase *in vivo* and may

play a role in DNA interaction during transposition [36]. The Ku protein, a member of the nonhomologous end-joining pathway of double-strand break (DSB) repair, was also shown to interact with *SB* transposase [37]. In addition, the transposase binds to the transcription factor Miz1, causing an extension of the G1 phase of the cell cycle [38]. This knowledge may be useful in predetermining the fitness of a particular tissue for transposition by evaluating the levels of these host proteins. Although it has been suggested that it may be beneficial to transiently introduce extra doses of one or more of these host proteins to increase transposition rates, such a strategy increases the complexity of the system and may be difficult or unsafe in practice.

There are several limiting factors to *SB* transposition beyond host cofactor requirements. Both the size of the transgene within the transposon, as well as the overall size of the transposon-delivering plasmid, have been shown to affect efficiency [39,40]. There is a decrease in transposition as the size of the transgene increases, and this inverse relationship becomes more pronounced when prokaryotic DNA is used as the transposon cargo instead of eukaryotic DNA [33,39,40]. Similarly, it has also been shown that transposition increases when the transposon ends are brought closer to each other, either by decreasing the size of the transposon or the non-transposon portion of the plasmid vector [40]. The methylation state of the transposon also plays a role in transposition. Methylation of the transposon at CpG sites was found to increase overall transposition rates by 11-fold in mouse ES cells [41]. Yusa et al. [41] hypothesized that the DNA condensation brought about by histone binding to the methylated transposon sequence may bring the ends of the transposon together physically. Thus it seems that some of the limiting factors for *SB* transposition may be at least partially explained by steric properties, since it appears that transposition increases whenever the transposon ends are closer in physical proximity to one another.

A related issue is the phenomenon of overexpression inhibition, which was first identified in *mariner* transposons [42]. Because dimers of *SB* binding both ends of the transposon must come together to form a tetrameric complex for excision to occur, it is thought that an abundance of *SB* transposase may result in the formation of tetrameric complexes containing only one transposon end [25]. Thus, an increase in transposase protein levels beyond the optimal amount results in a decrease in transposition efficiency [33]. Since different cell types and transfection methods result in varying steady-state levels of transposase protein, the transposase-to-transposon ratios must be optimized for each application of the *SB* system [17]. This optimization limits comparisons between studies and necessitates a substantial input of time and resources whenever new methods using the *SB* system are tested.

31.2.2.3 Integration Site Preferences

The integration preference of the *SB* transposon into the host genome is essentially random within host genomes; all that is absolutely required is a TA dinucleotide sequence [43].

The few statistically significant preferences that have been identified are for AT-rich DNA, microsatellite repeats, and a small bias toward genes and regulatory sequences [44]. *SB* transposase has been demonstrated to have an affinity for heterochromatic regions and the efficiency of transposition is increased 100-fold when DNA is made heterochromatic [45]. Within those insertions into genes, transcriptional activity did not play a significant role [44]. Slightly longer consensus sequences (AYATATRT or (AT)⁴) have been identified from rescued genomic integration sites [43,44,46]. Also, highly favored sites have been shown to occur during integration into plasmids, although this consensus did not match the genomic consensus sequences [47]. A common theme from each of these integration site studies is that *SB* transposase favors TA dinucleotides that are surrounded by highly deformable sequence. While the random nature of *SB* transposition is preferable to the retroviral preference for promoter regions, random integration is also used as a tool for insertional mutagenesis [48–50]. This feature indicates that gene therapy with the *SB* system could theoretically result in oncogenic transformation as well. This risk should not be taken lightly. Treatment with a nonspecifically integrating retrovirus resulted in insertion events near the LMO2 proto-oncogene, resulting in four cases of leukemia (one of which was lethal) after a clinical trial involving 11 patients [2,51,52].

31.2.2.4 Strategies to Make *SB* More Specific

To reduce the risk of insertional mutagenesis, steps have been taken to improve the *SB* system by attempting to make it more site-specific in order for gene therapy to proceed toward the clinic, especially in tissues that are at high risk for transformation. The idea that a chimeric fusion protein could be produced, which would direct transposition to a more specific site in the genome, is appealing. While it has been noted that directing transposition to a specific site should also be coupled with a mechanism to decrease insertion into random sites, experiments to date have only focused on the former [53]. Wilson et al. first tested the feasibility of this approach in cell culture by expressing a fusion protein containing a zinc finger (ZF) protein fused to the C-terminus of SB12 transposase [54]. Transposition activity was fully preserved and overexpression inhibition was abolished. However, it was not demonstrated that the ZF portion actually redirected transposition activity toward its DNA-binding site [54]. In a second study, a hyperactive version of the transposase, HSB5, was fused to a DNA-binding domain at the N-terminus and was shown to be 15-fold more specific than wild-type HSB5 in an extrachromosomal assay in HeLa cells [53]. A third group also made a fusion protein in which a ZF protein was tethered to the N-terminus of the transposase [55]. While transposition activity was maintained, targeting was not successful. Two other strategies were also tested in which a separate tethering protein was expressed that contained two fused domains. One domain bound to a specific chromosomal region, while the second domain bound either a DNA sequence in the transposon

or the transposase protein directly. *SB* transposase was also introduced without modification. Using the targeting protein that bound to the transposase, about 10% of integration events were observed at the expected genomic DNA sequence in cultured human cells, a 10⁷-fold enrichment compared to transposase alone [55]. This approach may be preferable to the creation of transposase fusion proteins because these chimeric enzymes often lose activity [53–55]. Also, it may be possible to further refine the tethering protein system to reduce random integration. However, an increase in specificity of *SB* is yet to be demonstrated *in vivo*.

31.2.2.5 Bioengineering with *SB*

The *SB* system has proven useful for a number of genomic engineering techniques in addition to gene therapy. For example, *SB* has been shown to be active when expressed in the cells of many vertebrates [40]. It has been used effectively as a tool for the creation of transgenic organisms such as fish (zebrafish and medaka), frogs, and rats [56–59]. The random integration feature of *SB* makes it useful for gene discovery to identify the expression profiles of genes in zebrafish [60]. Another successful application of the *SB* system is cancer gene discovery by insertional mutagenesis in mouse and rat [49,50,61]. Transposon systems are an improvement over the traditional retroviral method of cancer gene discovery, because transposons may be designed to mutagenize any tissue of choice by expressing the transposase under a tissue-specific promoter [62,63].

31.2.2.6 Strategies for Transposon Gene Therapy

To achieve gene therapy, all nonviral integrating systems must be coupled with delivery methods to introduce the component parts into the cell. Because the transposon DNA must be introduced, it is often easiest to introduce the transposase gene as DNA as well, either outside the transposon region on the same plasmid (*cis*) or on a different plasmid (*trans*) [64]. It is theoretically possible to use purified transposase protein for gene therapy, although it has not yet been demonstrated. It has been shown that UTR-stabilized *SB* transposase mRNA is capable of mediating transposition in mouse liver [26]. Regardless of the mode of delivery, each new method used must be optimized for transposon-to-transposase ratios since an excess of transposase is detrimental due to overexpression inhibition.

Nonviral transfection methods frequently use either lipophilic reagents or physical methods of delivery. The first use of *SB* for gene therapy in mice used hydrodynamic tail vein injection, a procedure for *in vivo* transfection of hepatocytes in which a large volume of a dilute solution of naked nucleic acids in saline is introduced into the tail vein of the mouse [17,65,66]. Both the human alpha-1 antitrypsin (hAAT) gene and the human Factor IX (hFIX) genes were used as transgenes in normal mice, and *SB* groups had significantly higher levels of transgene product from several months after administration until the termination of the experiment [17]. Also, in a mouse model of hemophilia B, after treatment with the *SB*

system, bleeding time was decreased to about twice that of normal mice, indicating a substantial amelioration of the disease in the mouse model [17]. Since then, hydrodynamic tail vein injection has been used with *SB* successfully for therapeutic correction of tyrosemia type I, diabetes, hemophilia A, and mucopolysaccharidosis type I [67–70].

DNA–polyethylenimine (PEI) complexes containing transposon DNA carrying the luciferase gene were found to transfect mouse lung cells, and luciferase expression was prolonged when the *SB* transposase was available to mediate genomic integration [71]. The most common type of cell to express luciferase in this study was a type II pneumocyte [71]. It was also possible to target expression to endothelial cells using DNA–PEI complexes together with an endothelial-specific promoter, and it was shown that secreted alkaline phosphatase levels in serum were an order of magnitude higher when appropriate *SB* transposase levels were provided with the transposon [32]. This system was applied to a mouse model of hemophilia A and delivery of an *SB* transposon carrying the B-domain deleted Factor VIII gene corrected the bleeding disorder when expressed in lung endothelial cells [72]. DNA–PEI complexes have also been used for lung delivery of the indoleamine 2,3-dioxygenase in rat, with the aim of creating a gene therapy for obliterative bronchiolitis after lung transplantation [73]. In a similar study, the endothelial nitric oxide synthase gene was delivered in the same way to reduce the effect of subsequent pulmonary hypertension in rats [74]. The other major use for DNA–PEI complexes has been in cancer gene therapy. *SB* has been used in a mouse model of glioblastoma to prolong transgene expression, resulting in tumor regression and increased survival times when therapeutic genes were delivered [75–77].

SB was first used for *ex vivo* gene therapy for functional correction of junctional epidermolysis bullosa by introducing the *LAMB3* gene into human primary keratinocytes derived from junctional epidermolysis bullosa patients and grafted onto immune-deficient mice [78]. Peripheral blood leukocytes have also been manipulated using nucleofection and the *SB* system to stably express a suicide gene for cancer gene therapy [64]. Both immortalized K-562 hematopoietic cells and CD34+ hematopoietic stem cells were nucleofected with the *SB* system carrying the reporter gene GFP [79]. While both cell types showed high levels of transposition, the hematopoietic stem cells engrafted at extremely low numbers after nucleofection [79]. A lipophilic reagent has also been used to transfect K-562 cells with an erythroid-specific *SB* system to mediate stable beta-globin expression with the eventual goal of treating sickle cell disease [80]. Blood outgrowth endothelial cells were transfected by a commercially available lipophilic reagent with an *SB* system to secrete hAAT, hFIX, and hFVIII [81].

The transposon system can also be used as a delivery vehicle for the cellular manufacture of short-interfering RNAs or short hairpin RNAs for RNA interference to drastically decrease the cellular levels of a protein by preventing the translation of its mRNA. Both *SB* and *Frog Prince* have been used to deliver RNA interference constructs in tissue culture to successfully knock down genes such as lamin A and huntingtin [82,83]. The toxicity of short hairpin RNAs has

been shown to be variable when expressed strongly in liver cells, resulting in the deaths of some mice, so *in vivo* application will require optimization of the construct not only for effectiveness, but also safety [84].

31.3 PHAGE INTEGRASE SYSTEMS

31.3.1 BACKGROUND

Bacteriophages are ubiquitous viral parasites of bacteria that have been studied for decades. A staggering diversity and abundance of phages exist in the world. It is estimated that 10^{27} bacteriophages are found in the ocean alone and that these tiny particles sequester about 20 times as much carbon as all living whales combined [85]. Temperate phages are able to enter either the lytic or lysogenic cycle based on the environment of the host upon infection. If the lysogenic cycle is favored, the phage DNA integrates into the bacterial genome to emerge at a later date when conditions change. Natural selection favoring those phages that are capable of infecting a diversity of bacteria is expected to occur, so it is not surprising that some phages do not require host-specific cofactors for integration [86]. Integration is generally performed by a site-specific recombinase. There are two major classes of site-specific recombinases: tyrosine and serine, which refers to the catalytic residue used to cut the DNA. Tyrosine recombinases include lambda integrase, as well as resolvases such as Cre and FLP. Both of these resolvases are more efficient at excision reactions since recombination takes place between, and generates, the same recognition sites. Serine integrases are better suited to gene therapy due to the unidirectional mechanism of integration between unlike recognition sites, together with their lack of cofactor requirements [86]. Serine integrases include phiC31, phiBT1, R4, and TP901-1 [87–90]. Several serine integrases have been tested for their ability to integrate efficiently into native sites in mammalian genomes, and of these, phiC31 integrase was found to have the most favorable properties for gene therapy [88,91]. Therefore, the following discussion will focus on phiC31 as the hallmark of the phage integrase systems currently under development.

31.3.2 PHIC31 INTEGRASE

PhiC31 integrase was originally isolated from the actinophage phiC31 of *Streptomyces*, a soil bacterium that produces a diversity of antibiotic metabolites and has a complex life cycle [92–94]. The semipalindromic DNA sequences that the serine integrase attaches to are termed *attB* for bacterial attachment site and *attP* for phage attachment site. The most likely mechanism of recombination, as shown by supershift studies of phiC31 and the structure of family member gamma–delta resolvase, is that two molecules of phiC31 attach to each *att* site and come together to form a tetrameric complex that positions both strands of DNA next to each other (Figure 31.2) [95,96]. The formation of the tetramer allows the DNA to be cleaved at the core. Simultaneously, a flat, hydrophobic surface forms perpendicular to the DNA strands between the halves of each original dimer [96]. Rotation at the hydrophobic surface allows for recombination and the

FIGURE 31.2 Mode of action of phiC31 integrase-mediated gene therapy. A donor plasmid containing a short *attB* sequence and the desired transgene is introduced into cells, together with a source of phiC31 integrase. A phiC31 integrase molecule binds to each half-site of both the *attB* site on the donor plasmid and endogenous pseudo *attP* sites naturally present in the genome for a total of four integrase molecules. The two dimers come together to form a tetrameric complex including the pseudo *attP* site in the genomic DNA and the *attB* site on the donor plasmid. This complex cleaves both the pseudo *attP* and the *attB* sites in a staggered manner at the core sequence, simultaneously swapping the DNA strands. The new hybrid sites, *attR* and *attL*, are formed, and the entire donor plasmid is now integrated into the genomic DNA.

formation of new sites *attR* and *attL*, named for their right or left proximity to the phage sequence after integration into the bacterial genome. Presumably because phiC31 integrase cannot form a stable synapse between the hybrid *attR* and *attL* sites, the reaction is unidirectional [94,95].

31.3.2.1 Use of PhiC31 Integrase in Mammalian Cells

The inherent properties of phiC31 integrase seemed to indicate that it might fulfill the needs of gene therapists for a nonviral, site-specific enzyme for genomic integration. It was first shown to be capable of recombination in mammalian cells between

extrachromosomal *attB* and *attP* sites [87]. The length of the minimal sites for recombination was determined in *Escherichia coli* to be 34bp for *attB* and 39bp for *attP* [87]. For human gene therapy, an integrating enzyme must be able to find suitable preexisting genomic sites. For site-specific recombinases, such sites are generally termed pseudo sites, or sites that share common sequence features with the actual recognition site, but may be degenerate. PhiC31 integrase was demonstrated to mediate recombination into a chromosomally placed *attP* site in a human cell line [97]. The next step was to determine what, if any, pseudo sites existed. Integration was tested by using an *attB*-containing plasmid to find pseudo *attP* sites and an *attP*-containing plasmid to search for pseudo *attB* sites. Surprisingly, phiC31 integrase has a definite preference for integration into pseudo *attP* sites rather than pseudo *attB* sites [97]. This bias may be related to the lower GC content of the *attP* site; possibly either because methylated CpGs inhibit the reaction or simply due to the general rarity of GC-rich regions in mammalian genomes [8]. Therefore, for use in transgenic organisms and gene therapy, the system usually consists of a coding region for the phiC31 integrase introduced as a plasmid or mRNA, as well as a separate donor plasmid containing the *attB* site and transgene of choice.

31.3.2.2 Integration Site Analysis of PhiC31 Integrase in the Human Genome

The ideal gene augmentation strategy would involve integration at one safe site in the genome. The integration specificity of phiC31 integrase has been evaluated extensively by plasmid rescue in three human cell lines [98]. It was found that integration is indeed sequence-specific, enabling the identification of a ~30bp consensus pseudo *attP* sequence. Nineteen pseudo *attP* sites were found more than once, representing just over half of all integration events. The most common pseudo site, present on chromosome 19, was found in 7.5% of genomic integrations. With regard to safety, while none of the rescued events showed any reasonable chance of causing insertional mutagenesis after comparison to a list of known cancer genes, about 10% of rescues involved aberrant events, either translocations or large deletions of the chromosomes [98]. The translocation events that were rescued in this study were incapable of producing fusion proteins, because the two chromosome arms were separated by the donor plasmid, which is several kilobases long. In general, phiC31 integrase appears to be safer than other integrating systems, although more experiments are needed to address the cancer risk of a phiC31 integrase-mediated gene therapy. However, there is already a growing body of evidence that phiC31 integrase does not mediate chromosomal translocations at a detrimental rate *in vivo*. No tumors have been found in normal mice, rats, or rabbits given phiC31 integrase-based gene therapies. Also, phiC31 integrase has been expressed constitutively in mice, and these strains exhibit normal fertility and development [99,100]. Additionally, other experiments are under way to mutate the enzyme to better recognize one of the chromosomal locations that was a preferred integration site. We predict that phiC31 integrase will evolve over the coming years

into a more ideal enzyme with higher efficiency in mammalian cells and more specificity in the human genome.

31.3.2.3 Genetic Engineering with PhiC31 Integrase

In addition to its utility for gene therapy, the unique properties of phiC31 integrase have made it popular for applications in transgenic organisms. In mice, the integrase has been transiently expressed for transgene integration into embryonic genomes [101]. Additionally, two separate strains of mice have been created in which phiC31 integrase is constitutively expressed for genomic manipulation by crossing [99,100]. In *Drosophila*, phiC31 integrase has been used for both the creation of transgenics and cassette exchange [102,103]. Other genomes in which chromosomal manipulations with phiC31 integrase have been successful include fission yeast, tobacco plastid, mosquito, silkworm, *Xenopus laevis*, Chinese hamster ovary cells, mouse, rat, rabbit synovial cells, and bovine fibroblasts [19,104–111]. It has been reported that phiC31 integrase was incapable of finding pseudo *attP* sites in chicken fibroblasts; however, it is unknown exactly why integration was unsuccessful [112].

31.3.2.4 Gene Therapy Mediated by PhiC31 Integrase

In the gene therapy arena, phiC31 integrase has been shown to be effective in mediating long-term gene expression in many preclinical treatment models. Hydrodynamic tail vein injection has been used as a method to transfect hepatocytes with the phiC31 integrase system, resulting in permanent, high levels of transgene product [113–115]. Fumarylacetoacetate hydrolase, hFIX, and hAAT have been successfully used as transgenes. Protein levels were consistently greater in groups that received integrase in comparison to groups that received no active integrase. In the 2002 study, some mice in both hFIX groups were given partial hepatectomies to encourage liver regeneration [113]. A decrease in hFIX levels was only seen in the nonintegrase group, indicating that maintenance after cell division was specific to those hepatocytes receiving integrase as well as the donor plasmid. In the same study, the mouse *mpsL1* pseudo *attP* site was identified, and phiC31 integrase-mediated integration at this site was shown to have occurred in every liver sample tested [113]. Using this *in vivo* hepatocyte transfection technique, phiC31 integrase was demonstrated to be capable of imparting significantly higher levels of hFIX than the *SB* system when comparable backbone sequences were used for the hFIX-containing plasmid [115]. Notably, after liver regeneration was induced by a two-thirds partial hepatectomy, phiC31 integrase-treated hepatocytes maintained hFIX expression better than *SB*-treated hepatocytes, indicating that phiC31 integrase may also be the better choice for long-term therapeutic gene product expression [115].

Additionally, phiC31 integrase has proven effective for genomic integration of transgenes after *in vivo* electroporation [116–118]. Rats were injected subretinally with a solution containing a luciferase donor plasmid and a plasmid coding for phiC31 integrase, then subjected to *in situ* electroporation.

This treatment resulted in long-term luciferase expression in the retinal pigment epithelium for the duration of the study (4.5 months) [116]. In other studies, long-term transgene expression in the muscles of juvenile mice was seen after *in vivo* electroporation of donor and integrase plasmids for treatment of muscular dystrophy and peripheral ischemia [117,118].

In a rabbit model of arthritis, joints were intra-articularly injected with naked DNA with and without phiC31 integrase. When phiC31 integrase was present, transgene levels were significantly higher; however, transfection was relatively inefficient [119].

Ex vivo approaches using phiC31 integrase are also promising. The first use of phiC31 integrase for *ex vivo* gene therapy was for recessive dystrophic epidermolysis bullosa (RDEB) [120]. RDEB patients have defects in both copies of their collagen VII genes. Human keratinocytes obtained from an RDEB patient registry were stably modified by phiC31 integrase to express collagen VII. After regenerating skin from cells engrafted onto recipient *scid* mice, the skin was biopsied and shown to be pathologically indistinguishable from skin generated from normal keratinocytes at time points up to 14 weeks post-transplant [120]. To further explore potential treatments for RDEB, transfection of fibroblasts with plasmids expressing collagen VII and phiC31 integrase, followed by intradermal injection into grafts of RDEB skin on immune-deficient mice, was also successful [121]. While wild-type cells were incapable of correcting the RDEB phenotype, phiC31-mediated correction of fibroblasts resulted in levels of collagen VII that exceeded wild-type, allowing the regeneration of normal skin from these fibroblasts [121]. Robust expression of transgenes placed in the genome is a commonly observed feature of the phiC31 integrase system, possibly due to genomic placement at chromatin regions that are accessible, not only to phiC31 integrase but also to proteins involved in transcription [98,121].

Patients with junctional epidermolysis bullosa are lacking laminin V expression. PhiC31 integrase was used to mediate integration of the laminin V gene into patient keratinocytes, resulting in functional correction of the disease when grafts were generated on immune-deficient mice [122]. Another *ex vivo* approach used electroporation in a human T-cell line derived from an X-linked severe combined immune deficiency patient, which was functionally corrected by genomic integration of the common cytokine receptor gamma chain gene with phiC31 integrase [123]. Muscle precursor cells were nucleofected with the dystrophin gene and phiC31 integrase, resulting in long-term dystrophin expression after engraftment [124,125].

31.4 HOMOLOGOUS RECOMBINATION FOR GENE CORRECTION

31.4.1 BACKGROUND

Homologous recombination, a process of exchanging similar DNA sequences between sister chromatids, naturally occurs

in organisms ranging from bacteria to humans. The process has been selected for over time for two purposes: (1) to prevent catastrophic somatic mutations, which could result in cell death or cancer, by repairing DNA that has lost its molecular integrity through a DSB and (2) to increase the diversity of individuals in a population by recombining paternal and maternal chromosomes during meiosis to create new hybrid chromosomes that are passed on through gametes to the next generation. Homologous recombination has also been taken advantage of as a method for genomic manipulation of organisms such as bacteria, yeast, plants, and mice. Recently, the natural host machinery has also been harnessed for gene therapy applications, allowing for gene correction rather than simply gene addition.

There are two major strategies that have been devised for gene therapy via homologous recombination, specially designed oligonucleotides and ZFNs. Because spontaneous homologous recombination occurs at a very low background rate (in about one in a million somatic cells after DNA introduction), DNA manipulations of either the genomic DNA strand or the introduced template molecule are necessary to stimulate the homologous recombination machinery to act on the targeted area of genomic DNA. Chimeraplasts are short RNA–DNA nucleic acid hybrid molecules that are introduced into cells, triggering homologous recombination by virtue of their abnormal structure [126]. Unfortunately, gene therapy studies using chimeraplasty have been notable for their inconsistent results [127]. While the laboratories of Kmiec and Steer have published accounts of chimeraplasty working well some of the time, many accounts of failure have also been documented [127,128]. This form of gene therapy through homologous recombination, and the similar single- or triple-stranded DNA oligonucleotide correction vehicles, may be better understood in the future. Although they are appealing in principle, because the genomic DNA is left intact until correction occurs, an alternative route to homologous recombination induction in human cells using ZFNs is currently under development and will be discussed in Section 31.4.2. It should be noted that ZFNs constitute a gene therapy technology that is less developed than either the *SB* or *phiC31* integrase systems.

31.4.2 ZINC FINGER NUCLEASES

31.4.2.1 ZF Motifs

A ZF motif is a 30 amino acid folded protein domain that chelates a zinc ion. It is capable of binding DNA by virtue of an alpha helix that inserts itself into the major groove of the DNA [129]. Certain residues along this alpha helix have been found to determine the exact DNA sequence that the ZF binds to [129–131]. These ZFs may be linked together like beads on a string to extend the length of the recognized DNA sequence [132–134]. Other domains can also be fused to the ZF motifs, including the nonspecific *FokI* cleavage domain, to create a ZFN [135–138].

So far the ability to design ZFNs is limited by the availability of ZF motifs that recognize triplet sequences [139].

Because multiple ZF modules are linked together, the long recognition site desired to increase specificity of the ZFN must be balanced against the availability of ZF motifs that recognize the sequence. Since for genetic correction, it is desirable to make a DSB as close to the mutation site as possible, it would be helpful to ZF designers to have a ZF motif for every possible triplet DNA sequence [139].

31.4.2.2 Restriction Endonuclease *FokI*

Most restriction enzymes cleave DNA at a simple, palindromic recognition site, because cleavage and site recognition are coupled events within the same protein domain. *FokI* is a different type of enzyme, in that it cleaves the DNA 9/13 nucleotides downstream of the nonpalindromic recognition site. This unique cleavage pattern occurs because *FokI* consists of two separate domains, a N-terminal sequence-recognition domain and a separate C-terminal nuclease domain [140,141]. Normally, the N-terminal domain must recognize the sequence before the C-terminal domain can cut the DNA due to protein–protein interactions between the two domains [142]. However, it has been shown that single amino acid mutations can disrupt those interactions, decoupling the two processes [143,144]. Additionally, the endonuclease domain requires dimerization for cleavage of the DNA to occur [145]. This dimerization requirement also applies to fusion proteins containing this domain, such as ZFNs [136,146]. Proof of concept for chimeric proteins containing the *FokI* endonuclease domain first occurred after fusion to the *Drosophila Ubx* homeodomain, which showed cleavage at the *Ubx* recognition sequence [147]. Since then, other DNA-binding motifs have been fused to the cleavage domain of *FokI*, including transcription factors [148].

31.4.2.3 Designing ZFNs

The mechanism of the ZFN method of homologous recombination for gene substitution is relatively straightforward in principle, but far from trivial to achieve. First, the investigator designs right-side and left-side ZFNs containing at least three ZF motifs that will each recognize one half of the sequence flanking the cut site. Practically, this involves a deep understanding of the ZF motifs available for use and an application of this knowledge to the immediate sequence surrounding the disease-causing mutation. Then, optimization of the alpha helices must be performed to maintain protein structure integrity [149]. Putative designed ZFNs are made and tested for activity. Cells are transfected with both a donor plasmid carrying the correct DNA sequence and another plasmid encoding the ZFN protein. Within the cell, the ZFN cleaves the DNA at the target site, creating a DSB (Figure 31.3). This DSB recruits the homologous recombination machinery to the site. The donor plasmid is available at high numbers in the cell and is matched with the damaged chromosomal sequence and used as a template. The treated cells are then analyzed for gene correction. Correction efficiencies of 18% have been found without selection, including 7% of cells that were homozygous for the desired modification [149].

FIGURE 31.3 Gene correction by induction of homologous recombination via ZFNs. A known mutation in the genomic DNA is identified and ZFNs are designed for each half of the sequence flanking the mutation. A source of both ZFN proteins is introduced into the cell, as well as a plasmid containing wild-type DNA that is homologous to the sequence surrounding the DNA mutation. The ZFNs bind to their specific DNA sequences, determined by the ZF motifs selected and then dimerize at the *FokI* nuclease domain. The DNA is then cleaved near the harmful mutation by the ZFNs. Host homologous repair machinery initiates strand invasion and the cleaved DNA is repaired using the correct sequence found on abundant donor plasmids as a template. The genomic DNA is now permanently modified to carry the correct DNA sequence instead of a harmful genetic mutation.

31.4.2.4 Gene Therapy with ZFNs

So far, only two gene therapy applications of ZFNs have been demonstrated, both in cultured cells and chosen to highlight the potential of the technology. First, a therapy for X-linked severe combined immune deficiency was devised

targeting a common mutation in exon 5 of the *IL2R γ* gene in both K-562 immortalized hematopoietic cells and primary human CD4⁺T-cells [149]. In human T-cells, observed levels of gene correction were 5.3% corresponding to 20% of the cells that were successfully transfected by nucleofection [149]. Other ZFNs have also been made against the *IL2R γ* gene [150]. Additionally, ZFNs exist that target the human CD8 α gene, although a therapeutic application of these is unclear [150]. Sickle cell anemia is a disease caused by a defect in the β -globin gene, which could potentially be cured by gene correction with a ZFN. Toward this end, a ZFN was designed and demonstrated to target the β -globin gene in human cells [150].

ZFN-mediated gene therapy is still in its infancy. Much work remains to be done before homologous recombination will be ready for the clinic. First, it is difficult to design ZFNs and one must be an experienced ZF specialist to understand how to make a working ZFN [151]. Second, much of the promising technology, including ZF libraries, ZFNs, and patents, is owned by one company, Sangamo, which, in order to protect its intellectual property, does not freely distribute its techniques and products. This makes it difficult for academic scientists to gain access to these materials. Third, ZFNs must be shown to mediate long-term, safe gene therapy when used in human cells *ex vivo* that are reintroduced to irradiated *scid* mice. Fourth, ZFNs must be optimized to mediate gene correction at a usable frequency, while limiting off-target DSBs. For greater safety, it would be helpful to make ZF motifs more specific [152].

31.5 COMPARISON OF INTEGRATING SYSTEMS

All three of the developed systems for nonviral integration have their advantages and disadvantages. It is possible that all three will eventually be put to clinical use for different indications. Nonintegrating plasmid vectors may be adequate for gene therapy in quiescent tissues such as brain, for DNA vaccines, and for short-term therapies, on the order of days to months, in proliferating tissues. Transposon systems may be best suited for gene therapy in tissues such as muscle, where oncogenesis is rare. Theoretically, they may also be useful for dominant negative genetic diseases for which a DNA-binding domain is already known, so that a tethering fusion protein could be constructed. *Ex vivo* screening could possibly allow the isolation of stem cells with insertions that disrupt and replace the defective gene. Phage integrases, with their limited number of insertion sites *in vivo*, may represent the best choice for *in vivo* transfection protocols for proliferating cells for treatment of monogenic diseases, as well as long-term cancer therapies. Treatment for recessive diseases is an obvious application, but treatment for dominant negative diseases may also be possible by designing a vector that would carry an RNA interference component to reduce levels of the defective gene product, along with a substantially different, engineered DNA sequence encoding the correct endogenous gene. This approach would couple knockdown of the defective

gene to expression of the correct gene. The strategy would only work if the RNA interference could be designed to be nontoxic and a small amount of defective gene product would not be an issue, because RNA interference usually reduces steady-state protein levels by only about 90%. Additionally, phage integrases are preferred for many *ex vivo* approaches, because the identification of the insertion site can be accomplished by a simple PCR for the most common insertion sites. While it may be possible to engineer a phage integrase to preferentially integrate at one selected site by using mutagenesis screens, it will most likely not be possible to design a different phage integrase for every dominant negative gene due to constraints on sequence recognition [153]. ZFNs are well suited to clonal *ex vivo* approaches for correction of dominant negative diseases, because they edit and correct genetic mutations. The modular nature of this approach may allow adaptation to a number of genetic diseases. However, due to the potentially oncogenic nature of DSBs, this approach may not have a favorable risk/benefit profile for *in vivo* transfection of cells that commonly become transformed into cancers. A second disadvantage of this approach is that for every new disease application, a new ZFN must be designed, made, and tested. However, the possibility of correcting a genetic disease by actually replacing the defective DNA with correct, native DNA, leaving no leftover traces of the therapeutic machinery, is an approach of as yet unparalleled elegance in the field of gene therapy [151]. Table 31.1 compares and contrasts the

features of nonreplicating episomal, transposon, integrase and ZFN systems for gene therapy.

Knowledge of the limitations as well as abilities of each system will be key to thoughtfully evaluating which approaches should advance to the clinic. Hopefully in the coming decades, gene therapy will find a routine place in human medicine. However, it is crucial to success that the cure is not worse than the disease. Systems should be rigorously evaluated in sensitive models to assess the contribution of the gene therapy to cancer formation. Gene therapy in humans would require administration of the therapy to a greater number of cells, since humans are much larger than the rodent models commonly used in gene therapy experiments [152]. Other important differences exist between rodent models and humans, such as tumor spectrum, genomic composition, and immune response. There is no way to be absolutely sure that a gene therapy system is safe prior to clinical trials in human patients, but the predicted risk to the patient should not exceed the expected benefit.

In conclusion, while the promise of gene therapy is yet to be realized, new strategies are under development to address the problems that have been encountered to date in the clinic. Nonviral genome modifying systems may soon emerge as revolutionary new human medicines. Many of the strategies proposed go beyond simple administration of a pharmaceutical and couple surgery or stem cells with a permanent gene transfer system to mediate potential disease cures.

TABLE 31.1
Comparison of Nonviral Systems for Gene Therapy

	Episomal	SB Transposon	PhiC31 Integrase	Zinc Finger Nuclease
Is there prolonged gene expression (up to a few months)?	In some tissues	Yes	Yes	Yes
Is expression theoretically permanent for the life of the cell and its progenitors?	No	Yes	Yes	Yes
What levels of transgene product have been observed?	High, tapering over time	Low to high	Usually high	Endogenous levels
Is an immune response expected?	No	No	No	No
Is the cost to produce probably lower than that of viral vectors?	Yes	Yes	Yes	Yes
Has the system been used in a model system for dominant negative disorders?	No	No	No	Yes
Is the dose critical to success?	No	Yes, due to overexpression inhibition	No	Possibly, due to off-target DSB toxicity
Has targeting to known genomic sites been demonstrated?	N/A	Yes, in modified systems in cell culture	Yes, in cell culture and <i>in vivo</i>	Yes, in cell culture
Are there free DSBs?	No	No	No	Yes
Have chromosomal recombination and/or deletion events been detected?	No	No	Yes, in cell culture	Not reported, but likely, due to DSBs
What is the expected risk of oncogenesis?	Lowest	Higher, because randomly integrating	Lower, because integration is sequence-specific	Higher, because of off-target DSBs
How toxic would the therapy be?	Low	Low	Low	Higher if administered <i>in vivo</i> ; lower if administered <i>ex vivo</i>

32.1 INTRODUCTION

Hematopoietic stem cells (HSCs) maintain hematopoiesis or the generation of blood cells throughout an organism's lifetime. This is accomplished by the capacity of HSCs to self-renew as well as differentiate into the various cell types of the blood. In view of this ability, the HSCs are a promising target for gene therapy, as genetically altering the HSC results in modifications of the myeloid and lymphoid lineages. Furthermore, the availability of surface markers and dyes allows for isolation of pure HSCs with potential to be manipulated for gene therapy. Despite the advantages of HSCs, there are drawbacks. Efficient gene transfer to HSCs has proven to be difficult. Limitations in our knowledge of regulators of the self-renewal and differentiation process has inhibited our ability to fully manipulate the HSCs, such as expansion of HSC *ex vivo*, which would have tremendous advantages for the clinical use of HSCs and bone marrow transplantations.

In this chapter, we will review basic biology of murine and human HSCs, the latest advances made in the understanding of molecular regulators of HSC function, and the recent clinical attempts in HSC gene therapy.

The presence of HSCs was first demonstrated with bone marrow transplantation experiments in which lethally irradiated mice were injected with whole bone marrow (WBM) and rescue was achieved [1,2]. Since then, it has become apparent that there are different populations of progenitors with varying degrees of "stemness." Based on the extent of the self-renewing ability, they are referred to as "long-term HSC" (LT-HSC), "short-term HSC" (ST-HSC), or multipotent progenitor (MMP) [3–5] (Figure 32.1). These progenitors comprise a hierarchy according to their ability to self-renew and to give rise to multilineage blood progenies. The LT-HSC has, in theory, an infinite self-renewing and repopulating ability, while the ST-HSC and MMP has respectively less. Furthermore, while the LT-HSC is mainly quiescent, the ST-HSC is actively cycling [5,6].

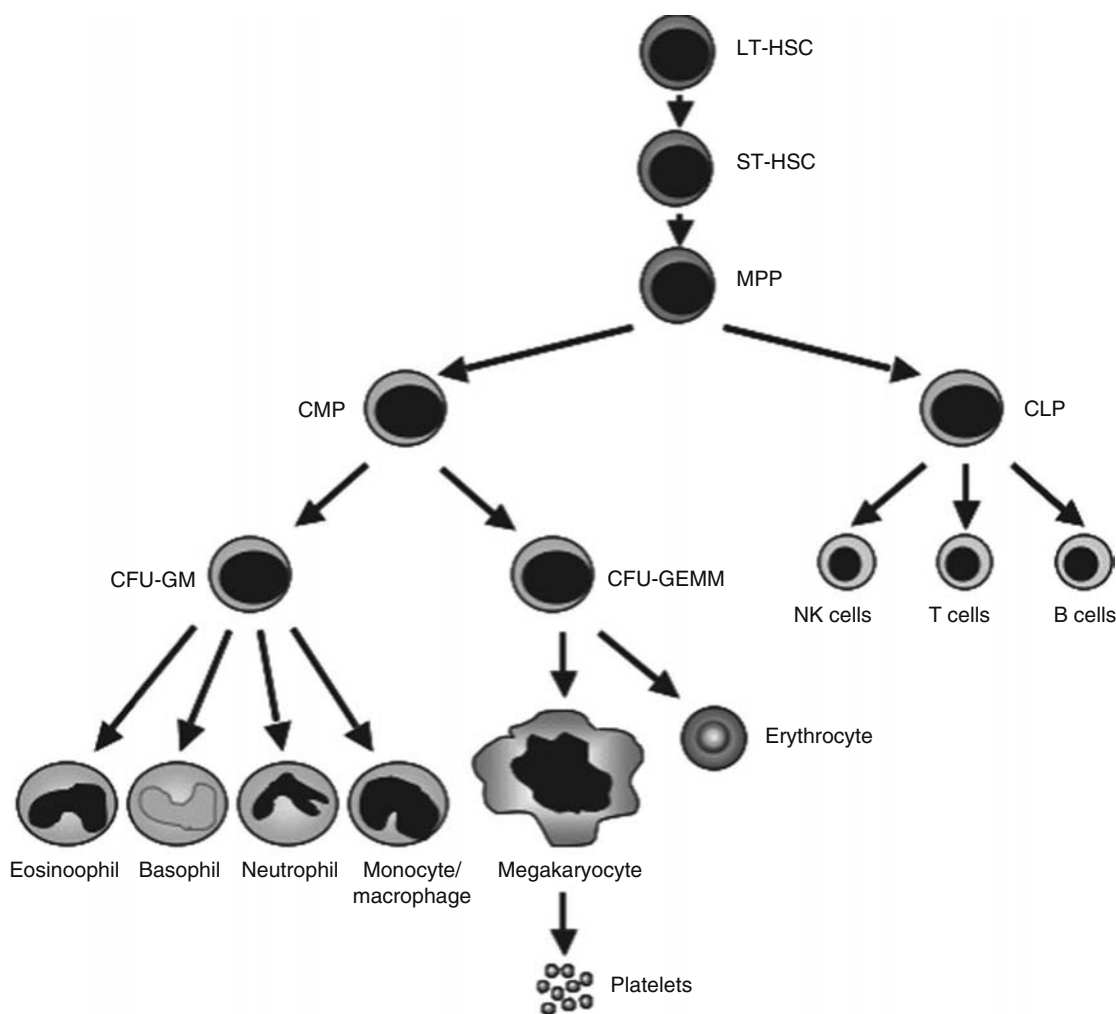

FIGURE 32.1 Hematopoietic differentiation: The hierarchy of the HSC, hematopoietic progenitors, and blood progenies. The hematopoiesis tree starts from LT-HSCs, which are the most primitive stem cells that are able to indefinitely self-renew as well as differentiate. The self-renewal capacity of progenitors degenerates when cells are differentiating toward the end of the hematopoiesis tree. ST-HSCs possess a limited capacity and remain multipotent, while the multipotent progenitors only have the capacity to differentiate into all the blood lineages.

32.2 ISOLATION OF HSCs

32.2.1 SOURCES

The existence of HSCs was first suggested by Ford et al. when they rescued lethally irradiated mice with WBM cells [1,7]. Several approaches such as sedimentation rates and fluorescence activated cell sorting (FACS) were then exploited to identify the regenerating precursors in the adult bone marrow. In addition to WBM, peripheral blood is another source for HSCs in the adult. Brecher and Cronkite first discovered that lethally irradiated mice can be rescued by nonirradiated partners through parabiosis, that is, surgically joining of the circulatory systems [8]. It was further established by Goodman and Hodgson that lethally irradiated mice can be rescued by transplanting more than 5 million peripheral blood cells [9]. However, the requirement of high peripheral blood cell numbers and the low engraftment ability suggest HSCs in the peripheral blood are of low frequency as well as less primitive.

In humans, HSCs are present in ample amounts in WBM while the HSCs in peripheral blood are infrequent and less potent [10,11]. However, because the procedure to acquire peripheral blood is less complicated, and the infusion of granulocyte-macrophage colony stimulating factor (GM-CSF), a cytokine, can greatly increase the frequency of HSCs in human peripheral blood [12]. GM-CSF mobilized peripheral blood is a frequently used source for HSCs for bone marrow transplantations.

Human cord blood (CB) is highly enriched with the HSCs relative to normal peripheral blood. Because CB-HSCs are found to be primitive and resistant to extensive handling such as cryopreservation, as performed in cord blood banks and for cell culture, they have shown great promise for cell-based therapy. In 1989, Gluckman et al. reported the first case of successful hematopoietic reconstitution of a pediatric patient with cord blood cells to correct Fanconi's anemia [13]. Since then, thousands of successful transplantations in children

have been performed to cure both malignant and benign blood diseases. Through these studies, and the increasing interest in national CB banking, CB transplantation has increased. CB is primarily used as a source of HSC for pediatric patients due to the limited total volume of CB that can be obtained: one unit of CB does not provide a sufficient number of HSC to transplant a typical adult-sized patient. However, numerous strategies to overcome this limitation are being examined, such as limited expansion of the CB-HSC or combining CB units from different sources into the same patient [14].

During early embryonic development, two waves of hematopoiesis occur [15,16]. The first wave of hematopoiesis, which gives rise to primitive (embryonic) erythroblasts (EryP), occurs in yolk sac around day 7 of gestation in mice [16]. The second wave of hematopoiesis occurs around day 9–10 of gestation from the aorta-gonad-mesonephros (AGM), a mesoderm-derived region, which gives rise to definitive (adult) hematopoietic progenitors [17,18]. It has been found that the embryonic precursors from yolk sac are not able to reconstitute lethally irradiated recipients, while the definitive precursors from AGMs are capable of engrafting. The definitive HSCs are later found in the fetal liver (at day 11 of gestation), where they are thought to have migrated from the AGM. Ultimately, the HSC migrate to the bone marrow where they reside in the adult. Additionally, Gekas et al. has found the placenta as a site of definitive hematopoiesis, which emerges at day 12.5–13.5 of gestation after the AGM and during the fetal liver hematopoiesis [19].

Mouse and human embryonic stem (ES) cells also generate hematopoietic cells during *in vitro* differentiation. The differentiation pattern is thought to recapitulate the hematopoiesis in early embryonic development [20]. The idea that ES cells can be indefinitely expanded and then made to differentiate into desired numbers of potent HSCs has drawn scientists to the attempt of deriving HSC from ES cells. Doetschman et al. were the first to generate blood cells *in vitro* from ES cell suspension cultures (with no feeder layers or the supply of leukemia inhibitory factor) in 1985 [21]. However, ES-derived blood cells are found to resemble embryonic hematopoietic progenitors that are destined to produce embryonic erythrocytes and lack the ability to produce lymphocytes [20]. Furthermore, these differentiated hematopoietic cells were reported to possess limited ability to engraft in adult animals [20,22], which presents a major drawback for the idea of using ES-derived HSCs as a clinical source. However, a few studies have been able to reconstitute certain hematopoietic components in immune-compromised mice by infusion with HSC-enriched ES-derived hematopoietic cells [23,24]. These studies indicate that although adult hematopoietic precursors occur transiently and are of low frequency, one may utilize strategies to improve the generation of adult hematopoietic precursors from ES cells. Therefore, several approaches, such as supplementing with hematopoietic cytokines and gene targeting, have been undertaken to improve the derivation of adult HSCs from ES cells. Enforced expression of transcription factors such as BCR/Abl [25], Hoxb4 [26], or Cdx4 [27] enhances the generation of definitive (adult) hematopoiesis to allow engraftment in lethally

irradiated mice. Moreover, a study showed that by combining strategies, culturing cells with hematopoietic cytokines, and purifying hematopoietic progenitors with flow cytometry, ES-derived HSCs are able to engraft in major histocompatibility complex (MHC)-mismatched recipient mice [28]. Thus, with further development long-term, we may see ES-derived HSCs moved into the clinic.

32.2.2 CELL SURFACE MARKERS AND DYES

32.2.2.1 Cell Surface Phenotype of Murine and Human HSC

Since bone marrow is a heterogeneous mixture of cells, identification of the cells within marrow that are responsible for engraftment of irradiated hosts has been a focus of interest for some time. Physical properties, such as sedimentation rates, of bone marrow (BM) cell subsets were initially exploited to enrich for HSCs, followed by antigenic or dye staining properties that could be identified by FACS.

Class I major histocompatibility antigens (MHC I) were one of the first molecules exploited for fractionating WBM [29]. Depletion of activity assays, which utilized antibodies capable of fixing complement and directing the lysis of target cells, were employed to show that the murine HSC did not express MHC I [29]. In contrast, human primitive progenitors do express MHC I [30], establishing the first of many phenotypic differences between murine and human HSCs. Ultimately, it was shown that murine progenitors and HSCs do not express MHC I, while human progenitors express high levels of MHC I, and human HSCs express low levels [31–34].

Cell “panning” has also been employed to fractionate WBM, where an antibody is fixed to the surface of a tissue culture plate and BM cells, which adhere to the antibodies, are collected and assayed for the enrichment or depletion of primitive hematopoietic potential. Cell panning helped identify c-Kit [35] expression by HSC as well as their ability to bind wheat germ agglutinin [36].

The development of flow cytometry allowed multiple antigens or fluorescent dye efflux characteristics to be utilized together for improved purification. A major advance was to use a cocktail of antibodies against antigens specific for the differentiated lineages to deplete the BM of the 90% differentiated cells [37]. Such “lineage”-negative BM is depleted of T cells, B cells, granulocytes, macrophages, and erythrocyte progenitors. This lineage cocktail is commonly used in purification schemes of murine HSC. In human progenitor purifications, antibodies against CD33 are used, as it is expressed by progenitors but not the HSC [38]. Similarly, CD38 is present on human progenitors but absent from HSC [39] so it can be used for negative selection of differentiated cells.

Another major breakthrough in HSC purification entailed the use of the CD34 antigen for positive selection of human HSC [33,40]. Primate studies ushered in the use of CD34 as a tool for isolating HSC for bone marrow transplantation [41], and CD34 became the most clinically exploited molecule expressed by HSC.

In the studies of HSC biology using the mouse as a model, multiple purification schemes are exploited. The first strategy that utilizes the Thy-1 antigen was reported by Spangrude et al. to enrich for murine HSCs [37]. Thereafter, different combinations of cell surface makers were discovered by various laboratories in the attempt to further enrich for HSCs from bone marrow. Although the strategies among different laboratories vary, there is a core element that utilizes the expression of Sca-1 (stem cell antigen), c-Kit, and the absent expression of lineage markers, resulting in an HSC-enriched cell population usually called the c-Kit + Sca-1 + Lineage- (KSL) cells. The KSL cell population comprises ~0.1% of murine WBM cells and is a heterogeneous population that contains lineage-primed progenitors as well as stem cells [42]. Therefore, several additional markers such as Thy1.1 [3], CD34 [43], and Flk-2 [4] were individually utilized to exclude differentiated progenitors by various laboratories to advance the enrichment scheme, which as a result lead to a variety of cell surface marker combinations. The resulting cell populations from these schemes are thought to be highly overlapping with each other if not identical. More recently, Kiel et al. used a new set of cell surface markers, CD150, CD244, and CD48, which belong to the SLAM family, to purify HSCs [44]. However, it is still to be determined how similar and homogeneous SLAM-purified cells are compared with other well-characterized populations.

Although multiple surface markers are expressed on murine HSCs, the expression of these markers does not always translate into human studies. For example, although Sca-1 is routinely used to purify murine HSC, a human homolog for Sca-1 has never been identified. Likewise, high expression of CD34 is critical for purification of human HSCs, but CD34 is expressed at very low levels on murine HSCs [45]. C-kit expression, on the other hand, has also been used to purify both human and murine HSC [42,46–49].

In summary, murine and human HSC can be selected on the basis of the expression of a number of antigens in combination: Sca-1, lineage^{neg} c-Kit^{pos} with either Thy1.1 (low), CD34^{low}, or Flk-2 in the mouse, and CD34⁺, CD38⁻, lineage^{neg}, and c-kit^{pos} in the human.

32.2.2.2 Vital Dye Enrichments

Vital dyes have also been used alone or in combination with cell surface markers. Most WBM cells stain brightly with the DNA-binding dye Hoechst 33342, but progenitors stain dimly [50–52]. Hoechst-based enrichment for stem cells was refined with the observation that with the use of two emission wavelengths, multiple populations could be defined. A small population can be observed on the side of the profile (the so-called side population, or SP, Figure 32.2) [53], which contains all of the hematopoietic reconstituting potential of mouse bone marrow. An SP has been observed in multiple species [45] and appears to be due to a multidrug resistance (MDR)-like mediated efflux of the Hoechst dye [53]. The efflux of Hoechst dye by HSC is thought to be due to the transporter ABCG2 [54], but additional drug pumps are likely also involved. While the

FIGURE 32.2 Representative Hoechst 33342 staining profile of murine bone marrow. When mouse bone marrow is stained with the DNA-binding dye Hoechst 33342, multiple populations are observed. All the hematopoietic reconstituting cells are found in the small population on the side, the “side population” or SP (boxed).

natural substrate of the dye efflux is currently unknown, we hypothesize that it may be a molecule that otherwise would cause the cells to differentiate. FACS purification using the SP profile alone affords 1000- to 3000-fold enrichment. When used in combination with additional cell surface marker expression such as c-Kit, lineage markers, and Sca-1, another 15% or so of non-stem cells can be eliminated, resulting in a remarkably pure and homogenous HSC population “SPKLS” (pronounced as “sparkle”) in which one out of every three cells has functional stem cell activity, which approaches a theoretical maximum [2,45,53,55,56].

Rhodamine 123 (Rh123) is another vital dye used for HSC enrichment. Murine and human rhodamine^{Low} WBM cells are enriched for HSCs [57,58]. When Hoechst^{Low} WBM cells were fractionated into rhodamine^{Medium} and rhodamine^{Low} populations [52], Rhodamine^{Low} cells were shown to be more primitive [52]. Rh123 binds mitochondria and therefore Rh123 fluorescence is thought to directly reflect cellular metabolic activity [59]. However, since Rh123 is also a substrate for MDR transporters, low Rh123 may simply reflect dye efflux, as is the case with Hoechst 33342.

32.3 MOLECULAR REGULATION OF HSC FUNCTIONS

Under normal conditions, HSCs remain in a quiescent state. However, when given appropriate signals such as stress, they have the ability to self-renew, differentiate to generate mature blood cells, or undergo apoptosis (Figure 32.3). What molecularly dictates this fate determining process is poorly understood; however, to date several key players have been identified (Figure 32.4).

FIGURE 32.3 HSC cell fate decisions during its lifespan. Multiple mechanisms in regulating cell cycle and cell survival are found to be involved in HSC cell fate decisions.

32.3.1 INTRACELLULAR FACTORS MEDIATING SELF-RENEWAL

The cyclin-dependent kinase inhibitors (CKIs) such as p21cip/waf1, p27 kip1, and p18 INK4A have been shown to play a role in the regulation of stem cell quiescence. p21 KO mice have an increased number of HSCs with elevated numbers progressing through cell cycle [60], suggesting that p21 negatively regulates HSC cell cycle entry. P27 has been shown to play a similar role; however, rather than increasing the HSC pool and the number of proliferating HSCs, it seems to affect the number of mature progenitors without changing the number of HSCs [61]. Furthermore, p18 has been shown to

regulate the frequency of self-renewing HSCs [62] suggested by an improved long-term engraftment of p18 KO bone marrow cells in transplantation assays. This group of cell cycle checkpoint regulators demonstrates the complexity of the HSC self-renewal regulation. Though the function of these three CKIs is to regulate cell cycle, they have distinct roles in regulating HSCs kinetics.

Several transcription factors have been identified to regulate HSC self-renewal. Among these are the homeobox genes. The Hox genes, well studied for their role in embryogenesis, have recently been implicated to play an important role in hematopoiesis. Several independent studies have shown that HoxB4 promotes HSC expansion both *in vitro* and *in vivo* [63,64]. Overexpression of HoxB4 was associated with an engraftment advantage compared to that of wild-type [63]. Similarly, Hoxb3 has been shown to play a role in regulating stem cell regeneration [65]. Pbx-1, a cofactor for Hox transcription factors, has been shown to be essential for the maintenance rather than the initiation of hematopoiesis [66].

Another group of genes implicated in HSC self-renewal are antiapoptotic genes such as Bcl2 and Mcl-1. Mice overexpressing Bcl2 were found to have increased numbers of HSCs [67]. Loss of Mcl-1 expression in mice resulted in loss of progenitors and HSCs [68]. Together these findings suggest that apoptosis plays a significant role in controlling HSC homeostasis.

FIGURE 32.4 Key players that regulate HSC self-renewal. Examples are the intrinsic factors that regulate HSC cell cycle, survival, and epigenetic programming, and the extrinsic factors needed for the expression of ligands on the support cells (osteoblasts and stromal cells) to stimulate the downstream pathways.

32.3.2 EXTRACELLULAR FACTORS/SIGNALING PATHWAYS MEDIATING SELF-RENEWAL

Signaling pathways such as the Notch, Wnt, and Hedgehog are classically known for their involvement in embryonic development and have recently been shown to also play critical roles in HSC self-renewal. The evolutionarily well-conserved Notch receptors and their ligands have been shown to play different roles in hematopoiesis both in the expansion of HSCs as well as the differentiation process [69–74]. Though there have been conflicting results, several studies have implicated members of the Wnt pathway such as β -catenin in maintaining hematopoiesis homeostasis [75–81]. Overexpressing β -catenin has been shown to improve long-term engraftment. Furthermore, when the Wnt signaling pathway was blocked, a reduction in HSC growth was observed both *in vitro* and *in vivo* [75]. As with the Notch pathway, activating the Hedgehog pathway has recently been demonstrated to control HSC pool by inhibiting differentiation [82–85]. Moreover it seems that the Hedgehog signaling pathway regulates the pool of pluripotent hematopoietic repopulating cells by utilizing the BMP signaling pathway.

Recently, researchers have uncovered another level of regulation of HSC homeostasis. Various laboratories have demonstrated the importance of epigenetic modifications in HSC fate determination [86–91]. The Polycomb group (PcG) chromatin-modifying proteins have been implicated in the epigenetic regulation of HSC self-renewal, differentiation, and quiescence. Bmi-1, a member of the PcG family, has been shown to increase HSC self-renewal when it is overexpressed, while loss of its expression was associated with an overall decrease in HSC self-renewal [88]. Other PcG proteins such as Rae28 have shown to be necessary in maintaining hematopoiesis by regulating HSC activity [89], and Ezh2, involved in histone methylation and deacetylation, has been shown to prevent HSC exhaustion and fully conserve long-term repopulating potential of HSCs [90,91]. An alternative approach to demonstrate the importance of epigenetic modification in HSC homeostasis was taken by Milhem et al. [87]. They chemically blocked DNA methylation and histone deacetylation by using 5azaD and TSA and observed changes in HSC and progenitors cell fate.

As our understanding of HSC development and its basic regulators deepens, we increase the number of potential targets for gene therapy. Once we know the players involved, we may be able to manipulate the pathways to expand HSC numbers and achieve therapeutic levels of desired cell types.

32.3.3 HSC NICHE

The interaction of an HSC with its microenvironment “niche” is critical for HSC homeostasis. The role of the HSC niche is proposed to regulate a balance between differentiation and self-renewal. Schofield in 1978 was the first to propose the idea of a niche [92]. Nowadays the “HSC niche” most commonly refers to the BM encapsulated by bone or more specifically osteoblasts and stromal cells. Direct evidence of the important roles

the niche exerts in nurturing HSC comes from one study that found by increasing the number of osteoblastic cells in the trabecular region of murine hind legs, the absolute number of HSCs increased accordingly [93]. The microenvironment may provide direct cell–cell contact to HSCs through surface molecules as well as provide growth factors such as stem cell factor (SCF), the ligand to c-Kit on HSCs [94], Wnt molecules, ligands of Wingless pathway [95], and Jagged1, a ligand of Notch [72], which will be discussed in further detail below. In addition, a more recent study found that osteoblasts also secrete a small glycoprotein, osteopontin, to regulate HSC cell numbers [96].

As discussed in the self-renewal portion, Notch signaling is involved in HSC expansion. HSCs express Notch and the osteoblasts express their ligand Jagged. The osteoblasts are therefore directly involved in regulating HSC differentiation and self-renewal. C-Kit is another receptor expressed on HSCs. It is relatively well characterized and has been shown to be essential for HSC survival. The absence of c-Kit expression in HSC [97] or its ligand SCF that is expressed by the support cells in the niche lead to hematopoietic failures in both murine and human, again demonstrating the importance of the communication between the HSC and its niche [94].

Tie2 is also a receptor expressed on the surface of HSCs. The ligand Ang-1, expressed on osteoblasts, has been shown to allow the adhesion of HSCs to osteoblasts. Furthermore, this receptor pair has been shown to maintain HSC quiescence [98]. Another receptor, which was more recently discovered to be involved in confining HSCs to the niche, is CaR. It has been found that loss of CaR is associated with a loss of HSC attachment to the osteoblasts in the niche even though they were able to home to bone marrow properly [99].

Besides providing direct contact with the HSCs, osteoblasts produce hematopoietic growth factors that help regulate HSC differentiation [100–102]. Some of these factors are IL-1, IL-6 [103–105], GM-CSF, M-CSF [106,107], and G-CSF [108]. Though it has been clearly demonstrated that these factors are needed for HSC survival and expansion *in vivo*, when added *in vitro*, these factors are not enough to maintain HSCs in culture for long periods of time.

In the context of BM transplantations, transplanted HSC must successfully migrate to their niche in order to repopulate the ablated bone marrow. How the HSCs find their way to the niche, so called “home” to the niche, is not well understood. Nevertheless, a number of players have been identified. Adhesion molecules and their respective receptors, integrins, and selectins as well as chemokines have been shown to be involved in HSC homing to the BM [109,110]. Specifically, the involvement SDF-1, a potent HSC chemoattractant, and its receptor CXCR4 (present on the HSCs), was found to be necessary not only for HSC mobilization and homing but also HSC survival [111–116]. SDF-1 from endothelial cells and osteoblasts attracts HSCs to migrate into the niche through a process that is suggested to be mediated by E and P selectins [110,115,117,118].

Another adhesion molecule shown to be involved in the homing of HSCs is VLA-4 and its interaction with vascular cell adhesion molecule-1 (VCAM-1) (expressed on endothelial

and stromal cells). It has been demonstrated that by blocking this interaction with antibodies, HSCs remain mobilized in peripheral blood and are not able to home to the bone marrow niche [109,119–121]. CD44 and RHAMM, two receptors for HA (hyaluronan) expressed on the HSCs, have also been implicated in HSC mobilization. Mice lacking CD44 have decreased mobilization. Furthermore, inhibiting CD44 signaling has been shown to block homing of HSCs to the BM [122–125].

32.3.4 HSC AND AGING

Under homeostasis, the pool of HSCs is maintained to support an individual throughout a lifetime. HSCs therefore have to be present in ample amounts in both young and old mice, which is also for humans with a much longer lifespan than mice. In fact, the HSC compartment of older mice is expanded relative to that of younger mice [126–128]. Even though HSCs derived from both old and young mice have the ability to reconstitute and rescue a lethally irradiated recipient, there is a decline of HSC function on a per-HSC basis [128]. This suggests that the “stemness” of HSCs decreases with age or possibly with each self-renewal division [129–132]. Another indication of this phenomenon is seen among different strains of mice. For instance, C57Bl/6 mice live longer than DBA mice, and if one compares the HSCs function of the two strains, C57Bl/6-derived HSCs outcompete HSCs derived from DBA mice. Furthermore, the DBA HSCs have been shown to divide faster than that of C57Bl/6 and might therefore be “aging” faster [133,134]. Again, this suggests that increased division leads to faster cell exhaustion.

32.4 GENETIC MANIPULATION OF HSC

As discussed earlier, HSCs have the ability to give rise to all the different blood cell types. Any genetic manipulation made to the HSC is therefore passed on to its progeny, making HSCs ideal targets for gene therapy. Thus far, HSCs have been targeted using different vectors, some of which are listed below and reviewed in more detail elsewhere in this book. It is important to note that there is no one good system for targeting, and depending on the type of “disease,” the vector system needs to be chosen accordingly.

32.4.1 RETROVIRAL AND LENTIVIRAL VECTORS

Retrovirus and lentivirus have been extensively used in pre-clinical and clinical gene therapy trials. These viruses are particularly advantageous because they integrate into the host genome, allowing for stable long-term expression. In the absence of integration, the viral DNA would be lost as the stem and progenitor cells proliferate and differentiate. However, with the advantage of stable chromosomal integration comes the risk of potential insertional mutagenesis, which has been one of the major setbacks in using these vector systems in human clinical trials [135–138]. Another disadvantage to retroviral and lentiviral gene transfer is the inability, or compromised ability, to infect nondividing cells. When

aiming to target HSCs, this proves to be a major problem since most HSCs are quiescent. However, this problem can be overcome by stimulation of the HSCs to proliferate. When using these vectors, there is also a limit to the insert size as the retro- and lentiviruses can only package approximately 10 kb of genetic material.

A second major advantage of using one of these two vector systems is the ability “pseudotype” the viruses. This means that the envelope of these viruses can be replaced with the envelope of another, allowing for a broader host range. This technique has also been widely utilized to make viruses that specifically or preferentially infect a certain cell type, a desired feature for gene therapy.

32.4.2 ADENO-ASSOCIATED VIRUS

Adeno-associated virus (AAV) is a defective virus requiring coinfection with a helper virus (i.e., Ad). AAV can persist as an episome or in the absence of helper virus, it can stably integrate into a specific site on chromosome 19 of the host genome where it remains dormant until rescued by a helper virus. A major advantage of AAV is that it can infect both dividing and nondividing cells, making it a useful tool for HSC targeting. One major disadvantage; however, is its minimal capacity. AAV can only accommodate ~4.7 kb, limiting the number of possible therapeutic genes. Furthermore, the difficulty of achieving high titers has kept AAV from being more widely used in clinical trials.

Despite its limitations, AAV possesses qualities desirable for gene therapy. AAV does not appear to be immunogenic, allowing for multiple administrations; furthermore it has a broad host range. AAV has been shown to stably transduce HSCs; however, the extent of its efficacy has been controversial where independent studies have shown transduction efficiency varying from 4% to 80% [139–142]. Nonetheless, it has proven to be a potential tool for targeting HSCs.

32.4.3 ADENOVIRUS

Long-term expression of the gene of interest is not always desired, in which case Adenovirus (Ad) has a great advantage. This vector has a large packaging capacity and therefore allows for large inserts unlike AAV. Because Ad does not integrate, it allows for transient transductions and expression. One major drawback is that Ad viral proteins have been shown to be immunogenic. There does appear to be a dose-dependent toxicity so repeated administration needs to be avoided.

Similar to AAV, it can infect both dividing and nondividing cells, which is again advantageous for targeting HSCs. The first demonstration of Ad’s ability to transduce hematopoietic cells was as shown early as 1985 [142]. Another major advantage of using Ad is that it allows for high expression levels of the therapeutic gene. Furthermore, with Ad, one can achieve high titers and thereby sufficient virus for large-scale transductions as with clinical trials.

32.4.4 NONVIRAL ALTERNATIVES

During the recent years, nonviral alternatives for gene delivery have become more attractive. Some general advantages that the nonviral delivery methods mentioned below have in common are that they allow for a wide range of cells to be targeted, as they are not limited by receptors, nor do they have a major limitation of DNA insert size. Furthermore, because there is no major toxicity issues as with the viral particles, repeated administrations can be performed.

Injection of naked DNA is conceptually the simplest method for gene delivery. The major disadvantage of this technique; however, is that it only allows for targeting of one cell at a time. Though this may be desirable for certain applications, it is not ideal for targeting the large number of cells commonly needed to achieve for therapeutic targeting. Furthermore, though this method has proven to be efficient, it is slow and rather laborious.

Lipofection is also a well-established technique used as an alternative to viral gene delivery [143]. It involves the delivery of RNA and/or DNA to cells by the use of positively charged lipids. This method takes advantage of the negatively charged nucleic acids. The electrostatic interaction between the positively charged macromolecules and DNA/RNA creates complexes that are more easily taken up by the cells through fusion with the cell membrane. Lipofection provides an efficient alternative to viral delivery. It has been shown to work for transduction of a wide range of cell types, however, only provides a transient transduction.

Another nonviral method for gene delivery is electroporation, which involves the exposure of cells to a high-voltage electrical current that creates pores in the cell membrane, allowing for entry of nucleic acids, proteins, and even certain drugs. Electroporation has been used not only for gene delivery *in vitro* but also *in vivo*. The main target cell for *in vivo* studies has been skin cells, however, as the technology develops, tissues that reside deeper in the body may be targeted. As with the lipofection and injection of naked DNA, the expression of inserted DNA is transient. However, combining these techniques with homologous recombination [144] could allow for long-term correction. Unlike the naked DNA injection, electroporation allows for targeting a large number of cells at once and is significantly faster and more effortless. Electroporation had been used in a gene therapy trial for *ex vivo* gene transfer of IL-2 to natural killer cells for treatment of certain cancers [145]. As the technology develops, its use will most likely expand. Recently, a modification of electroporation has been made, referred to as “nucleofection.” Nucleofection allows for DNA/RNA to enter directly into the nucleus and therefore increases the efficacy of gene expression. This method has already proven to be a promising tool for gene therapy, as it is tailored for certain cell types, allowing for transduction of various primary cells and cell lines that have in the past shown to be difficult to transfect [146].

32.5 THERAPEUTIC APPLICATIONS

The ability of HSCs to consistently supply blood progeny throughout one's lifespan has been utilized in human clinical treatments. Hematopoietic stem cell transplantation (HSCT) is one of the most potent therapeutic strategies to correct hematopoietic diseases with blood cell malfunction such as immunodeficiency, autoimmune diseases, anemia, and leukemia. Many of these diseases are corrected by grafting HSCs enriched from healthy donors into patients. However, the most successful allogenic blood engraftment has matched MHC molecules between donor and recipients, and very often it is hard to find a perfect match for each patient. On the other hand, HSC are among the few tissue cells that can be easily isolated, gene modified by virus transduction, and reinfused into patients. It has therefore been successful to combine gene targeting in HSCs and autologous transplantation to correct hematopoietic diseases with genetic defects. In addition, with the development of umbilical cord blood banks, it has been proposed to utilize self-umbilical cord blood that is enriched for HSCs as a source for stem cell gene targeting. Discussed below are different strategies currently used to treat a range of hematopoietic disorders.

32.5.1 HEMATOPOIETIC DISORDERS AND HSC TRANSPLANTATION

The first successful bone marrow transplantation was reported by E. Donnall Thomas in 1975 [147]. After this report, bone marrow transplantation was gradually accepted to treat blood-borne malignancy. More recently, it was discovered that peripheral blood could be a rich source for HSCs when treating donors with G-CSF to mobilize the HSC from bone marrow. With the combination of FACS or magnetic beads in conjunction with antibodies to HSC surface markers such as CD34, HSCs can be further purified. To date, HSCT has been utilized in combination with chemotherapy regimens to treat malignant blood diseases such as myeloid and lymphoid leukemia [148–152]. Recently, HSCTs have also been performed to treat autoimmune diseases [153].

32.5.2 GENETIC DEFECTS IN HEMATOPOIETIC DISEASE AND POTENTIAL GENE THERAPY

Allogeneic transplantations are often accompanied by side effects such as graft-versus-host disease in which the engrafted donor immune cells attack host cells and therefore present a certain risk. With some diseases such as Wiskott–Aldrich syndrome (WAS), a genetic defect resulting in immunodeficiency, autologous transplantations have been demonstrated to be the best option to avoid high mortality [154,155]. Fortunately, HSCs are relatively easy to isolate, genetically manipulated, and reinfused. Gene targeting in HSCs have been proposed to correct some genetic hematopoietic defects. There are a number of mouse models for

human immunodeficiencies that have served as templates for gene therapy trials in human (Table 32.1) and these are discussed below.

32.5.2.1 Animal and *in Vitro* Models for Gene Therapy

JAK-3 is a protein tyrosine kinase that is involved in cytokine signaling [156]. It associates with the common gamma chain, which is used by the cytokines IL-2, 4, 7, 9, and 15 [156]. Lack of JAK-3 function results in low T and NK cell numbers, leading to opportunistic infections and often death [157]. It is estimated that about 7% of human severe combined immunodeficiency (SCID) cases are due to defective JAK-3 expression. JAK-3 null mice have a similar phenotype to humans, although they have low levels of B cells as well [158–160]. One group has used retrovirus expressing JAK-3 to transduce murine HSC, which are then transplanted into JAK-3 null mice. These studies have shown that restoration of JAK-3 by this method increases the numbers of B and T cells. Most importantly, these mice were able to generate normal immune responses after immunization [161] as well as after challenge with influenza A virus [162]. Since human JAK-3-deficient patients are often prone to virus infections, these studies show that the use of gene therapy of HSC to restore JAK-3 expression may be applicable in humans.

Another immunodeficiency in which gene therapy may be useful is WAS. WAS is an X-linked disorder that is characterized by thrombocytopenia, eczema, and abnormalities in cell-mediated and antibody immune responses [163]. The protein involved in this disorder is the WAS protein (WASP). Studies have shown that retroviral-mediated restoration of WASP in B cell lines, T cell lines, and primary T cells from WAS patients can partially restore normal function in these cells [164,165]. More recently, the WASP-null mice have been used to set up a therapeutic protocol, which combines an improved vector design and a HSC transduction setting. In this series of studies, WASP is expressed under control of its autologous promoter and purified precursor cells were transduced and subsequently

generate blood cells expressing WASP protein. These strategies have successfully restored T cell proliferation, immune synapse formation, and cytokine secretion, which are important to correct the T cell defect in the WAS syndrome [166,167]. However, how the animals respond to pathogens is yet to be determined.

Chronic granulomatous disease (CGD) results from a mutation in one of four proteins that make up nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. NADPH oxidase generates large amounts of superoxide in the respiratory burst. CGD patients have diminished NADPH activity; as a result, they are susceptible to bacterial and fungal infections [168]. Several investigators have used mouse models for CGD to test restoration of NADPH oxidase activity by retroviral transfer of the defective protein subunit [169–172]. In these studies, WBM (or bone marrow partially enriched for HSC) was transduced with a retroviral vector carrying a functional NADPH oxidase subunit gene. The cells were then transplanted into irradiated recipients, which lack that gene. In all cases, NADPH oxidase activity was only partially restored, as protein levels of the expressed gene was detected at low amounts. However, this partial restoration of NADPH activity was sufficient to achieve marked improvement in defense against pathogens that would decimate mice lacking the gene entirely. One study [173] has shown that retroviral transduction of a phox gene into human CD34+ cells from CGD patients results in restoration of about half the phox activity in these cells. Protein levels of the transduced gene were similar to those in wild-type cells. More recently, two studies have further showed successful restoration of phox genes in CD34 human progenitors cells *ex vivo* with lentiviral vectors, and these corrected cells can further differentiate into neutrophil cells *in vivo* in NOD/SCID mice [174,175].

Fanconi anemia (FA) is a disorder in which cells are hypersensitive to DNA cross-linking agents such as mitomycin C [176]. The disease, which is due to mutations in the FANCA gene, often results in bone marrow failure and predisposition to malignancies [176]. A retrovirus carrying a functional FANCA gene was used to transduce bone marrow from

FANC-C deficient mice [177]. The cells were then transplanted into FANC-C deficient mice and subjected to treatment with mitomycin C. Mice receiving the corrected gene exhibited normal blood counts, while mice not receiving the gene exhibited decreased blood counts, leading to death. Therefore, phenotypic correction was established by retroviral transfer of the FANC-C gene. In addition, proof-of-principle studies using human CD34 cells from FA patients have demonstrated that AAV [178] or retroviral [178] delivery of the human FANC-C gene can restore resistance to mitomycin C *in vitro*. Similarly, sickle cell anemia and β -thalassemia have been corrected in mouse models by lentiviral transduction of HSC [179,180].

In summary, gene therapy of HSC in mouse models of human diseases has provided proof-of-principle evidence that gene therapy can be used to correct some genetic disorders, although the translation from mouse to human studies can be quite difficult. The use of mouse models for human disease does provide a template to design and test gene therapy protocols for future human trials.

32.5.2.2 Clinical Trials of Gene Therapy for Human Hematopoietic Disorders

There are many human hematopoietic disorders that could potentially be treated using gene therapy (Table 32.2). In most of these diseases, transplantation of bone marrow from a healthy donor could potentially cure the patient. However, a suitable donor is not always available and the transplantation procedure itself can be toxic. Therefore, the use of gene therapy as an alternative treatment would be a significant advance. The first disorder in which a gene therapy protocol was used in clinical trials was ADA-SCID, which occurs due to deficiency in adenosine deaminase (ADA) expression, resulting in SCID. Patients can be successfully treated by receiving exogenous ADA (PEG-ADA), but must continue this regimen for life. Early gene therapy trials used a retrovirus expressing an ADA minigene to transduce umbilical cord blood or bone marrow cells or peripheral blood lymphocytes [165,181,182]. Although some transduced cells persisted and were functional, patients were still dependent on PEG-ADA treatment; removal of PEG-ADA resulted in a relapse into immunodeficiency.

Correction of ADA-SCID by gene therapy has now been improved with better HSC transduction and transplantation protocols [183]. Two patients were reinfused with their

transduced bone marrow after a nonmyeloablative-conditioning regimen. Normalization of the patient's immune system in the absence of PEG-ADA was achieved and had been sustained for about 1 year at the time of the report [183].

The first successful human gene therapy trials were performed on patients with X-linked SCID (SCID-X1). SCID-X1 is caused by mutations in the common gamma chain, which is a signaling chain used by several cytokines. Lack of this chain results in drastically reduced T- and NK-cell development, leading to SCID. CD34 cells from SCID-X1 patients were transduced with a retrovirus carrying the common gamma chain and infused, without myeloablation, into the patients. Nearly 1 year after this, immune function was normal and patients were living normal lives at home [184,185]. However, two of the 10 patients treated in this manner developed a leukemia-like disease due to integration of the retrovirus into the LMO2 locus, activating this powerful known proto-oncogene [186], raising questions as to the safety of integrating viruses for gene therapy.

Retroviral transduction of HSC has also been conducted for disorders such as CGD and FA as discussed earlier [187]. Although these studies have shown long-term expression of the defective genes, the expression level and transduction rates have been too low to show any lasting clinical benefit.

While the successful trials with SCID-X1 and ADA-SCID patients reflect the promise of gene therapy, failures of other trials represents the obstacles needed to be overcome. One of these obstacles is the frequent problem of low expression levels of the transgene following transduction. However, as demonstrated by the mouse CGD experiments described earlier, low transgene expression may be sufficient to restore function to the affected cells. In other situations, even low levels of transgene expression may be sufficient for preferential selection of the transduced cells, bypassing the need for high transduction efficiencies and high gene expression levels. Another question is how many HSCs must be transduced in order to achieve lasting therapeutic effect. It is likely that these questions must be empirically answered for each disorder being treated.

The retroviral-linked leukemia in also outlines another problem in gene therapy that needs to be addressed [186]. Studies regarding the safety of different integrating retroviruses, and the study of stable expression via nonintegrating episomes may provide more information on the plausibility of safe gene therapy treatments. Although gene therapy of

TABLE 32.2
Clinical Trials Using Gene Therapy of HSC

Disorder	Vector Used	Result	References
ADA-SCID	Retrovirus	Partial correction	[181,182,189,190]
SCID-X1	Retrovirus	Complete correction	[184,185]
CGD	Retrovirus	Very few cells corrected	[191]
FA	Retrovirus	Partial transient correction	[187]

HSC has shown great promise, these questions must be answered before this type of treatment can be used on a regular basis.

33.1 INTRODUCTION

Clinical gene transfer to hematopoietic cells began on May 22, 1989 when autologous T-lymphocytes from a cancer patient were gene marked and transplanted back into the patient [1]. Since then, over 500 patients have been enrolled in hematopoietic cell gene marking or gene therapy protocols, and studies such as this one have played an important role in the evolution of the field of gene therapy (Table 33.1). This chapter will review the practical issues involved in the

conduct of a clinical gene therapy trial, as well as the published trials to date involving actual transfusion of genetically modified cells.

There are two general strategies to clinical gene transfer protocols for hematopoietic cells. The first strategy is to target the pluripotent hematopoietic stem cell (HSC) with the goal of permanent gene transfer to all three hematopoietic cell lineages. Clinical HSC trials have involved transfer of both marker genes as well as therapeutic genes. The second strategy involves gene transfer into a single, terminally differentiated

TABLE 33.1

Summary of the Published Clinical Gene Transfer Trials Involving Hematopoietic Cells

Gene	Vector Type	Cellular Target	Reference
Neomycin resistance ^a	Retroviral	HSC	[2–7]
P47 (chronic granulomatous disease [CGD])	Retroviral	HSC	[8]
GP91 (CGD)	Retroviral	HSC	[9,10]
Adenosine deaminase (ADA) (severe combined immunodeficiency [SCID])	Retroviral	HSC	[11–16]
Multidrug resistance 1 [MDR1]	Retroviral	HSC	[17–20]
Glucocerebrosidase (Gaucher's disease)	Retroviral	HSC	[21]
CD18 (leukocyte adhesion deficiency)	Retroviral	HSC	[22]
Rev responsive element decoy	Retroviral	HSC	[23]
Common gamma chain (X-linked severe combined immunodeficiency)	Retroviral	HSC	[24–27]
Transdominant rev protein (HIV)	Retroviral	HSC	[28]
Neomycin resistance ^a	Retroviral	Lymphocyte	[1,29–31]
ADA (SCID)	Retroviral	Lymphocyte	[12,14,32]

hematopoietic cell lineage. With this strategy, persistence of gene corrected cells is dependent on the lifespan of the target cell. At present, this approach has been applied clinically to allogeneic and autologous lymphocytes but other cell types such as dendritic cells are being explored. There are three broad categories of genes that have been used in clinical trials targeting hematopoietic cells: (1) marker genes, (2) suicide genes, and (3) therapeutic genes. Marker genes provide a mechanism for detection of the transduced cells by introducing a gene product that is easily detectable by flow cytometry, enzymatic activity, or by conferring a drug resistance phenotype. Antibiotic resistance genes such as the bacterial neomycin phosphotransferase gene are most commonly used as markers. Suicide genes allow for *in vivo* elimination of transduced cells. The herpes thymidine kinase, for example, confers sensitivity of the transduced cell to the drug ganciclovir. There are a number of different types of therapeutic transgenes that have been utilized in clinical trials. Some are designed to interfere with the life cycle of the human immunodeficiency virus, some are designed to protect normal HSCs from chemotherapy, some are designed to augment tumor killing, and others are designed to correct inherited monogenic disorders.

33.2 MURINE-BASED RETROVIRAL VECTORS

All clinical gene therapy trials to date targeting hematopoietic cells have utilized murine-based retroviral vectors from the oncoviridae subfamily. As discussed in Chapter 1, the simplicity of the murine retroviral genome has facilitated the

development of a class of replication-incompetent vectors that can be produced by specially engineered producer cell lines. However, murine retroviral vectors can efficiently transfer genes only to actively replicating target cells [41]. Relatively quiescent target cells such as HSCs, which reside predominantly in the G₀/G₁ phase of the cell cycle, are inefficiently transduced by murine retroviruses. Most retroviral vectors that have been used clinically for hematopoietic cell gene transfer are based on the oncovirus called Moloney murine leukemia virus (MoMLV) [42], though other vectors used clinically have been derived from either the Harvey murine sarcoma virus (HaMSV), murine stem cell virus (MSCV), or the spleen focus forming virus (SFFV). HaMSV, MSCV, and SFFV are similar to MoMLV in overall structure and function, as are the modifications incorporated to make them replication-incompetent and safe to use in humans. The HaMSV and MSCV long terminal repeats (LTRs) may function better in HSCs and may be less subject to silencing, but this has not been proven in humans or nonhuman primates. The SFFV has been used in some trials due to its purportedly increased expression in myeloid lines. Modifications to the MoMLV T1 LTR have been made by some investigators to achieve a similar goal of preventing silencing related to methylation by altering methylation-sensitive sites [43]. The general description below of MoMLV also applies to the other related oncoviridae. The MoMLV is composed of two copies of RNA ranging in size from 2 to 9 kb. In order to render these vectors replication-incompetent, the *gag* (core proteins), *pol* (reverse transcriptase and integrase), and *env* (envelope protein determining the host cell range or tropism of the retrovirus)

genes are deleted. What remains are the 5' and 3' LTR sequences on each end of the construct along with the packaging (Ψ) site. The 5' LTR functions as the promoter and enhancer region and the 3' LTR contains the poly-A signal. The Ψ region serves as a binding site for the *gag* polyprotein, which packages the RNA into a viral core. The transgene is cloned into a site downstream of this region. In some vectors, splice donor and acceptor sites are retained or deliberately engineered into the Ψ region to generate, from a portion of the full-length mRNA, a subgenomic mRNA that more efficiently translates the downstream inserted cDNA open reading frame. Replication-incompetent viral particles are produced in specifically engineered "packaging cells." Packaging cell lines such as PA317 [44], (NIH3T3-derived murine fibroblasts), AM12 [45], Ψ crip [46], or 293SPA (293 derived human embryonal kidney cells) [47] constitutively express the *gag*, *pol*, and *env* proteins and therefore secrete empty virions into the culture media. When plasmid DNA of the retroviral vector is transfected into the packaging cells, clones of producer cells can be selected that secrete into the culture media replication-incompetent but infectious virions containing the transgene. The culture media, known as "viral supernatant" can then be collected and used *ex vivo* to infect the desired target cells. An important issue regarding retrovirus vector transduction of hematopoietic cells is that stem cells and lymphocytes express relatively low levels of the surface receptor required for binding of the most widely used amphotropic envelope packaging element [48]. Some studies have suggested that packaging lines using the envelope proteins of the Gibbon ape leukemia virus (GALV) or the feline endogenous virus (RD114) may be advantageous for targeting both stem cells and T lymphocytes because these cells have higher levels of receptor for this envelope [49,50]. There is considerable current interest in bringing lentivirus vectors to the clinic due to a number of desirable characteristics, including their ability to transduce nondividing cells (although even lentivectors may poorly transduce highly quiescent cells in G_0), as well as evidence that their insertion site pattern relative to gamma retrovirus vectors may be less prone to causing leukemogenesis [51–55]. Although a number of groups are planning and a few are conducting clinical studies using a lentivirus based vector, the current requirement for a four plasmid transfection-mediated transient production of replication incompetent vector has made large-scale production of lentiviral vectors cumbersome. Despite numerous attempts, there are yet no available stable high titer producer cell lines for lentiviral production and current safety requirements for most "third-generation" systems designed to limit possible combinatorial events, require four plasmids for transfection. To date, only one group has published a clinical study using a lentiviral vector and that notably involves only patients already infected with HIV [40] (as discussed in Chapter 9). There are many groups working toward improved methods of production and it is likely that production issues will be resolved over the next few years.

33.3 PRACTICAL CONSIDERATIONS OF HEMATOPOIETIC CELL GENE THERAPY

The following section outlines the three phases of a retroviral-based HSC and lymphocyte gene transfer protocol: (1) hematopoietic cell procurement, (2) *ex vivo* gene transfer, and (3) infusion of the corrected cells (Figure 33.1).

33.3.1 GENE TRANSFER TO HSCs

33.3.1.1 HSC Procurement

Collection of large numbers of autologous HSCs is the first step in an HSC gene therapy protocol. The three sites from which HSC can be harvested are: (1) bone marrow, (2) cytokine or chemotherapy/cytokine-mobilized peripheral blood, and (3) umbilical cord blood. Although the precise phenotype of a true HSC is unknown, large numbers of HSCs are contained in a population of cells expressing the CD34 antigen [56]. CD34 cells make up 0.5%–5% of nucleated cells in the bone marrow and only a fraction of these are HSCs. The actual function of CD34 is unknown and investigators have been exploring other markers such as AC133 or characteristics such as the ability to extrude specific dyes to try to select for more primitive cells. Studies using these markers include a description of one patient receiving autologous CD133-positive cells postchemotherapy; however to date, all clinical gene therapy protocols have used CD34 to characterize their progenitor population [57–61]. HSCs can be safely aspirated from bone marrow of the posterior superior iliac crest in a minor operative procedure. The major side effects of this procedure include mild discomfort at the aspiration site and an occasional hematoma. For smaller individuals, symptomatic anemia may require a blood transfusion, which, if anticipated in advance, can be an autologous unit. The

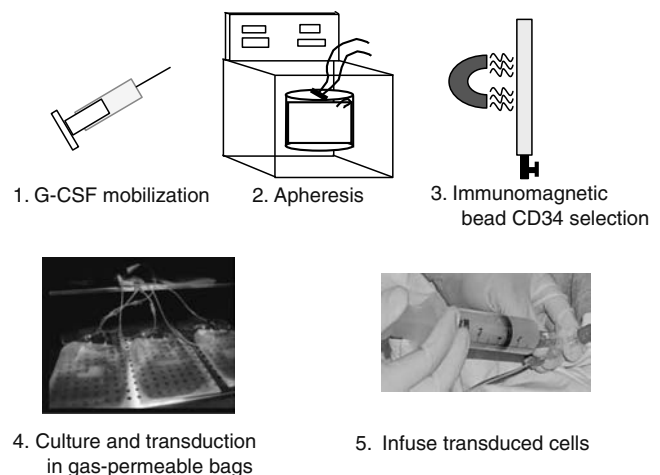

FIGURE 33.1 Clinical scale HSC gene therapy scheme.

major disadvantage of large volume bone marrow aspiration is that it must be done under general anesthesia. Because of these issues, repeated large-scale marrow harvests are not desirable.

In most individuals, administration of granulocyte-colony stimulating factor (G-CSF) at 10–16 $\mu\text{g}/\text{kg}$ per day subcutaneously for 5 or 6 days results in a transient 20- to 100-fold increase in the absolute number of CD34 hematopoietic progenitor and stem cells in the circulation (from a baseline of about 1.4 CD34 positive cells per microliter to an average of 78 CD34 positive cells per microliter; this phenomenon termed stem cell mobilization). Other growth factors have been investigated for their potential to induce mobilization including Flt-3-ligand (Flt3-L) [62–64], granulocyte-macrophage colony stimulating factor (GM-CSF) [65–68], and stem cell factor (SCF) [69,70], though none are as safe and effective as G-CSF. Food and Drug Administration approved formulations only exist for human recombinant G-CSF or GM-CSF, and in the standard clinical setting, only G-CSF or (in poor mobilizers) the combination of G-CSF with GM-CSF is used for mobilization of stem cells. For gene therapy, it may be desirable to obtain larger numbers of CD34-positive stem cells from an individual patient than can be mobilized, collected, and purified from one cycle of mobilization. As well, patients with CGD and possibly other chronic illnesses may mobilize less efficiently than healthy volunteers [71]. However, the mobilization process may be safely repeated at 4- to 8-week intervals. Thus, very large numbers of CD34 cells (exceeding in total 10–15 $\times 10^6$ cells/kg patient body weight) may be obtained by cryopreserving and then pooling cells collected from several repeated cycles of mobilization and apheresis at 6-week intervals. Unlike the procurement of bone marrow, no operative procedure is needed and the entire process can be done without a hospital admission.

Dunbar et al. [72] have demonstrated improved gene marking in nonhuman primates when peripheral blood HSC mobilized with G-CSF and SCF are compared to bone marrow HSC. The same group later showed superior *in vivo* gene marking of nonhuman primate HSC mobilized with G-CSF and SCF compared to HSC mobilized with G-CSF and Flt-3 ligand or G-CSF alone [73]. High-resolution cell cycle analysis of cytokine-mobilized peripheral blood HSC has revealed that these cells are more likely to have entered cell cycle and express higher levels of the amphotropic receptor mRNA [74–76]. While certainly easier to collect, human gene marking studies have yet to demonstrate unequivocally that cytokine-mobilized peripheral blood HSCs are better targets for retroviral transduction than bone marrow HSCs. However, the logistical advantages to obtaining very large numbers of peripheral blood HSCs dictate these as the preferred source for gene therapy and other transplant purposes except when the donor has a poor CD34 mobilization response to cytokine administration.

Recently there has been significant interest in the stem cell mobilizing activity of an experimental new small molecule in advanced stage of clinical testing for HSC mobilization, known as AMD3100, this bicyclam molecule initially developed

for its ability to act as a competitive inhibitor of CXCR4 for use in HIV treatment (CXCR4 is one of the several known coreceptors for HIV entry). CXCR4 is a G-protein-coupled receptor found on primitive HSCs. It is the cognate receptor for SDF-1 (chemokine CXCL12) expressed on and secreted by marrow stromal cells. SDF-1 binding to CXCR4 mediates homing and retention of HSCs in the bone marrow. G-CSF administration appears to facilitate a transient reduction in CXCR4 on HSCs and increased degradation of SDF-1 that requires about 5 days to reach peak effect on mobilization of HSC from marrow to peripheral blood. However, AMD3100 acts by directly binding to CXCR4 without activating the receptor, effectively blocking interaction with SDF-1, achieving maximum effect on mobilization of HSCs from the marrow to peripheral blood within 6 hours. There is animal data proving the reconstitutive potential of AMD3100-mobilized cells as well as clinical data showing synergy in mobilization using G-CSF and AMD3100 in combination. AMD3100 may be particularly useful for those patients who do not respond adequately to GCSF alone. Studies are still in progress to determine its exact dosing and best indication for use at this time [77–81].

Umbilical cord blood contains a higher concentration of primitive hematopoietic progenitors than bone marrow [82]. Recent data suggest that the HSCs from umbilical cord blood may also express higher levels of the amphotropic retrovirus receptor [83], which may result in more efficient transduction with amphotropic retroviral vectors. On average 20×10^6 CD34 cells can be collected from the placenta at the time of delivery, which is approximately 10-fold less than what can be collected from mobilized peripheral blood of an adult. Because of the low efficiency of HSC transduction with current techniques, clinical application for gene-corrected umbilical cord blood stem cells may only be practical in neonates.

33.3.1.2 *Ex Vivo* Gene Transfer

Optimization of *ex vivo* retroviral transduction conditions for HSCs has proven to be a formidable task. It appears that 48 to 72 h of culture in growth factors is required for quiescent lineage negative CD34 cells to enter the cell cycle and thus become receptive targets for retroviral transduction [84]. However, studies have shown that prolonged *ex vivo* culture of HSCs results in loss of long-term repopulating ability as a consequence of lineage commitment and of an acquired defect in the ability of cycling cells to engraft [85,86]. This loss of repopulating potential with *ex vivo* culture may be gradual and to some degree reversible. Takatoku et al. manipulated the *ex vivo* culture conditions and growth factor combinations such that HSCs from nonhuman primates were first induced into cell cycle by using a combination of active cytokines, thereby facilitating retroviral transduction. Then, before the cells were transplanted back into the animal, they were returned to a quiescent state by incubating the cells in media containing only SCF. This method of “resting” stem cells prior to infusion resulted in improved engraftment of

gene-marked cells [87]. Measurable gene transfer into HSCs in the clinical setting has been reported with *ex vivo* transduction periods ranging from 6 to 72h [3,15]. While the report using a 6h regimen appeared to succeed in achieving measurable gene transfer without use of growth factors [3], most investigators have found that growth factors and an *ex vivo* culture period of 48–96h are required for optimum transduction. Growth factors are also essential to prevent apoptosis of HSCs during prolonged *ex vivo* culture [21,88–90]. Many studies have focused on determination of growth factor combinations used without stromal layers that can achieve highest transduction while maintaining reconstitutive potential of the transduced HSC. Flt3-L [91] and thrombopoietin (TPO) [91,92] have emerged as important agents to add to the *ex vivo* culture in relatively high concentrations (100–300ng/mL) to achieve these dual goals. These growth factors work optimally in synergy with other growth factors. The presence of SCF in the culture at more modest concentrations of 50–100ng/mL appears to be important as well to maintaining viability and achieving cycling of the most primitive HSCs. While interleukin 3 (IL-3) and IL-6 have also been widely used *ex vivo* in the transduction culture in clinical trials to enhance cycling, there is controversy regarding the necessity, utility, and helpful effects of these cytokine growth factors. In fact, use of concentrations of IL-3 higher than 30–50ng/mL may be detrimental to preservation of cells with long-term engraftment potential. Low doses of IL-3 in the culture in the range of 1–20ng/mL may be sufficient to achieve synergy with other factors in enhancing cycling of primitive HSCs without also inducing undesired loss of engraftment potential. Given current concerns about vector insertional mutagenesis and the likelihood that there could be correlation between gene activation at the time of transduction and vector gene insertion targeting, it is probably best to use the lowest concentration of all growth factors in the transduction culture that achieves the desired level of transduction of primitive HSCs. Other factors essential for maintenance and development of lymphoid progenitors from stem cells, such as IL-7, have not been used clinically, but may in the future prove to be useful for the transduction of lymphocytes [93,94].

A number of techniques have been devised to encourage the interaction of hematopoietic progenitors with viral particles during the *ex vivo* transduction period. Most investigators have opted to transduce a cell population enriched for CD34 expression. CD34 cell enrichment enables an improved stem cell/viral particle ratio, thereby optimizing the multiplicity of infection while using less of the valuable clinical grade retroviral supernatant. A variety of stem cell selection devices that use monoclonal antibodies specific for the CD34 antigen have been employed in experimental clinical protocols (reviewed in Refs. [95,96]). These devices are able to select large numbers of CD34 cells from a bone marrow or mobilized peripheral blood apheresis graft at 50%–80% efficiency yielding a product, which consists of 60%–90% CD34 cells. For reasons that are not well defined, centrifugation of target cells during incubation in a retrovirus vector supernatant increases transduction

efficiency, a technique that has been termed “spinoculation” [97]. The g-forces employed to achieve the effect are as low as 1200g for 20min, making it unlikely that the effect is due to sedimentation of individual virus particles. Cocultivation of the target cells on a confluent layer of retrovirus producer cells has also been shown to enhance transduction. However, regulatory issues related to the safety of cocultivation of HSC with producer lines make this approach impractical for clinical application. One of the more exciting techniques to be described is the finding that a specific proteolytic fragment of fibronectin facilitates stem cell–retroviral particle interaction when this peptide is used to coat the surface of the culture vessel [98]. Fibronectin, a prominent component of the extracellular matrix of bone marrow stromal cells, has numerous hematopoietic cell-binding domains. Moritz et al. have demonstrated binding of both viral particles and hematopoietic target cells to a proteolytic fragment of fibronectin that contains the CS1 binding site [99]. The CS1 binding site of fibronectin interacts with the VLA4 adhesion molecule found on HSCs [100]. Thus, when HSCs are incubated with retroviral particles in the presence of this specific fibronectin fragment, transduction efficiency is improved. The availability of a clinical grade recombinant human C-terminal fibronectin fragment (CH-296; RetroNectin™) has facilitated its use in many clinical gene therapy trials targeting HSCs. Prior to the use of this fibronectin fragment, autologous stroma was used to help maintain the cells during the transduction period in many animal studies [88,90,101], however this is technically and logistically much more difficult than use of this fibronectin fragment to coat the culture vessel. Rhesus studies have shown equivalence if not improvement in using fibronectin fragment CH-296 compared to stroma and now, even with retrovirus vectors of modest titer, acceptable transduction of CD34 cells can be achieved [102]. Importantly, with retrovirus vectors at titers 5×10^6 infective particles per mL, the use of CH-296 fibronectin fragment-coated culture vessels can achieve transduction of 50%–70% of CD34 cells routinely at clinical scale. It is also possible that use of fibronectin fragment coating may help to preserve the long-term engraftment potential of cultured HSC [103] and this has become the standard in most human clinical HSC transduction methods.

33.3.1.3 Transplantation of Transduced HSC

Following *ex vivo* transduction, the extensively washed HSCs are resuspended in physiologic saline and infused into a peripheral vein of the patient. Within 24h, the majority of the HSCs have homed to the bone marrow. Experience with stem cell transplantation for treatment of hematological malignancies has shown that the bone marrow can be completely reconstituted by transplanted HSCs (autologous or allogeneic) following myeloablative doses of chemotherapy or radiation. Because loss of long-term repopulating ability may occur during *ex vivo* transduction of HSC, it is unethical to rescue hematopoiesis in a myeloablated patient with *ex vivo* manipulated HSCs only. However, preclinical and clinical studies suggest that some degree of cytoreductive therapy administered

prior to infusion is required to establish clinically relevant levels of gene marking. Using clinically applicable tools, long-term marking at levels of 5%–10% can be achieved in nonhuman primates following the administration of high-dose total body irradiation [78,104,105]. Aiuti and colleagues have been the first to employ nonmyeloablative bone marrow conditioning in a human gene therapy study for children with ADA-deficient SCID (discussed in more detail in Section 33.4.1.3) [73].

33.3.2 GENE TRANSFER TO LYMPHOCYTES

33.3.2.1 Lymphocyte Procurement

With few exceptions, large numbers of lymphocytes circulate in the peripheral blood and are therefore easily harvested from gene therapy candidates using apheresis. Lymphocytes may also be harvested from special sites such as tumors. These cells are of particular interest since they may possess unique antitumor properties.

33.3.2.2 *Ex Vivo* Gene Transfer and Infusion

Compared to HSC, fewer hurdles exist in the quest to optimize retroviral gene transfer of lymphocytes. Since these cells are terminally differentiated, loss of phenotype during *ex vivo* manipulation is not a concern. T-lymphocytes, which are the most common target for lymphocyte-based gene therapy, are expanded in culture with agents such as IL-2 or monoclonal antibodies to CD3. While being cultured, many of the cells are stimulated into active phase of the cell cycle and become susceptible to permanent retroviral integration. It has been observed that with long-term culture of T-lymphocytes, enrichment of CD8 T-lymphocytes relative to CD4 T-lymphocytes develops. This issue may be addressed by altering the ratio of cells added to the initial culture mixture [32]. Techniques that have been shown to improve lymphocyte transduction efficiency include: (1) the use of retroviral vectors pseudotyped with the GALV envelope protein, (2) upregulation of amphotropic or GALV retroviral receptor expression by growth in phosphate depleted media, and (3) transduction in a culture vessel coated with the CS1 fibronectin fragment [106,107]. Incorporation of these techniques together in the same protocol can yield transduction efficiency of 50%–60%. Given that lymphocytes are the natural target of HIV and other viruses, lentiviral-based vectors pseudotyped with vesicular stomatitis virus G (VSV-G) are a particularly attractive option for T cell mediated gene therapy. Infusion of the gene-corrected lymphocytes takes place as would any routine infusion of cell products. Although it has previously been assumed that cytoreductive conditioning of the recipient is not necessary to achieve persistence of the transplanted lymphocytes, where the therapeutic gene may provide a survival advantage, there clearly are clinical settings in which modest cytoreductive chemotherapy conditioning aimed at marrow stem cells (or in some cases at T lymphocytes) may significantly enhance the clinical outcome from gene therapy. This will be discussed in more detail in later sections of this chapter.

33.3.3 CLINICAL SCALE-UP

The transition from a laboratory-based gene transfer assay to one that is ready for inclusion in a clinical protocol can be quite challenging. The most obvious differences relate to the number of hematopoietic progenitors that must be transduced at one time. Large volumes of retroviral supernatant must be produced in a facility licensed to provide clinical grade material (GMP). It is common to find a decrement in the viral titer of the clinical material compared to titers that can be achieved at small scale in the laboratory. Besides the requisite sterility and endotoxin testing, the product must always be tested for the presence of replication-competent retrovirus. Regulatory and proprietary issues regarding use of reagents or devices often hinder the ability to replicate in the clinical setting what is done with ease in the laboratory. Performing retroviral transduction in a clinically approved facility may require modifications of a laboratory-optimized assay [108]. Use of closed-system, gas-permeable, culture containers compatible with the standard sterile transfer techniques used by blood banks is one method that has been adapted for this purpose [8].

33.4 HUMAN GENE TRANSFER TRIALS

33.4.1 HSC GENE TRANSFER STUDIES

33.4.1.1 Marker Gene Studies

The insertion of marker genes into HSCs has been useful in the evolution of gene transfer technology and has led to a better understanding of autologous stem cell transplantation. The first and still pivotal gene marking study was reported by Brenner et al. in 1993 [3]. This study enrolled 20 patients under the age of 20 who were candidates for autologous bone marrow transplantation for acute myelogenous leukemia or neuroblastoma. Bone marrow was harvested as the patient recovered from a cycle of cytotoxic chemotherapy. Two-thirds of the harvest was immediately frozen and the remaining one-third was transduced with a retroviral vector containing the neomycin resistance gene. *In vitro* transduction efficiency, measured as a percentage of hematopoietic colonies resistant to G418 (neomycin analog), ranged from 2%–14%. The transduced and unmanipulated bone marrow cells were infused after the administration of high-dose chemotherapy. Using polymerase chain reaction (PCR) analysis, the marker gene was detected in approximately 5% of bone marrow mononuclear cells 1 month following transplantation. G418 resistance was observed in 5%–20% of bone marrow colony forming units (CFU) in 5 of 5 evaluable patients at 1 year, and in 2 patients at 18 months.

Three important principles emerged from this study. First, the study proved that long-term repopulating cells could be successfully gene marked *ex vivo*. Second, the study demonstrated that autologous marrow infusion following high-dose chemotherapy participates in the marrow recovery. Finally, the authors also reported that tumor cells obtained

from patients who relapsed after the gene marked, autologous BMT contained the neomycin resistance gene, suggesting tumor cell contamination of the autologous stem cell graft [4]. Deisseroth et al. performed a similar gene marked, autologous, BMT study in patients with chronic myelogenous leukemia where gene marking of normal bone marrow CFU was demonstrated 6 months postinfusion. The investigators also demonstrated gene-marked tumor cells at relapse, again suggesting tumor contamination of the autograft [5]. Two other studies were unsuccessful at demonstrating tumor contamination of autografts, which may be a consequence of much lower rates of *ex vivo* gene transfer [2,109]. Dunbar et al. employed HSC transduction conditions optimized by others with animal models in an attempt to improve the low *ex vivo* transduction efficiency reported by Brenner et al. [3,4]. This gene-marking study also set out to compare the engraftment capabilities of bone marrow and peripheral blood stem cells (PBSC) and their suitability as targets for retroviral transduction. Bone marrow and chemotherapy/cytokine-mobilized peripheral blood mononuclear cells were procured from breast cancer and multiple myeloma patients who were candidates for autologous stem cell transplantation. Two-thirds of each product was cryopreserved without manipulation. CD34+ cells were purified from the remaining one-third of the mobilized peripheral blood, and bone marrow product and retroviral transduction of each product was performed using one of the two molecularly distinct retroviral vectors containing the neomycin resistance gene. Since the bone marrow and peripheral blood CD34 cells were not transduced with the same vector, the contribution of each to engraftment following autologous stem cell transplantation could be tracked using PCR. *Ex vivo* transduction conditions consisted of a 72 h culture of the target cells with retroviral supernatant supplemented with the hematopoietic cytokines IL-3, SCF, and IL-6 (IL-6 was omitted from the culture of CD34 cells from multiple myeloma patients). All transduced and unmanipulated cells were pooled and infused following high-dose chemotherapy administration. The *ex vivo* transduction efficiency as measured by a clonogenic assay was 18%–24%. Following transplantation, gene-marked bone marrow and peripheral blood cells were detected in 10 of 10 evaluable patients at a frequency of 0.1%–1% using a semiquantitative PCR technique. At 600 days postinfusion, only one patient had detectable levels of gene-marked cells. The authors did not identify any significant difference between bone marrow or PBSC as targets for retroviral gene transduction [6].

33.4.1.2 X-Linked SCID

The majority of patients with SCID have an X-linked form caused by mutations in the common gamma chain of the receptors for interleukin 2, 4, 7, 9, 15, and 21. Without a functional gamma chain, there is complete absence of T-cell and NK cell development and failure to complete B-cell maturation, resulting in a profound immunodeficiency in cell-mediated and humeral immunity that is usually fatal in the first year of

life. Standard therapy for infants with an HLA-identical sibling is a T-cell-depleted bone marrow transplant with no (or very low level) cytoreductive conditioning that often results in restoration of the T-cell compartment and in many cases also some prolonged restoration of B-cell and NK cell functions. For infants with no HLA-matched sibling, it has become common practice to transplant such children with a T-cell-depleted HLA-haploidentical graft from a parent (usually the mother), usually without cytoreductive conditioning. Surprisingly, in 70%–90% of children, there is sufficient engraftment of donor T-cells to provide adequate prolonged T-cell function, but there is seldom restoration of B-cell or NK cell function. Almost all of these patients require intravenous gamma globulin and in some cases, there is slow decrease in the functionality of donor T-cell function, leading to recurrent infections, gastrointestinal dysfunction, poor growth, and alloimmune phenomena. As noted, B-cell function is often deficient in patients who are transplanted without marrow conditioning. Such patients are dependent on lifelong immunoglobulin supplementation to remain healthy. The residual humoral immune defect, along with risks of graft versus host disease (GVHD) and conditioning-related toxicity for patients treated with a traditional stem cell transplant led investigators from the Long-Necker hospital in Paris to conduct the first stem cell gene transfer trial for X-linked SCID. To date, CD34-selected bone marrow cells from a total of 11 affected boys were transduced with an MoMLV (MFG) packaged in the crip producer line and infused without bone marrow conditioning. In 10 of 11 patients, normal functioning gene-corrected T-cells and NK cells were detected in peripheral circulation approximately 3 months after the transplant. Gene-corrected cells were never detected in one of the patients and he was subsequently successfully treated with allogeneic stem cell transplantation [112]. As a result of the selective advantage for gene-corrected T-cells, total T-cell numbers reached normal levels within 6 months. Serum immunoglobulin levels normalized in 9 of 11 patients and were low but detectable in the fourth patient. All patients with successful engraftment of gene-corrected stem cell showed resolution of all stigmata of profound immunodeficiency, making this the first gene therapy trial to provide clear-cut clinical benefit.

Unfortunately, the unequivocal clinical benefit that accrued to these patients and the appropriate enthusiasm and excitement surrounding the success of this trial has been tempered by the development of T-cell leukemia in four patients in the Paris cohort. Analysis from the tumor cells of three of the four patients revealed that malignant transformation most likely occurred at least in part as a consequence of insertional mutagenesis of LMO-2, a gene linked to T-cell leukemia as well as other genes [113,114]. Gaspar et al. have published results on clinically beneficial gene therapy in four infants with X-linked SCID and have additional positive results in additional infants using a GALV (as opposed to amphotropic) pseudotyped MFG gamma retrovirus vector [27]. They also used bone marrow as the stem cell source and all patients were less than 3 years of age with the oldest patient

of 33 months having the longest time to T-cell recovery. The authors have also noted that the kinetics of their reconstitution in general were slower than that seen in the study published by Cavazzano-Calvo et al. Of note, despite some suggestion from animal studies that the common gamma chain of IL-2 itself has oncogenic properties, there have been no reports of leukemogenesis in this or any other X-SCID gene therapy trials [115,116] even with follow-up times similar to the trial from Long-Necker. Some differences between the Paris and London cohorts in the *ex vivo* transduction conditions were some very slight differences in the vector backbone sequence, the use of serum-free (London) versus fetal calf serum (Paris) in the medium, GALV envelope (London) versus amphotropic envelope (Paris), and the use of lower concentrations of growth factors particularly IL-3 in the London versus Paris cohort. It is completely speculative whether any of these factors might have made a difference in the observed frequency of leukemic events.

Interestingly, gene therapy for X-SCID has not been as successful in older patients. Two trials reported to date (U.S. and European cohorts) have shown only benefit in one of the five patients treated (one of the three in the U.S. cohort) [75,76]. Both groups used PBSC as the stem cell source and a retroviral vector encoding the common gamma chain pseudotyped with the GALV envelope for patients with X-linked SCID. In the trial in the United States by Chinen et al., only patients having failed a haploidentical transplant were eligible and of the three patients treated (aged 10–14 years old), only one patient (the youngest) had any significant prolonged clinical improvement with partial restoration of immunity postgene therapy. One of the patients had, in fact, rejected four attempts at transplantation from both his father and mother, but due to an aberrant mutation was able to produce a sufficient level of protein to allow survival, but with continued problems of recurrent infections and autoimmunity. Although there were detectable numbers of marked cells in all treated patients, including in the myeloid lineages, there was no proliferative outgrowth of corrected cells except in the youngest patient treated [26]. In the European trial of two patients with X-SCID performed by Thrasher et al., results were also limited with poor T cell development in the two patients, ages 20 and 15, who were treated. Of these patients, one again had an aberrant mutation able to produce some IL-2 receptor common gamma chain on T cells, but insufficient for normal immunity. The other had graft failure post a haploidentical transplant. [25] It is possible that the lack of thymic function in these older patients is a barrier to success as well as a replete, albeit dysfunctional T cell compartment, from either a poorly functional, but persistent graft or the patients' own T cells, which prevent expansion of the genetically modified autologous T lymphocytes.

33.4.1.3 Adenosine Deaminase Deficiency SCID

The inherited deficiency of ADA is responsible for approximately one-quarter of the cases of SCID. In the absence of

ADA, lymphocytes accumulate high levels of 2'-deoxyadenosine, which is converted to the toxic compound deoxyadenosine triphosphate. The result is a patient with profound T and B lymphocyte dysfunction that is susceptible to infections with opportunistic pathogens. ADA deficiency is an attractive target for gene therapy because corrected lymphocytes have a survival advantage over noncorrected, ADA-negative lymphocytes. Multiple gene therapy trials for ADA deficiency SCID (ADA-SCID) targeting HSC as well as lymphocytes have been performed [12–16,117]. Discussion in this section will focus on HSCs as the target for gene therapy.

Van Beusechem et al. laid the groundwork for HSC-based, ADA gene transfer by demonstrating in nonhuman primates that prolonged low-level expression of human ADA from peripheral blood cells was possible after bone marrow cells were transduced with retrovirus containing the ADA cDNA [118]. In 1995, Bordignon et al. in Milan, Italy, published results of a clinical trial in which both peripheral blood lymphocytes and HSCs were transduced with two molecularly distinct retroviral vectors carrying the ADA and neomycin resistance genes and then reinfused into the patient without cytoreductive preconditioning [12]. One patient received nine injections of gene-corrected cells over a two-year period. The other patient received five injections over 10 months. Prolonged detection of both transgenes was observed in both bone marrow and peripheral blood myeloid and lymphoid cells for the entire 35-month period of follow-up. Until the 35-month time point, the vector used for HSC correction was detected only in circulating T cells and bone marrow cells but not in the lymphocytes. Gene-marked lymphocytes contained only the vector used to transduce lymphocytes. At 35 months, however, lymphocytes derived from the gene-corrected HSCs were first detected and subsequently became more prevalent than those that carried the lymphocyte-specific vector. For ethical reasons, all patients treated in this study were treated concomitantly with polyethylene glycol (PEG)-ADA, thereby blunting the inherent selective advantage that exists for the gene-corrected cells. In one patient however, immune function became progressively dysfunctional despite PEG-ADA therapy and sustained long-term expression of the ADA gene in genetically modified lymphocytes. This provided the investigators with the rationale for discontinuation of PEG-ADA therapy, with hope of restoring a selective advantage to the corrected cells and improving immune function [98]. Prior to discontinuation of the PEG-ADA, the patient received additional gene-corrected autologous lymphocytes. The results of this intervention were positive. There was an increase in total peripheral blood T-cell numbers, an increase in intracellular ADA levels, and normalization of *in vitro* T-cell responsiveness to anti-CD3 and alloantigens. Finally, the patient showed evidence of improved humoral immune function as measured by generation of anti-X174 antibodies following vaccination. However, the investigators also measured a concomitant increase in the toxic metabolites of adenosine in red blood cells, suggesting that despite the encouraging clinical effects of PEG-ADA withdrawal, repair of the underlying metabolic defect was incomplete.

Kohn et al. transduced CD34 cells isolated from umbilical cord blood of three ADA-deficient neonates with an MoMLV-based retroviral vector containing human ADA cDNA as well as the cDNA encoding the bacterial neomycin resistance gene [15]. Cells were returned to the unconditioned recipient on the fourth day of life. *Ex vivo* transduction efficiency as measured by percent G418-resistant CFU ranged from 12% to 19%. Clonogenic myeloid precursors from the bone marrow were assayed at 1 year and found to be G418-resistant at a frequency of 4%–6%. Concurrent with the infusion of gene-corrected HSCs, the patients began ADA replacement therapy with PEG-ADA. As a result, the selective advantage of ADA-positive clones was partially blunted. By 4 years of follow-up, the levels of gene-corrected cells in the peripheral blood mononuclear cell fraction had increased 50- to 100-fold in all the three patients [14]. The frequency of gene-corrected T-lymphocytes increased to 1%–10%. This rate of increase was far greater than that observed in the granulocyte series (0.01%–0.03%). In an attempt to assess clinical efficacy of gene transfer, PEG-ADA administration was discontinued in the patient with the highest level of gene-corrected T-lymphocytes. This resulted in reduction of S-adenosylhomocysteine hydrolase activity and loss of antigen specific T-lymphocyte reactivity, suggesting inadequate ADA production by the transduced cells. After 2 months, PEG-ADA replacement was restarted when oral monilia, sinusitis, and an upper respiratory tract infection developed. Hence, despite the inability to demonstrate clinical benefit, the persistence of the transgene for over 4 years in both the lymphoid and the myeloid cell lines suggests that gene transfer into true long-term, repopulating HSCs is possible from cells collected from umbilical cord blood.

It became clear from gene therapy studies of ADA-SCID that whether the target of transduction was T lymphocytes, marrow stem cells, or cord blood stem cells, there appeared to be insufficient expansion and activity of autologous gene-corrected T lymphocytes to achieve significant and lasting clinical benefit. Using improved transduction methodology and for the first time in the setting of gene therapy for a non-malignant disorder, the use of low-intensity bone marrow conditioning (Busulfan 4 mg/kg), the Italian group of Aiuti and coworkers in collaboration with investigators from Israel initially transplanted 2 ADA-SCID patients with gene-corrected HSC [11]. These patients were either unable to obtain or did not tolerate PEG-ADA treatment and for this reason were not treated with PEG-ADA in addition to receiving low-dose busulfan conditioning. Using this approach, the patients demonstrated an impressive increase in the number of peripheral blood T-cells within 2 months following gene therapy, obviating the need for PEG-ADA therapy and thus preserving the selective advantage of the corrected cells. Concurrent with increased T-cell numbers was normalization of T cell proliferative responses, increased levels of IgM and IgA, and in one patient, a robust humoral response to vaccination with tetanus toxoid. The most notable finding from this trial is that one patient had sustained, high-level (5%–15%) gene-marking in multilineage bone marrow and

peripheral blood cells as measured by real-time PCR. Based on this data, other groups have begun to use nonmyeloablative conditioning prior to gene therapy as well as holding the PEG-ADA. The London group from Great Ormond Street Hospital has published their results of one patient using melphalan (140 mg/m²) conditioning and also stopping the PEG-ADA 1 month prior to the gene therapy. This patient appears to be doing well with evidence of T cell normalization and biochemical detoxification [16]. A total of 12 patients to date have been treated for ADA-SCID by various groups using nonmyeloablative conditioning regimens with clinical success in 11 of the 12 (as presented at platform session at the American Society for Gene Therapy National Meeting in June 2007).

33.4.1.4 Chronic Granulomatous Disease

CGD is an inherited immune deficiency caused by genetic mutations in any of the four subunits of the phagocyte NADPH oxidase (p47phox, p67phox, gp91phox, p22phox), resulting in the inability of phagocytes to produce microbicidal superoxide and hydrogen peroxide. CGD patients are prone to recurrent bacterial and fungal infections as well as granuloma formation [119]. Stem cell transplantation can cure CGD, indicating that stem cells are the appropriate target for gene therapy [120–124]. Preclinical work demonstrated that normal oxidase-positive neutrophils differentiate from CGD stem cells transduced with retroviral vectors encoding the corrective normal oxidase subunit cDNA [125–127].

Based on this work, investigators at the National Institutes of Health have undertaken a number of clinical gene transfer studies to treat CGD. However, unlike the two diseases discussed previously, there is no proliferative advantage conferred upon the corrected cells. The first study targeted CGD patients with deficiency of the p47phox subunit [8]. The p47phox cDNA was cloned into the MoMLV-based MFGS retrovirus vector and this vector was packaged by the murine crip amphotropic packaging cell line. Mobilized PBSC were apheresed from patients after treatment with G-CSF followed by CD34 enrichment using an immuno-paramagnetic bead-selection device. Retroviral transduction of the PBSC was performed in serum-free media for 6h in the presence of hematopoietic cytokines for 3 consecutive days. The transduced PBSC were then transfused into the patient without marrow conditioning. *Ex vivo* transduction efficiency was determined by several methods, including quantitative assessment of oxidase-positive (Nitroblue tetrazolium dye test) myeloid colonies as well as determination of vector copy number using Southern blot hybridization. The percent of oxidase-positive colonies ranged from 9% to 29%. This was closely correlated with the vector copy number of 0.05 to 0.18 (equivalent to 5%–18% of cells, assuming a copy number of one per transduced cell) found in transduced and cultured PBSC. Following intravenous infusion of these transduced autologous CD34 cells into patients, it was possible to demonstrate the appearance of oxidase-normal neutrophils in the peripheral blood as assessed using a highly sensitive flow

cytometry assay based on the increased fluorescence of dihydrorhodamine-123 oxidized by hydrogen peroxide [128]. Oxidase-normal neutrophils first appeared 2 weeks after transplantation and peak correction occurred after 3–6 weeks. The frequency of corrected neutrophils ranged from 0.004% to 0.05% though it is important to note that the oxidase activity in these rare gene-corrected neutrophils was equivalent to that seen in oxidase-normal neutrophils from healthy individuals.

The NIH investigators then performed a follow-up study that targeted CGD patients with the X-linked form of CGD caused by mutations in the transmembrane gp91phox subunit. All five patients enrolled in this trial had the gp91phox null form of X-linked CGD and had previously received allogeneic normal granulocytes as treatment for severe infection. A high-titer MFGS-gp91phox retroviral vector was prepared using the human-derived 293 (8) amphotropic envelope packaging cell line. The mobilized selected CD34-positive PBSC were exposed to retroviral supernatant in gas-permeable flexible plastic bag containers, which were coated with a clinical-grade preparation of the CH-296 fibronectin fragment (RetroNectin). As in the first trial, cells were then infused into the patient without marrow conditioning. Two or three cycles of gene therapy were administered at approximately 50-day intervals. *Ex vivo* transduction efficiency was assessed by flow cytometry using an anti-gp91 monoclonal antibody as well as by nitroblue tetrazolium dye testing for oxidase-positive colonies. Seventy-five percent to 85% of CD34 + CD38-, Lin-, HLA DR-cells were positive for the gp91 as detected by flow cytometry after 7 days of *in vitro* culture. In the case of myeloid CFUs, 50% were found to be oxidase-positive. Gene-corrected neutrophils were detected in three of the five patients beginning 2–3 weeks following the infusion of cells. One patient peaked at almost 0.15% oxidase-positive neutrophils. Similar peaks of corrected neutrophils were seen after each cycle, but the size of the peak correlated with the dose of gene-corrected cells that were infused. Gene-corrected cells gradually disappeared from the peripheral circulation approximately 3–6 months after the last cycle. In one patient, corrected neutrophils were recovered from the pus of a liver abscess that predated the time of enrollment in the study (gene therapy was administered partly in the hope for benefit in treating this infection). The inability to detect corrected neutrophils in two of the five patients may be a result of immune-mediated elimination of gene-corrected cells in this protein-null, inherited disorder as the therapeutic gene product might have been perceived by the patient immune system as a neoantigen.

In 2004, a group in Germany began a study using an SFFV based vector for transduction of G-CSF mobilized PBSC for patients with CGD and the results from two patients were published in 2006 [10]. Similar to the studies for ADA-SCID, the patients also received busulfan conditioning prior to the stem cell infusion this time at a dose of 8 mg/kg given as divided doses over 2 days. As noted, the vector used was an SFFV vector containing the GP91 transgene. The bulk transduction efficiency in the *ex vivo* culture was 39.5%–45.2%

and the number of cells infused ranged from 3.6 to 5.1×10^6 CD34s/kg. Of note is that there was resolution of underlying infections existing in both patients at the time of gene therapy. Early after gene therapy, 15% to 20% of circulating neutrophils were gene-marked and oxidase positive, but gene marking increased to greater than 40% and 60% in each patient, respectively, after 6 months. However, the majority of gene marking in both patients was due to contribution from only a few clones and was limited to the myeloid lineage. Analysis of the different insertion sites showed a predilection for the transgene to insert into myeloid-promoting genes, specifically SETBP1, PRDM16, and MDS/EVII. Despite the high levels of gene marking seen, the expression of the therapeutic transgene protein was limited, resulting in only 14% and 30%, respectively, of normal levels oxidase production per oxidase positive neutrophil. As recently communicated by these investigators at several international meetings, by 2 years after gene therapy, the high level of gene marking that persisted had become dominated by one or a few clones producing neutrophils that appear to have lost or very significantly diminished oxidase activity. More recently these investigators noted that both of their reported patients may have had the slow emergence of a clone of myeloid cells manifesting monosomy 7. One patient has succumbed to a severe infection, while the other patient appears to be stable. A third patient has also been treated and has not appeared to have this same clonal outgrowth noted in the first two published patients, but the marking is also significantly lower at less than 1% to date.

The investigators at NIH have also undertaken a new study using a nonmyeloablative conditioning regimen consisting of busulfan 10 mg/kg in divided doses over 2 days prior to gene therapy. Enrolling only patients who have an underlying infection unresponsive to conventional therapy and who also do not have an HLA-matched healthy sibling who could serve as a stem cell donor for transplant, the aim of the trial is to use gene therapy as a treatment for the infection. Other than the addition of nonmyeloablative busulfan conditioning, this new clinical trial remains very similar to the previously described NIH study, including using the exactly same amphotropic MFGS-gp91phox vector for the transduction. The RetroNectin-coated gas permeable bags with serum-free medium is used for transduction in the presence of SCF, Flt-3 ligand, TPO, and low-dose IL-3 as growth factors. This resulted in 73% bulk transduction in the *ex vivo* culture after 4 days of transduction of the first patient's PBSC. To date, the first patient treated has had early appearance of almost 24% oxidase-corrected neutrophils in peripheral blood. This slowly decreased over the first 6 months, stabilizing at about 1% of circulating neutrophils that were oxidase normal between 6 and 10 months post gene therapy. Thus, using the same vector and similar methods of transduction, the use of busulfan conditioning resulted in a 10- to 100-fold improvement from the prior trials. Most important is that there was clinical cure of a massive liver abscess that had previously been unresponsive to conventional therapy. In addition, throughout the follow-up period, the oxidase activity per gene-corrected cell remained equivalent to the fully normal level of oxidase activity

seen in neutrophils from a healthy donor. Neither oligoclonality of gene marking, nor outgrowth of gene marked clones, nor predilection for vector insertion in particular genes has been observed to date in follow-up.

33.4.1.5 Multidrug Resistance Gene Transfer

Some of the other chapters in this volume will discuss in great detail the use of certain mammalian genes that confer resistance that allowed for *in vivo* selective enhancement of gene marking. So this topic will not be discussed in detail in this chapter. However, the MDR1 gene as a selective marker is one of the first mammalian genes tried for this purpose and serves as a model for this concept and is not discussed in great detail elsewhere in this volume. Therefore, it will be reviewed here. The MDR1 gene encodes a drug efflux pump called P-glycoprotein (reviewed in Refs. [129–131]). This pump confers resistance to a variety of anticancer agents including doxorubicin, mitoxantrone, vincristine, etoposide, and taxol. MDR1 can be used as both a therapeutic gene and as a selectable marker for other therapeutic genes [132].

In most cases, myelosuppression is the dose-limiting toxicity of chemotherapeutic agents used to treat cancer. Therefore, if the transfer of MDR1 into HSC is able to attenuate myelosuppression, higher and potentially more effective doses of chemotherapy could be delivered safely to the patient. Proof of this principle was provided in transgenic mice engineered to constitutively express MDR1 [133]. These mice could tolerate several-fold higher doses of taxol and daunomycin than their wild-type counterparts [134,135]. A similar effect has been demonstrated using retroviral gene transfer of MDR1 into HSC [136–138].

Results from the early studies were severely compromised by low levels of *ex vivo* transduction of HSCs, a low transplanted dose of transduced HSCs, and by the advanced stage of the cancer patients who were treated [19,20]. Subsequent studies were notable for the fact that they provided evidence that in a few select patients, engrafted MDR1-transduced HSCs could reduce the intensity of the neutrophil nadir following high-dose chemotherapy and that repeated cycles of chemotherapy provided them with a selective advantage [17,18,139]. The most notable MDR1 clinical trial came from Abonour et al. [17]. The transgene vector consisted of an HMSV backbone packaged in the AM12 amphotropic packaging cell line. Autologous peripheral blood CD34 cells were transduced on dishes coated with the fibronectin derivative CH-296 in media containing fetal calf serum and cytokines (SCF and IL6 or G-CSF/mega-karyocyte growth and development factor [MGDF]/SCF) and infused into the patient following conditioning with VP16 and carboplatin. Transgenes containing peripheral blood cells were detected by quantitative real-time PCR in seven of 12 patients, with one patient as high as 5.6% 2 weeks following the transplant. No definitive evidence of hematopoietic chemoprotection was demonstrated when the gene therapy patients were treated with further chemotherapy. However, there was an increase in the percentage of transgene-containing cells in six patients following

additional chemotherapy, suggesting a selective advantage for these cells. Importantly, no unexpected adverse events occurred in the study participants. Safety issues regarding the use of MDR1 as a selectable marker have been brought into question by a recent study that demonstrates development of a myeloproliferative syndrome in mice transplanted with MDR1-transduced cells. However, here the transplanted cells had been subjected to prolonged *ex vivo* culture [140]. Further studies in large animal models are needed to confirm this possible toxicity. In addition to MDR1, other promising selectable mammalian genes that can be used for *in vivo* selection include mutant versions of dihydrofolate reductase and the 6-*O*-benzylguanine resistant P140K mutant of the DNA alkylation repair enzyme methylguanine methyltransferase (MGMT). As noted, the latter selective marker has attracted much recent interest and features in two ongoing clinical trials as will be discussed in Chapter 26.

33.4.1.6 Fanconi Anemia

Fanconi anemia (FA) is an autosomal recessive disorder manifested by aplastic anemia, physical malformations, and cancer susceptibility [141]. Eight separate genotypic groups of FA have been described (FA-A through FA-H) [142]. Cells carrying the FA mutation are hypersensitive to DNA-damaging agents such as mitomycin C [143]. Since stem cell transplantation successfully treats the hematological manifestations of FA [144,145], it is a logical candidate for stem cell gene therapy. In addition, there is evidence to suggest that normal stem cells may have a selective growth advantage over HSCs with the mutated FA gene [146]. After demonstrating *in vitro* that HSCs from patients with the FA group C (FAC), gene mutation could be functionally corrected by retroviral gene transfer of the normal FAC gene, Liu et al. initiated a clinical trial [147]. Three children and one adult with the FAC mutation were treated with sequential cycles of autologous, G-CSF-mobilized CD34 selected progenitor cells that were transduced with an MoMLV-based retroviral vector containing the cDNA for FAC and neomycin resistance. The cells were transduced in the presence of hematopoietic cytokines IL-3, IL-6, and SCF for 72 h and returned to the patients without cytotoxic bone marrow conditioning. The cell dose for patients 1 and 2 was extremely low due to poor CD34 cell mobilization in response to G-CSF. FAC vector sequence was detected by PCR in the peripheral blood and bone marrow of all three patients at levels that ranged from 0.01% to 3%. Multilineage, peripheral blood marking was detected in one patient for a 16-month period during which the patient received four cycles of gene transfer. The other patients had only transient bone marrow and peripheral blood positivity despite repeated cycles of gene therapy. Bone marrow sampling of each patient following the infusion of gene-corrected cells revealed an increase in the number of colonies resistant to the DNA-damaging effects of mitomycin C. Radiation therapy delivered to patient 4 approximately 50 days following gene therapy for treatment of squamous cell carcinoma of the vulva resulted in detection, for the first time, of gene-marked cells in the

peripheral blood. These gene-corrected cells were undetectable prior to radiation therapy, suggesting that they were afforded a selective advantage by the radiation treatments [148]. A large animal study using the same vector design as that used for the clinical study was also performed. The animals underwent low-dose radiation prior to infusion of the genetically modified cells, but were otherwise hematologically normal. In this setting, the modified cell did not have a selective advantage but the marking levels, while low, were detectable for greater than 1 year, suggesting that again as in the ADA-SCID trial, with low-dose conditioning and the selective advantage of corrected cells in the setting of abnormal cells, gene therapy may be more efficacious [149].

33.4.1.7 Gaucher's Disease

Gaucher's disease is an autosomal recessive disorder that results in a deficiency of the lysosomal enzyme glucocerebrosidase [150]. This leads to the accumulation of glucosylcerebroside in macrophages throughout the reticular endothelial system. Although the clinical course is quite variable, most patients develop hepatosplenomegaly and painful, lytic, bone lesions. Conventional treatment includes stem cell transplantation or glucocerebrosidase supplementation. Dunbar et al. published the first clinical gene therapy trial for Gaucher's disease [21]. Three patients received CD34-selected bone marrow or mobilized PB transduced on autologous stroma/cytokines with a retroviral vector containing the human glucocerebrosidase cDNA. Transduction efficiencies were low, ranging from 1% to 10% using a semiquantitative PCR assay. Transgene was detected in peripheral blood mononuclear cells (0.02%) for 3 months in the patient whose cells were transduced with the highest efficiency.

33.4.1.8 Wiskott–Aldrich Syndrome

Wiskott–Aldrich syndrome is a primary immunodeficiency characterized by recurrent sinobacterial infections, autoimmunity typically manifesting as eczema and thrombocytopenia with dysfunctional platelets. The spectrum of the disease is variable, but the majority of patients have thrombocytopenia and varying levels of immunocompromise. The WASP protein is a cytoskeletal protein found on all hematopoietic cells and necessary for actin polymerization. As it can be cured with allogeneic transplantation, WA is also a good candidate for gene therapy. Two patients have been reportedly treated using transduced HSCs; however as with many other gene therapies, the levels of marking have been low as the cells were infused without any prior bone marrow conditioning. A number of other trials are being planned internationally, and most are now designed to include some form of conditioning.

33.4.1.9 Human Immunodeficiency Virus

HSC and mature T-lymphocytes are targets for anti-HIV gene therapy. Strategies include transfer of gene-encoding

ribozyme, which target the viral RNA genome, RNA decoys, and mutant transactivator genes that interfere with viral gene expression [38,151–153]. These approaches, along with a review of the clinical trials, are discussed in Chapter 41.

33.4.1.10 Summary

Techniques for gene transfer to HSC have advanced to the point where definitive clinical benefit has been achieved by *ex vivo* HSC gene therapy in ADA-SCID, X-CID, and X-linked CGD. Sustained engraftment of transduced HSC whose progeny do not have a selective advantage is best demonstrated in the gene transfer studies where cytotoxic bone marrow conditioning was administered prior to the transplant [3,4,6,11]. Besides reducing the number of resident naive stem cells, marrow conditioning results in a bone marrow microenvironment that is more conducive for engraftment of transduced HSC. Improvement in retroviral transduction conditions that utilize cytokines such as SCF, FLT-3 ligand, TPO, and limited concentration of IL-3 have resulted in impressive rates of HSC gene transfer in myeloablated nonhuman primates [86,104] and in the human clinical trials of gene therapy for ADA-SCID, X-SCID, and X-CGD discussed above. Alternative vectors such as those derived from lentivirus hold considerable promise for improvements in future HSC-gene-transfer strategies, assuming that their safety can be maximized and production issues can be resolved. Given the newly described cases of insertional mutagenesis that has complicated one of the X-SCID trials and the insertion-mediated outgrowth of myeloid cells seen in one of the X-CGD trials, the risk versus benefit of gene therapy will need to be reevaluated for each candidate stem cell disorder and for different vector systems and transduction conditions.

33.4.2 LYMPHOCYTE GENE TRANSFER STUDIES

33.4.2.1 Gene Marking Studies

The first clinical gene therapy trial involved gene transfer into lymphocytes and was undertaken in the late 1980s as a means of characterizing tumor-infiltrating lymphocytes (TIL) [1]. TIL were isolated from tumors of patients with metastatic melanoma. These cells were expanded and then transduced with a retroviral vector containing the neomycin resistance gene. Following reinfusion, the marker gene was used to track the migration of the marked lymphocytes. TIL were consistently found in the peripheral blood as well as tumor deposits for up to 2 months. A similar approach was employed to study the persistence of Epstein–Barr virus (EBV)-specific cytotoxic T-lymphocytes (CTL) generated *ex vivo* and infused as treatment of post bone marrow transplant EBV-related lymphoproliferation [30,31]. EBV-specific CTLs marked with a neomycin-resistance vector were detectable in the peripheral circulation for 10 weeks postinfusion.

33.4.2.2 ADA Deficiency

Blaese et al. were the first to use a therapeutic gene in a retroviral gene transfer trial for ADA-deficient SCID patients [32]. Two patients with an incomplete response to PEG-ADA therapy were infused with T-lymphocytes transduced with an MoMLV-based retroviral vector containing the cDNA coding for ADA. The transduction efficiency of lymphocytes prior to infusion ranged from 0.1% to 10%. Patients were treated with multiple cycles of transduced T-cells over a period of 1–2 years. Gene-corrected cells were detected in circulation for 2 years following the final cycle of gene therapy, demonstrating a T-lymphocyte lifespan much longer than what was predicted. There was clear-cut evidence of improved cellular and humoral immune response following gene therapy in one of the two patients treated. This discrepancy in patient response was attributed to superior *ex vivo* transduction efficiency obtained in the responding patient. No toxicity was attributed to the conduct of the protocol. Using the identical experimental design and retroviral vector, Onodera et al. accomplished similar results in one patient treated in Japan [117]. These studies, in conjunction with the previously described Bordignon study [12], demonstrate the potential of lymphocyte-based gene therapy to provide prolonged clinical benefit.

33.4.2.3 Suicide Gene Transfer

The use of herpes simplex virus thymidine kinase (HSV-TK) gene and other “suicide” genes for gene therapy is discussed for the phosphorylation of nucleoside analogs such as ganciclovir. Once phosphorylated, ganciclovir becomes toxic to the cell as it is incorporated into DNA. There are three published hematopoietic cell gene therapy trials utilizing the HSV-TK. Lymphocytes were the target cells in these studies [33–35]. In an attempt to make HIV therapy with autologous cytotoxic T-cells safer, Riddell et al. transduced HIV-specific cytotoxic T-cells with the HSV-TK gene [33,34]. The transduced cells could then be eliminated with ganciclovir treatment if toxicity were to arise from their presence. The vector used to transduce the lymphocytes also carried the hygromycin phosphotransferase gene. Unexpectedly, the transduced lymphocytes were rejected by a brisk host CTL response against the transduced cells and thus efficacy could not be assessed.

In allogeneic bone marrow transplantation, lymphocytes taken from the bone marrow donor are often infused into the recipient to treat tumor relapse via the graft versus tumor effect, or to aid in immune reconstitution. Significant toxicity may arise if transplanted lymphocytes mount an immunological attack against the recipient (graft vs. host disease). As in the Riddell study, Bonini et al. studied HSV-TK-transduced donor lymphocyte infusions as a method of protecting against GVHD [33]. The vector used for transduction also carried the marker gene that coded for a truncated form of the human low-affinity receptor for nerve growth factor as well as the neomycin resistance gene. Gene-marked lymphocytes were

detected in seven of eight patients available for analysis with a range of 0.01% to 13.4% of the total circulating lymphocytes. Three of the patients developed GVHD and were treated with ganciclovir. The percent of genetically modified lymphocytes decreased dramatically with complete resolution of GVHD in two of the three patients. Partial resolution of GVHD occurred in the other. While there was no evidence of an immune-mediated elimination of the transduced cells, these bone marrow transplant patients were likely immunocompromised even more profoundly than the HIV patients studied by Riddell et al. Using a similar strategy, Tiberghien et al. infused donor lymphocytes transduced with an MoMuLV-derived retroviral vector carrying the genes for HSV-TK and neomycin resistance into recipients of a T-cell-depleted allogeneic stem cell transplantation [35]. Of the 12 patients treated, four developed clinically significant GVHD, prompting ganciclovir administration. Ganciclovir administration resulted in resolution of GVHD in three of the four patients and, as in the earlier study, correlated with a drop in the number of gene-marked lymphocytes.

33.4.2.4 Cancer Therapy

A number of investigators have been engineering lymphocytes and other immune system targets to more effectively target cancers. A common technique is to transduce dendritic cells to express tumor antigens and thereby expand *ex vivo* reactive T cells for infusion into the patient. (This is a technique that is also being used to generate virus specific T cells, as discussed further in Chapters 36 and 47.) Other groups have modified the T cells themselves. Morgan et al. treated 17 patients with treatment refractory melanoma using an HLA A*0201 TCR receptor specific for the MART-1 antigen. Peripheral blood lymphocytes were transduced with genes encoding the alpha and beta chains of the anti-Mart-1 TCR using a retroviral vector. The initial three patients had less than 2% positive cells 50 days postinfusion. As a result, the next 10 patients, including one patient from the first cohort, were treated with cells cultured for a shorter period of time. Here >9% positive cells were detectable 1 and 4 weeks posttreatment. For the third cohort of four patients, the cells underwent a second expansion to increase the cell dose. All patients received lympho-depleting chemotherapy with fludarabine prior to the infusion of cells. Two patients, one from the second cohort and the other from the third, had a clinical response with complete regression of tumor [39].

33.5 CONCLUSION

To date, all published clinical trials involving transduction of hematopoietic cells have utilized murine-based retroviral vectors. When lymphocytes are the target cell, modest clinical benefit was observed in both the ADA and HSV-TK trials. This is attributable to the relatively high level of transduction efficiency using the latest techniques. Though clinical applicability

of HSC gene transfer is much broader than for lymphocytes, long-term repopulating HSCs are less receptive to retroviral-based gene transfer. While alternate vectors such as lentivirus and adeno-associated viral vectors are promising, a number of studies have proven that the retroviral vector can successfully target the long term repopulating cell, albeit with an extremely low efficiency. To improve the ability to transduce HSC, further knowledge of stem cell biology such as their cell cycle characteristics, their trigger for self-replication versus lineage commitment, and the optimal *ex vivo* growth conditions will aid in the ability to transduce these cells. The production of high-titer, replication-defective, retroviral supernatant is another technique that must be perfected. It is unclear to what extent host immune rejection of cells expressing the transgene will hinder progress of gene therapy for protein-null disorders or disorders where a heterologous gene product is produced.

And finally, it is becoming clear that some degree of cyto-reductive bone marrow conditioning will be necessary to achieve clinically significant levels of HSC gene transfer.

34.1 INTRODUCTION

Gene therapy is a novel therapeutic branch of modern medicine. Its emergence is a direct consequence of the revolution heralded by the introduction of recombinant DNA methodology in the 1970s. Gene therapy is still highly experimental, but has the potential to become an important treatment regimen. In principle, it allows the transfer of genetic information into patient tissues and organs. Consequently, diseased genes can be eliminated or their normal functions rescued. Furthermore, the procedure allows the addition of new functions to cells, such as the production of immune system mediator proteins that help to combat cancer and other diseases.

Originally, monogenic inherited diseases (inherited single gene defects), such as cystic fibrosis, were considered primary targets for gene therapy. For instance, in pioneering studies, the correction of adenosine deaminase deficiency, a lymphocyte-associated severe combined immunodeficiency (SCID), was attempted (Mullen et al., 1996). Although no modulation of immune function was observed, data from this study, together with other early clinical trials, demonstrated the potential feasibility of gene transfer approaches as effective therapeutic strategies. The first successful clinical trials using gene therapy to treat a monogenic disorder involved a different type of SCID, caused by mutation of an X chromosome-linked lymphocyte growth factor receptor (Hacein-Bey-Abina et al., 2002). While the positive therapeutic outcome was celebrated as a breakthrough for gene therapy, a serious drawback subsequently became evident. By February 2005, 3 children out of 17 who had been successfully treated for X-linked SCID developed leukemia because the vector inserted near an oncogene (a cancer-causing gene) inadvertently

caused it to be inappropriately expressed in the genetically engineered lymphocyte target cell (Hacein-Bey-Abina et al., 2003a,b). On a more positive note, a small number of patients with adenosine deaminase-deficient SCID have been successfully treated by gene therapy without any adverse side effects (Aiuti et al., 2002).

A minority of more recent gene therapy clinical trials, however, are concerned with monogenic disorders. Out of the 1000 or so recorded clinical trials (January 2005), less than 10% target these diseases (Figure 34.1). The majority of current clinical trials focus on polygenic diseases, particularly cancer (66% of all trials).

Gene therapy relies on similar principles as traditional pharmacological therapy; specifically, regional specificity for the targeted tissue, specificity of the introduced gene function in relation to disease, and stability and controllability of expression of the introduced gene. To integrate all these aspects into a successful therapy is an exceedingly complex process that requires expertise from many disciplines, including molecular and cell biology, genetics, and virology, in addition to bioprocess manufacturing capability and clinical laboratory infrastructure.

34.2 TWO PATHS TO GENE THERAPY

Gene therapy can be performed either by direct transfer of genes into the patient or by using living cells as vehicles to transport the genes of interest. Both modes have certain advantages and disadvantages.

On the one hand, direct gene transfer is particularly attractive because of its relative simplicity. In this scenario, genes are directly delivered into a patient’s tissues or bloodstream by

The Journal of Gene Medicine, © 2005 John Wiley & Sons Ltd www.wiley.co.uk/genmed/clinical

FIGURE 34.1 (See color insert following blank page 206.) Percentage of diseases targeted by clinical gene therapy trials. (<http://www.wiley.co.uk/genmed/clinical/>)

packaging into liposomes (spherical vessels made up of the molecules that form the membranes of cells) or other biological microparticles. Alternatively, the genes are packaged into genetically engineered viruses, such as retroviruses or adenoviruses. Because of biosafety concerns, the viruses are typically altered so that they are not toxic or infectious (i.e., they are replication incompetent). These basic tools of gene therapists have been extensively optimized over the past 10 years. Their biggest strength, simplicity, however, is simultaneously their biggest weakness. In many cases, direct gene transfer does not allow very sophisticated control over the therapeutic gene. This is because the transferred gene either randomly integrates into the patient's chromosomes or persists unintegrated for a relatively short period of time in the targeted tissue. Additionally, the targeted organ or tissue is not always easily accessible for direct application of the therapeutic gene.

On the other hand, therapeutic genes can be delivered using living cells. This procedure is relatively complex in comparison to direct gene transfer and can be divided into three major steps. In the first step, cells from the patient or other sources are isolated and propagated in the laboratory. Secondly, the therapeutic gene is introduced into these cells, applying methods similar to those used in direct gene transfer. Finally, the genetically modified cells are returned to the patient. The use of cells as gene transfer vehicles has certain advantages. In the laboratory dish (*in vitro*), cells can be manipulated much more precisely than in the body (*in vivo*). Some of the cell types that continue to divide under laboratory conditions may be expanded significantly before reintroduction into the patient. Moreover, some cell types are able to localize to particular regions of the human body, such as hematopoietic (blood-forming) stem cells, which return to the bone marrow. This "homing" phenomenon may be useful for applying the therapeutic gene with regional specificity. A major disadvantage is the additional biological complexity brought into systems by living cells. Isolation of a specific cell type requires not only extensive knowledge of biological markers, but also insight into the requirements for that cell type to

stay alive *in vitro* and continue to divide. Unfortunately, specific biological markers are not known for many cell types, and the majority of normal human cells cannot be maintained for long periods of time *in vitro* without acquiring deleterious mutations.

34.3 STEM CELLS AS VEHICLES FOR GENE THERAPY

Stem cells can be classified as embryonic or adult, depending on their tissue of origin. The role of adult stem cells is to sustain an established repertoire of mature cell types in essentially steady-state numbers over the lifetime of the organism. Although adult tissues with a high turnover rate, such as blood, skin, and intestinal epithelium, are maintained by tissue-specific stem cells, the stem cells themselves rarely divide. However, in certain situations such as during tissue repair after injury or following transplantation, stem cell divisions can become more frequent.

The prototypic example of adult stem cells, the hematopoietic stem cell, has already been demonstrated to be of utility in gene therapy (Aiuti et al., 2002; Hacein-Bey-Abina et al., 2002). Although they are relatively rare in the human body, they can be readily isolated from bone marrow or after mobilization into peripheral blood. Specific surface markers allow the identification and enrichment of hematopoietic stem cells from a mixed population of bone marrow or peripheral blood cells. After *in vitro* manipulation, these cells can be transplanted back into patients by injection into the bloodstream, where they travel automatically to their place in the bone marrow in which they are functionally active. Hematopoietic stem cells that are explanted, *in vitro* manipulated, and re-transplanted into the same patient (autologous transplantation) or a different patient (allogeneic transplantation) retain the ability to contribute to all mature blood cell types of the recipient for an extended period of time (when patients' cells are temporarily grown "outside the body" before being returned to them, the *in vitro* process is typically referred to as an *ex vivo* approach).

Another adult bone marrow-derived stem cell type with potential use as a vehicle for gene transfer is the mesenchymal stem cell that has the ability to form cartilage, bone, adipose (fat) tissue, and marrow stroma (the bone marrow microenvironment) (Gregory et al., 2005). Recently, a related stem cell type, the multipotent adult progenitor cell, has been isolated from bone marrow that can differentiate into multiple lineages, including neurons, hepatocytes (liver cells), endothelial cells (such as the cells that form the lining of blood vessels), and other cell types (Jiang et al., 2002). Other adult stem cells have been identified, such as those in the central nervous system and heart, but these are less well characterized and not as easily accessible (Stocum, 2005).

The traditional way to introduce a therapeutic gene into hematopoietic stem cells from bone marrow or peripheral blood involves the use of a vector derived from a certain class of virus called the retrovirus. One type of retroviral vector

was initially employed to show proof-of-principle that a foreign gene (in that instance the gene was not therapeutic, but was used as a molecular tag to genetically mark the cells) introduced into bone marrow cells may be stably maintained for several months (Brenner et al., 1993). These particular retroviral vectors are only capable of transferring the therapeutic gene into actively dividing cells. Since most adult stem cells divide at a relatively slow rate, efficiency was rather low. Vectors derived from other types of retroviruses (the so-called lentiviruses) and adenoviruses have the potential to overcome this limitation, since they target nondividing cells as well. The major drawback of these methods is that the therapeutic gene frequently integrates more or less randomly into the chromosomes of the target cell. In principle, this is dangerous, because the gene therapy vector can potentially modify the activity of neighboring genes (positively or negatively) in close proximity to the insertion site or even inactivate host genes by integrating into them, a phenomenon referred to as "insertional mutagenesis." In extreme cases, like in the X-linked SCID gene therapy trials, these mutations contribute to the malignant transformation of the targeted cells, ultimately resulting in cancer.

Another major limitation of using adult stem cells is that it is still relatively difficult to maintain their stem cell state during *ex vivo* manipulations. Under current suboptimal conditions, adult stem cells tend to become more specialized giving rise to mature cell types through a process termed differentiation, concomitantly losing their stem cell properties. Recent advances in supportive culture conditions for mouse hematopoietic stem cells may ultimately facilitate more effective use of human hematopoietic stem cells in gene therapy applications (Reya et al., 2003; Willert et al., 2003).

34.4 EMBRYONIC STEM CELL: "THE ULTIMATE STEM CELL"

Embryonic stem cells are capable of unlimited self-renewal while maintaining the potential to differentiate into derivatives of all three germ layers. Even after months and years of growth in the laboratory, they retain the ability to form any cell type in the body. These properties reflect their origin from cells of the early embryo at a stage during which the cellular machinery is geared toward the rapid expansion and diversification of cell types.

Murine (mouse) embryonic stem cells were isolated over 20 years ago (Evans and Kaufman, 1981; Martin, 1981) and paved the way for the isolation of nonhuman primate and finally human embryonic stem cells (Thomson et al., 1998). Much of the anticipated potential surrounding human embryonic stem cells is an extrapolation from pioneering experiments in the mouse system. Experiments performed with human embryonic stem cells in the last couple of years indicate that these cells have the potential to make an important impact on medical science, at least in certain fields. In particular, this includes (a) differentiation of human embryonic stem cells into various cell types, such as neurons, cardiac,

vascular, hematopoietic, pancreatic, hepatic, and placental cells, (b) the derivation of new cell lines under alternative conditions, and (c) the establishment of protocols that allow the genetic modification of these cells.

34.5 POTENTIAL OF HUMAN EMBRYONIC STEM CELLS FOR GENE THERAPY

Due to their rapid growth, remarkable stability, ability to mature *in vitro* into multiple cell types of the body, and especially because after derivation, they are easily accessible for controlled and specific genetic manipulation, human embryonic stem cells are attractive potential tools for gene therapy. There are two possible scenarios whereby human embryonic stem cells may benefit the field of gene therapy.

One way is that human embryonic stem cells could be genetically manipulated to introduce the therapeutic gene. This gene may either be active or awaiting later activation once the modified embryonic stem cell has differentiated into the desired cell type. Recently published reports establish the feasibility of such an approach (Rideout et al., 2002). Skin cells from an immunodeficient mouse were used to generate cellular therapy that partially restored immune function in the mouse. In these experiments, embryonic stem cells were generated from an immunodeficient mouse by nuclear transfer technology. The nucleus of an egg cell was replaced with that from a skin cell of an adult mouse with the genetic immunodeficiency. The egg was developed to the blastula stage at which embryonic stem cells were derived. The genetic defect was corrected by a genetic modification strategy designated "gene targeting." These "cured" embryonic stem cells were differentiated into hematopoietic "stem" cells and transplanted into immunodeficient mice. Interestingly, the immune function in these animals was partially restored. In principle, this approach may be employed for treating human patients with immunodeficiency or other diseases correctable by cell transplantation. However, significant advances would need to be made: The levels of immune system reconstitution observed were quite modest (<1% normal) while the methodology employed to achieve hematopoietic engraftment, which involved using a more severely immunodeficient mouse as recipient (which also had the mouse equivalent of the human X-linked SCID mutation) and genetically engineering the hematopoietic engrafting cells with a potential oncogene prior to transplantation, would not be clinically feasible.

Embryonic stem cells may additionally be indirectly beneficial for cellular gene therapy. Since these cells can be differentiated *in vitro* into many cell types, including presumably tissue-specific stem cells, they may provide a constant *in vitro* source of cellular material. Such "adult" stem cells derived from embryonic stem cells may thus be utilized to optimize protocols for propagation and genetic manipulation techniques (Barberi et al., 2005). To acquire optimal cellular material from clinical samples in larger quantities for experimental and optimization purposes is usually rather difficult since access to these samples is limited.

34.6 GENETIC MANIPULATION OF STEM CELLS

The therapeutic gene needs to be introduced into the cell type used for therapy. Genes can be introduced into cells by transfection or transduction.

Transfection utilizes chemical or physical methods to introduce new genes into cells. Usually, small molecules, such as liposomes, as well as other cationic-lipid based particles are employed to facilitate the entry of DNA encoding the gene of interest into the cells. Brief electric shocks are additionally used to facilitate DNA entry into living cells. All these techniques have been applied to various stem cells, including human embryonic stem cells. However, the destiny of the introduced DNA is relatively poorly controlled using these procedures. In most cells, the DNA disappears after days or weeks, and in rare cases, integrates randomly into host chromosomal DNA. *In vitro* drug selection strategies allow the isolation and expansion of cells that are stably transfected, as long as they significantly express the newly introduced gene.

Transduction utilizes viral vectors for DNA transfer. Viruses, by nature, introduce DNA or RNA into cells very efficiently. Engineered viruses can be used to introduce almost any genetic information into cells. However, there are usually limitations in the size of the introduced gene. Additionally, some viruses (particularly retroviruses) only infect dividing cells effectively, whereas others (lentiviruses) do not require actively dividing cells. In most cases, the genetic information carried by the viral vector is stably integrated into the host cell genome (the total complement of chromosomes in the cell). An important parameter that has to be carefully monitored is this random integration into the host genome, since on the one hand, this process can induce mutations leading to malignant transformation or serious gene dysfunction, while on the other hand, several copies of the therapeutic gene integrated into the genome help to bypass positional effects and gene silencing. Positional effects are caused by certain areas within the genome and directly influence the activity of the introduced gene. Gene silencing refers to the phenomenon whereby over time, most artificially introduced active genes are turned off by the host cell, a mechanism that is not currently well understood. In these cases, integration of several copies may help to achieve stable gene expression, since a subset of the introduced genes may integrate into favorable sites. In the past, gene silencing and positional effects were a particular problem in mouse hematopoietic stem cells. These problems led to the optimization of retroviral and lentiviral vector systems, for example by addition of genetic control elements referred to as chromatin domain insulators and scaffold/matrix attachment regions into the vectors, resulting in more robust expression in differentiating cell systems, including human embryonic stem cells (Ma et al., 2003).

In some gene transfer systems, the foreign transgene does not integrate at a high rate and remains separate from the host genomic DNA, a status denoted "episomal." Specific proteins stabilizing these episomal DNA molecules have been identified

as well as viruses (adenovirus) that persist stably for some time in an episomal condition. Recently, episomal systems have been applied to embryonic stem cells (Aubert et al., 2002).

An elegant way to circumvent positional effects and gene silencing is to introduce the gene of interest specifically into a defined region of the genome by the gene targeting technique referred to previously (Kyba et al., 2002). The gene targeting technique takes advantage of a cellular DNA repair process known as homologous recombination (Smithies, 2001). Homologous recombination provides a precise mechanism for defined modifications of genomes in living cells and has been used extensively with mouse embryonic stem cells to investigate gene function and create mouse models of human diseases. Recombinant DNA is altered *in vitro* and the therapeutic gene is introduced into a copy of the genomic DNA that is targeted during this process. Next, recombinant DNA is introduced by transfection into the cell, where it recombines with the homologous part of the cell genome. This in turn results in the replacement of normal genomic DNA with recombinant DNA containing genetic modifications. Homologous recombination is a very rare event in cells, and thus a powerful selection strategy is necessary to identify the cells in which it occurs. Usually, the introduced construct has an additional gene coding for antibiotic resistance (referred to as a selectable marker), allowing cells that have incorporated the recombinant DNA to be positively selected in culture. However, antibiotic resistance only reveals that the cells have taken up recombinant DNA and incorporated it somewhere in the genome. To select for cells in which homologous recombination has occurred, the end of the recombination construct often includes the thymidine kinase gene from the herpes simplex virus. Cells that randomly incorporate recombinant DNA usually retain the entire DNA construct, including the herpes virus thymidine kinase gene. In cells displaying homologous recombination between the recombinant construct and cellular DNA, an exchange of homologous DNA sequences is involved and the nonhomologous thymidine kinase gene at the end of the construct is eliminated. Since cells expressing the thymidine kinase gene are killed by the antiviral drug (negative selection), ganciclovir, those undergoing homologous recombination are unique in that they are resistant to both the antibiotic and ganciclovir, allowing effective selection with these drugs (Figure 34.2).

Gene targeting by homologous recombination has recently been applied to human embryonic stem cells (Zwaka and Thomson, 2003). This is important for studying gene functions *in vitro* for lineage selection and marking. For therapeutic applications in transplantation medicine, the controlled modification of specific genes should be useful for purifying specific embryonic stem cell-derived, differentiated cell types from a mixed population, altering the antigenicity of embryonic stem cell derivatives and adding defined markers that allow the identification of transplanted cells. Additionally, since the therapeutic gene can now be introduced into defined regions of the human genome, controlled expression of the therapeutic gene should be possible. This also significantly reduces the risk of insertional mutagenesis.

FIGURE 34.2 Homologous recombination: endogenous locus is replaced by targeting vector.

34.7 FUTURE CHALLENGES FOR STEM CELL-BASED GENE THERAPY

Despite very promising scientific results with genetically modified stem cells, some major problems remain to be overcome. The more specific and extensive the genetic modification, the longer the stem cells have to remain *in vitro*. Although human embryonic stem cells in the culture dish remain remarkably stable, the cells could accumulate genetic and epigenetic changes that might be harmful to the patient (epigenetic changes regulate gene activity without altering the genetic blueprint of the cell). Indeed sporadic chromosomal abnormalities in human embryonic stem cell culture have been reported and these may occur more frequently when the cells are passaged as bulk populations, which reinforces the necessity to further optimize culture conditions, explore new human embryonic stem cell lines, and monitor the existing cell lines (Cowan et al., 2004; Draper et al., 2004; Mitalipova et al., 2005). Additionally undifferentiated embryonic stem cells have the potential to form a type of cancer called a teratocarcinoma. Safety precautions are therefore necessary, and currently, protocols are being developed to allow the complete depletion of any remaining undifferentiated embryonic stem cells (Gerecht-Nir and Itskovitz-Eldor, 2004). This may be achieved by rigorous purification of embryonic stem cell derivatives or introducing suicide genes that can be externally controlled.

Another issue is the patient's immune system response. Transgenic genes as well as vectors introducing these genes (such as those derived from viruses) potentially trigger immune system responses. If stem cells (for instance, human embryonic stem cells) are not autologous, they eventually cause immuno-rejection of the transplanted cell type. Strategies to circumvent these problems, such as the expression of immune system-modulating genes by stem cells, creation of chimeric, immunotolerable bone marrow or suppression of human leukocyte antigen (HLA) genes have been suggested (Gerecht-Nir and Itskovitz-Eldor, 2004).

The addition of human embryonic stem cells to the experimental gene therapy arsenal offers great promise in overcoming many of the existing problems of cellular-based gene therapy that have been encountered in clinic trials. Further research is essential to determine the full potential of both adult and embryonic stem cells in this exciting new field.

35.1 INTRODUCTION

The concept of gene therapy was introduced with great promise and high expectations. Manipulating gene expression to treat patients was novel and created the prospect to revolutionize clinical practice in genetic disorders as well as common ailments. For the last decade, the field of gene therapy has been transformed from treatments for rare monogenetic disorders to more complex polygenetic disorders. Despite advances in primary and secondary interventions, cardiovascular disease remains a major cause of morbidity and mortality in industrial countries, so successful gene therapy could have a profound impact.

The field of gene therapy has been rapidly evolving with a better understanding of pathophysiology and advances in gene delivery system. However, we should be aware of limitations of gene and cell therapy strategies, including technical issues and the development of more conventional treatments for the intended diseases. For example, vascular gene therapy to prevent postangioplasty restenosis, once an attractive gene therapy target, is no longer an issue because of development of drug-eluting vascular stents [1]. The possibility of cell therapy to

repair damaged heart muscle also has generated tremendous excitement. However, its clinical efficacy has not been as evident in large-scale randomized trials, perhaps due to our imperfect understanding of the biological process [2]. Careful evaluation of existing knowledge and diligence at integrating advances in the field may allow these therapies to become reality.

The topic of cardiovascular gene and cell therapy is broad. This chapter will review general strategies of gene and cell manipulation in the cardiovascular system and give an overview of potential gene therapy targets. It will also review examples of experimental gene therapy in animal and human trials.

35.2 GENETIC MANIPULATION OF CARDIOVASCULAR TISSUE

35.2.1 GENE AND CELL THERAPY STRATEGIES

35.2.1.1 Manipulation of Gene Expression

Gene therapy is a method that manipulates gene expression levels for the purpose of treating disease. This is achieved

through the introduction of therapeutic genetic materials (DNA or RNA) into cells in a process referred to as transduction or transfection. Transduction is the transfer of genetic information to a cell using a viral vector. Transfection is the uptake of genetic information by eukaryotic cells, often mediated by liposome–DNA or –RNA complexes. Gene transfer allows replacement of a missing gene product, augmentation of endogenous gene function, or interference with gene expression.

Gene replacement or augmentation involves the transfer of a gene that is missing from a cell, defective or underexpressed. The expressed protein may be active within the target cell or secreted to act in a paracrine, endocrine, or autocrine manner. Some proteins

require expression levels comparable to normal, while other gene products can function at lower levels to yield sufficient therapeutic results. In certain conditions, excessive expression of a therapeutic gene may unintentionally cause harmful effects.

In some cases, monogenic disease is caused by the expression of dominant negative mutant or excessive expression of a gene; in these cases, the gene requires silencing. There are four major strategies for gene silencing (Figure 35.1) [3]: (a) antisense oligodeoxynucleotides (ODNs), (b) catalytically active RNA ribozymes, (c) double-stranded small interfering RNAs (siRNA) that induce RNA degradation through RNA interference (RNAi), and (d) transcriptional decoys.

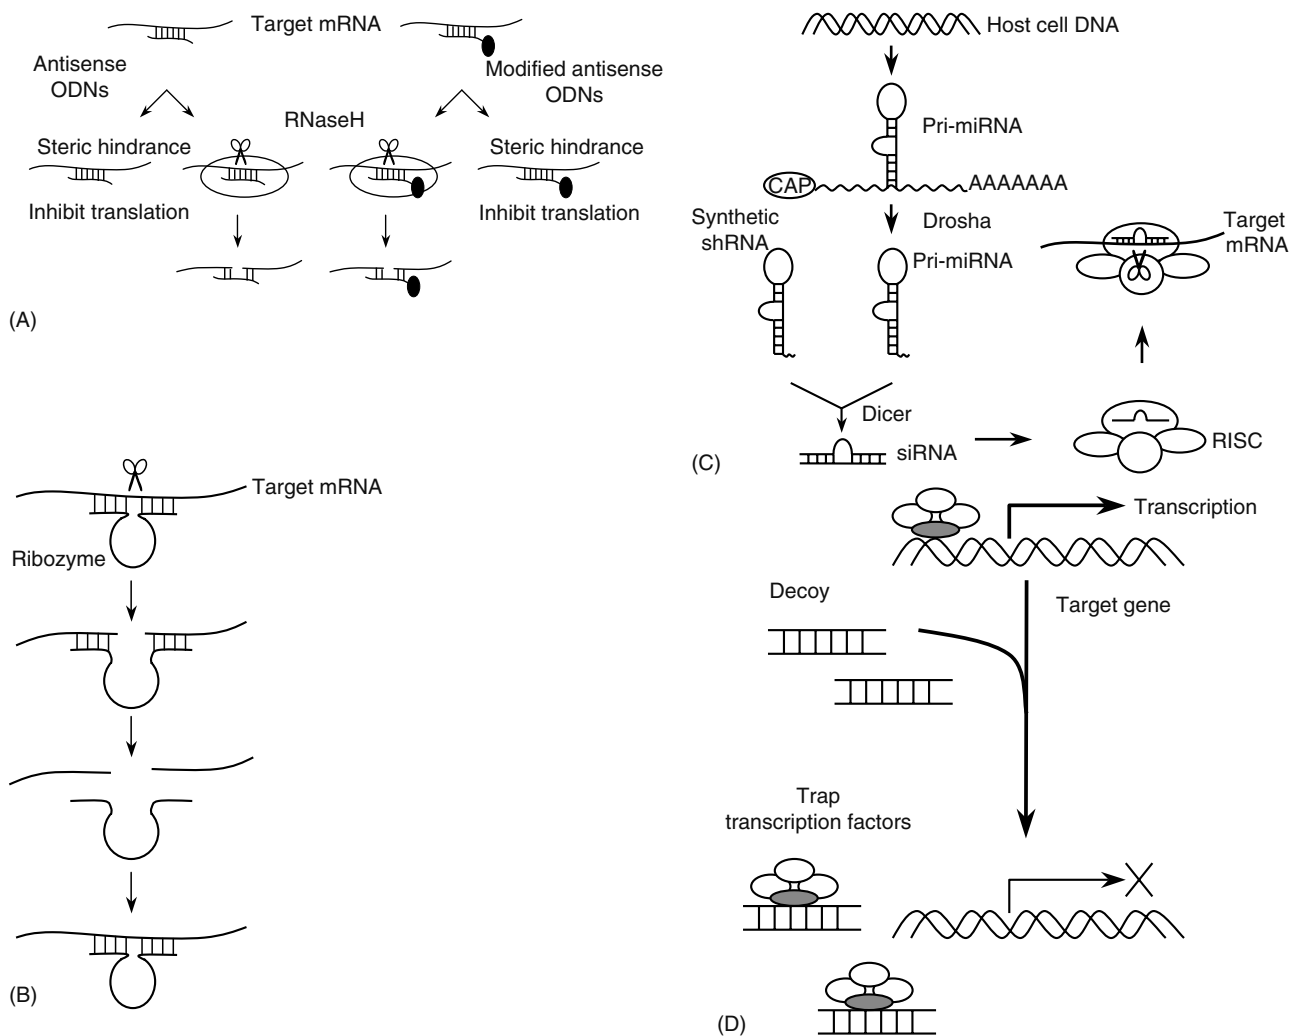

FIGURE 35.1 Strategies for gene silencing. There are four major categories for gene silencing. (A) Antisense ODNs are short single-stranded deoxynucleotides that have a base sequence complementary to a segment of target RNAs, which inhibit translation or recruit RNase H to cleave the target mRNA. Most ODNs are modified to enhance their stability. (B) Ribozymes are RNA with catalytic activity to cleave a target mRNA. Ribozymes bind the complementary target RNA through base-pairing. After cleaving the substrate, they release the cleaved products and are recycled like enzymes. (C) RNA interference (RNAi) is a naturally occurring gene regulatory mechanism. RNAi is mediated by short double-stranded RNA (dsRNA) termed small interfering RNA (siRNA) duplexes. These siRNA duplexes are generated by cleavage of long dsRNA or short hairpin RNA (shRNA) by Dicer. One strand of the siRNA duplex, referred to as the guide strand, is incorporated into a nuclease complex known as the RNA-induced silencing complex (RISC) while the second passenger strand is released and degraded. Upon incorporation into RISC, the siRNA guides the RISC to the complementary target mRNA for cleavage. MicroRNAs (miRNAs) are endogenous single-stranded noncoding RNAs. The primary transcripts of miRNAs, pri-miRNA, are transcribed from introns of protein-coding genes. The RNase Drosha processes the pri-miRNA to hairpin-shaped pre-miRNA. Pre-miRNA is exported to the cytoplasm where it is cleaved by Dicer. (D) Another strategy to interfere with gene transcription is a decoy for transcription factor. Decoys are double-stranded ODNs designed to mimic the chromosomal binding sites of transcription factors. They bind up the available transcription factors, which prevents the binding of transcription factor complexes to target genes and inhibit transcription.

1. *Antisense ODNs*. Antisense ODNs are short [15–20 nucleotides (nt) in length] single-stranded DNAs complementary to a target mRNA. Upon cellular uptake, the ODNs hybridize to the corresponding segment of mRNA to form a DNA–RNA duplex. Translation into protein is inhibited either by direct steric hindrance of ribosome translation machinery, interference with the splicing of pre-mRNA, or by recruiting RNase H to cleave the target mRNA. Major problems with antisense ODNs are their rapid degradation by ubiquitous DNase, the high dose required for a biological response, and the difficult delivery into target cells. Unmodified ODNs are degraded rapidly *in vivo*. Therapeutic ODNs are routinely modified to enhance their stability, mostly by chemical modification within their sugar phosphate backbone (i.e., phosphotioate, peptide nucleic acid, morpholino phosphoramidate and locked nucleic acid) [4].
2. *Ribozymes*. Certain RNA molecules catalyze RNA cleavage in the absence of protein cofactors. Ribozymes contain a catalytic region that cleaves other RNA molecules in a sequence-specific manner and an adjacent sequence conferring specificity. Hammerhead hairpin ribozymes are composed of small RNA of 40–160 nt in length complementary to target RNA through base-pairing. After cleaving the substrate, they release the cleaved products and are recycled, which allow cleavage of multiple substrates. Ribozymes can be administered to the patient either by vector mediated gene transfer or by direct injection of synthetic ribozymes. The limitations of this approach are variability in efficacy depending on the target cell [5].
3. *RNAi*. RNAi is an evolutionarily conserved gene regulatory mechanism. RNAi is mediated by 21–24 nt dsRNA having two nt 3' overhangs, termed short-interfering RNA (siRNA) duplexes. These siRNA duplexes can be generated by cleavage of long dsRNA or shRNA by the dsRNA-specific RNase III enzyme, Dicer. One strand of the siRNA duplex, referred to as the guide strand, is incorporated into a nuclease complex known as the RNA-induced silencing complex (RISC), while the second passenger strand is released and degraded. Upon incorporation into RISC, the siRNA guides the RISC to the complementary target sites within mRNA, which is cleaved by the RISC component, Argonaute2, leading to their degradation.

miRNAs are endogenous ~22 nt single-stranded noncoding RNAs, which appear to be functionally identical to siRNAs in mammalian cells. They are transcribed from introns of protein-coding genes. Since dsRNA occurs mostly in viruses, the RNAi pathway could have been evolved as a host defense against virus infection. Over the last years, RNAi has become the most widely used approach for gene knockdown due to its potency.

- The requirements for successful gene knockdown using siRNA are well known. These include methods of delivery, enhanced stability, minimization of off-target effects, and identification of effective sites in the target RNA. The Web sites for the design of siRNAs are available for free access to the public at <http://jura.wi.mit.edu/bioc/siRNAext/home.php> (Whitehead Institute) and http://www.ambion.com/techlib/misc/siRNA_finder.html (Ambion). However, the algorithms are not perfect and several target-specific siRNA sequences should be tested in cells. Synthetic siRNA or expressing plasmid DNAs can be transfected into cells using liposome. However, a more effective approach is to continuously express siRNA in the relevant cells using vectors derived from adenovirus (Ad), retrovirus (RV), or lentivirus (LV). The RNAi consortium (TRC) is a collaborative effort based at the Broad Institute of MIT and Harvard; it has created lentiviral shRNA libraries targeting 15,000 human and 15,000 mouse annotated genes. The shRNA for a specific gene can be searched by gene symbol, GenBank accession number, or clone ID, and be purchased through Open Biosystems at <http://www.openbiosystems.com/> or Sigma-Aldrich at <http://www.sigmaaldrich.com/>.
4. *Decoy*. An additional approach to gene regulation is the blockade of transcription factors. Transcription factors regulate gene expression by binding to chromosomal DNA at regulatory sequences or by forming transcription regulatory complexes; these interactions affect the activity of the RNA Polymerase II complex. Double-stranded ODNs are designed to mimic the chromosomal binding sites of these transcription factors and act as decoys that titrate the available transcription factors, preventing them from binding to target genes.

35.2.1.2 Cell-Based Therapy

Cell-based therapy refers to treatments using cells instead of DNA or RNA. The most well-known procedure is bone marrow transplantation (BMT). The interest for cell-based therapy for cardiovascular disease has increased tremendously in recent years since the demonstration of homing and incorporation of BM-derived endothelial progenitor cells (EPCs) into ischemic tissues [6] and regeneration of infarcted myocardium by transplanted BM cells [7,8]. The most widely used cell sources in clinical trials have been skeletal myoblasts, BM mononuclear cells, peripheral blood cells, and mesenchymal stem cells [9]. Other potential cells for this type of treatment include embryonic stem cells, stem cells in cord blood, and cardiac stem cells. These cells can be genetically modified prior to transplantation. The use of stem cells to generate replacement cells for damaged myocardium, vessels, and valves holds great promise for treatments of acute myocardial infarction (MI), restenosis, chronic heart failure, and other cardiovascular repairs.

35.2.2 GENE DELIVERY APPROACH

There are two approaches for how to deliver therapeutic genes (Figure 35.2). The *ex vivo* approach refers to manipulation of

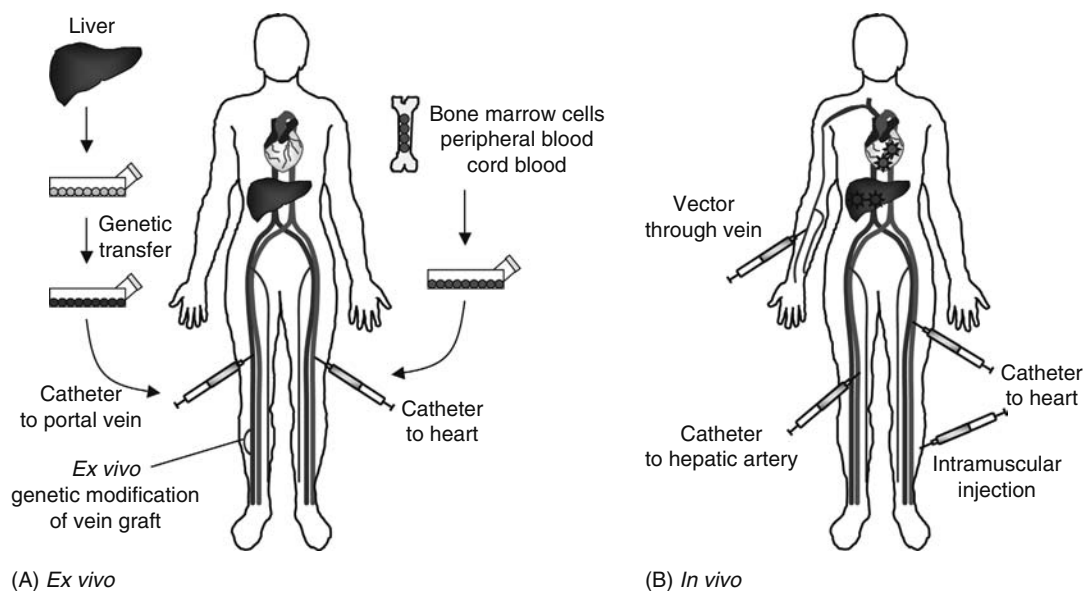

FIGURE 35.2 Gene and cell delivery approaches. (A) *Ex vivo* approach. In *ex vivo* approach, cells or tissues are isolated from the body and genetically modified *in vitro* before transplantation. Cells or tissues can be autologous (cells originated from the host) or be from donors. (B) *In vivo* approach. In this approach, gene transfer vectors are directly injected into the body.

cells or tissues outside of the body, where they can be genetically modified before transplantation. The advantage is that the gene delivery vector does not circulate *in vivo* and transduction efficiency can be monitored before transplantation. It is also possible to select cells with a desired phenotype. Most cell-based therapies, including stem cell therapy, use this approach.

The *in vivo* approach is the most direct strategy for gene transfer. The vector containing therapeutic gene is directly administered to the organ of interest or into blood circulation. When specific physical or biological targeting methods are available, this is a preferred approach. However, engineering targeted vectors is a challenge [10]. Physical targeting includes catheter-based gene delivery, direct intramuscular injection, and injection of biodegradable microspheres or nanoparticles coated with gene delivery vectors. Diagnostic ultrasound in conjunction with microbubble contrast agent complexed with gene delivery vector may improve the efficiency of targeted gene transfer [11].

35.2.3 VECTORS FOR GENE TRANSFER

The underlying concept of gene therapy is that transfer of genetic information as DNA will modify a disease, yielding therapeutic results. The “holy grail” of gene therapy is a vector that delivers genetic materials efficiently and safely to the target cells. An ideal vector must overcome the following hurdles: (1) The therapeutic gene must reach the target cell within the desired organs; (2) it must enter the cell, travel through the plasma membrane, traffic through cytoplasm, and reach the nucleus; (3) it must recruit the endogenous transcriptional machinery to unleash its encrypted information; and (4) it cannot have detrimental consequences on cell function other than intended effects.

Gene transfer vectors can be divided into two categories: nonviral and viral. Nonviral methods require direct transfection of naked DNA into cells or tissues. Unfortunately, it is relatively inefficient. To achieve gene transfer, the gene is usually complexed with liposomes, coupled with nanoparticles, or incorporated in a recombinant viral vector.

35.2.3.1 Physical and Chemical Delivery of Nonviral DNA

The use of naked plasmid DNA has obvious advantages including the relative ease of DNA preparation and storage. It can be handled as a chemical instead of as a biological substance. Furthermore, it is less immunogenic and allows repeated administration. Gene expression is low with local injection of plasmid DNA into the muscle, liver, skin, or lung airway [12]. Nevertheless, nonviral DNA vector may have greater utility in the treatment of acute disease and DNA-based immunization. The major limitation for transfection of the liver by naked DNA is poor transduction efficiency by systemic administration. To overcome this problem, a hydrodynamic delivery method has been developed. The procedure involves the rapid injection of plasmid DNA in a large volume (approximately 8%–12% of the body weight) within 5–8 s. This results in a transient increase in intravascular pressure, leading to more than a 1000-fold increased transgene expression, mainly in the liver [13]. Increased hepatic transgene expression with this method has been reported with lentiviral [14] and adenoviral vectors [15]. This method has recently been adopted for hepatic injection of plasmid DNA or Ad into large animal models using a balloon catheter [16,17]. Other physical methods for plasmid DNA delivery include electroporation and ballistic delivery [18].

35.2.3.2 Nonviral Vectors

The expression of therapeutic genes delivered by nonviral vectors is mostly transient and cannot be maintained over an extended time period. To prolong transgene expression, recently developed nonviral vectors have incorporated an integration system. Insertional mutagenesis is the primary concern in viral vectors. However, the integration of a transgene into a predetermined safe site in the host chromosome could avoid this problem, at least in theory.

1. *Phage integrase*. Phage integrases are enzymes that mediate unidirectional site-specific recombination between two DNA recognition sequences: the phage attachment site, *attP*, and the bacterial attachment site, *attB* [19]. Some integrases such as Φ C31 or R4 integrase do not require host cofactors, while others act with the aid of phage cofactors or bacterial host factors. Φ C31 integrase is functional in mammalian cells and it can integrate plasmid DNA containing an *attB* site into pseudo-*attP* sites in the mammalian genome. The Φ C31 integrase-mediated gene transfer has been used in small animal experiments [20–22]. The integrase system has no apparent upper size limit and repeated injections can be made without inducing a host immune response to the vector. Multiple coinjections of a plasmid expressing phiBT1 integrase and a phenylalanine hydroxylase have been reported to correct the phenotype, a mouse model of phenylketonuria [23].

Plasmid DNA is degraded rapidly if it is not integrated. This might be ideal for a plasmid coding for integrase since it should be eliminated from cells when recombination is complete. Although the *attP* recognition sequence is 39 base pair (bp) in length, 101 integration sites have been identified in human cell lines [24]. Despite a more restricted pattern of integration sites compared with Sleeping Beauty transposon [25], chromosomal abnormalities including chromosome translocation have been reported with the Φ C31 integrase-mediated integration [26,27]. This may be due to DNA breakage catalyzed by the integrase.

2. *Adeno-associated virus Rep protein-mediated integration*. Adeno-associated viruses (AAVs) are the only known mammalian virus capable of site-specific integration in a human chromosome. During latency in humans, AAV2 preferentially integrates at a site on chromosome 19q13.3-qtr, the so-called “AAVS1” site [28]. This site-specific integration is mediated by AAV Rep protein by targeting a sequence composed of a *rep*-binding element and terminal resolution site identical to the viral-inverted terminal repeats (ITRs) [29]. Similar sites have been identified in an African Green Monkey kidney cell line, CV-1 [30], and on mouse chromosome 7 [31]. Despite its proximity to the muscle-specific myosin-binding subunit 85 gene, integration into the AAVS1 site has not been associated

with any diseases. The absence of Rep function allows the transgene flanked by AAV ITRs to randomly integrate at chromosome breaks. This integration has no apparent strict size limitation [32]. The 138bp p5 promoter called p5 integration efficiency element enhances integration efficiency and is sufficient to mediate AAVS1 integration without ITRs [33]. It should be noted that Rep protein arrests the cell cycle [34].

3. *Transposon-mediated integration of transgene*. Another nonviral integrating system is based on DNA transposable elements. The Sleeping Beauty transposon has been used for gene delivery in animal models [22,35]. Integration mediated by transposon is efficient, but occurs randomly. In order to achieve site-specific integration, DNA-binding domains such as custom-designed zinc finger proteins (ZFPs) have been fused to a transposase. Although this modification increases site-specific targeting, it may interfere with the activity of transposase [36,37]. Nevertheless, this approach has potential for safe transgene integration.

35.2.3.3 Viral Vectors

Viruses are highly evolved biological machines whose sole purpose is to gain access to the host cell and replicate using the host's cellular machinery. Therefore, viruses have evolved highly efficient gene transfer mechanisms, fully tested in nature. There are two major groups of viruses according to the essence of their genetic materials: DNA virus and RNA virus. The sequences of RNA viruses are reverse transcribed into the host chromosome before the viral gene is expressed. Although attempts to identify new viral species for vector development are in progress, AAV, Ad, RV, LV, and foamy virus (FV) are the best characterized vectors for cardiovascular gene therapy. Key features of each viral system are summarized in Table 35.1. Each viral system has its advantage and limitations. It is important to choose the best fit system for the application.

35.2.3.3.1 DNA Viral Vectors

AAV. AAVs are single-stranded DNA viruses, which were first described as a contaminant of a tissue culture-grown simian Ad [38,39]. AAV is a member of the *Parvoviridae* family and has a capsid with icosahedral symmetry approximately 20 nm in diameter [40]. Taking advantage of the natural diversity and evolution of AAV in primate species, more than 100 unique AAV capsid sequences have been identified [41]. Several AAV receptors and coreceptors have been identified, which include heparan sulfate proteoglycan [42], $\alpha_v\beta_5$ integrins [43], fibroblast growth factor receptor-1 [44], platelet-derived growth factor (PDGF) receptor [45], and sialic acid [46]. The 37/67 kDa laminin receptor has recently been identified as a receptor for serotypes 2, 3, 8, and 9 [47]. The presence of these receptors or coreceptors in tissues determines cell type- or tissue-specific transduction. Species-dependent tropism of AAV serotypes

TABLE 35.1
Main Features of Viral Vectors

Vector	Genetic Material	Particle Size (nm)	Cloning Capacity (kb)	Transduction	Integration ^a	Immune Problems	Special Feature
AAV	ssDNA	20–25	~4.7 (~10) ^b	Dividing cells Nondividing cells	Mainly episomal	Low	Nonpathogenic
FGAd	dsDNA	70–100	8–10	Dividing cells Nondividing cells	Episomal	Extensive	
HDAd	dsDNA	70–100	~37	Dividing cells Nondividing cells	Essentially Episomal ^c	moderate	
RV	RNA	100	7–10	Dividing cells	Integrated	Low	
LV	RNA	100	9–10	Dividing cells Nondividing cells	Integrated	Low	
FV	RNA	100–140	~9.2	Dividing cells Nondividing cells	Integrated	Low	Nonpathogenic

AAV, adeno-associated virus; FGAd, first generation adenovirus; HDAd, helper-dependent adenovirus.

^a The major advantage of integrating vectors is a persistent gene transfer. However, this feature can be disadvantageous as it may induce oncogenesis in some applications.

^b This capacity can be achieved by an intermolecular joining method using two AAV vectors.

^c Minimal but significantly higher integration frequency of HDAd vector than FGAd has been reported.

has also been reported [48]. This is an important issue for AAV-mediated gene delivery. To date, 11 AAV serotypes have been characterized for gene therapy. AAV vectors express the transgene mostly in an episomal form (>90%), but also in an integrated form (<10%) [49]. One disadvantage of AAV vectors is their limited cloning capacity (4.7 kb), though this size limitation can be partly overcome by an intermolecular joining of two AAV vectors [50–52]. AAV vectors package a single-stranded genome and require host cell synthesis of the complementary strand for transduction. This causes a relatively long latent period between vector delivery and initiation of transgene expression. An AAV vector containing self-complementary genome can overcome this problem; however, it reduces the vector-cloning capacity for transgene to half [53].

In contrast to the cellular pathogenic response induced by an Ad vector infection, AAV vectors induce a nonpathogenic response affecting antiproliferative genes [54]. There is no known human disease associated with an AAV infection, making this vector a popular gene therapy vehicle. However, the potential for oncogenesis may exist. In the absence of *rep* gene, AAV genome has been shown to integrate randomly into the mouse genome with propensity toward gene regulatory sequences, albeit at low frequency [55]. Although studies involving large numbers of mice have failed to confirm an association between AAV vector treatment and tumor formation [56,57], there have been reports of a potential role of AAV2 in spontaneous abortion [58] and hepatocellular carcinoma in mice [59]. Donsante et al. have determined AAV integration sites in mouse hepatocellular carcinoma and mapped two of the insertions to chromosome 12 close to miRNA transcript. Furthermore, microarray analysis revealed upregulation of genes adjacent and telomeric to the AAV vector proviruses. These results have raised safety concerns over the human use because a syntenic locus on human chromosome 14 has been linked to several cancers [60].

Preexisting immunity against AAV has not been considered a serious problem until recently. The majority of the population is infected with AAV during childhood. Although AAV has a tremendously safety record in animal studies in diverse species and in humans, preexisting immunity may challenge its efficacy for *in vivo* transduction of tissues in humans. Transient self-limited liver toxicity has been reported in hemophilia B clinical trial [61]. The subsequent study of cytotoxic T cell (CTL) responses in one patient revealed that the expansion and contraction of the capsid-specific CD8+ T cell population paralleled the rise and fall of serum transaminase in the patient, while no such expansion occurred in mice. T-cell responses to AAV apparently targeted the conserved peptide sequence of the AAV capsid [62]. Preexisting CD8+ T cells to AAV capsid neither targeted AAV-transduced hepatocytes in mice [63,64] nor prevented AAV8-mediated Factor IX expression in hemophilia B dogs [65]. These studies highlighted critical differences in immunological responses against AAV among animal species.

Adenoviral vector. Adenoviruses (Ads) are nonenveloped, dsDNA viruses of ~70–100 nm in diameter. They have an icosahedral protein shell surrounding a protein core that contains the linear viral genome of ~35 kb. Ad infects cells independent of the cell cycle. The primary attachment sites of the Ad fiber protein subgroup C to cell surface receptors are “coxsackievirus and adenovirus receptor” (CAR) [66]. The internalization of Ad vector is mediated by interaction of the penton base protein with integrin $\alpha_v\beta_3$ or $\alpha_v\beta_5$ as the secondary internalization receptors [67]. Heparan sulfate proteoglycans have been also reported as cellular attachment sites for this subgroup of Ads [68]. In contrast, subgroup B, exemplified by serotype 11 and 35, uses CD46 as the entry site [69,70]. Of the over 50 different Ad serotypes, subgroup B serotypes 2 and 5 are the most characterized.

First-generation Ad vectors (FGAd) contain all of the essential Ad genome except E1A, which encodes the key regulators of early gene expression. FGAd is replication-defective. FGAd vectors induce strong host innate and adaptive immune responses, which is characterized by the generation of Ad-specific MHC Class I restricted CD8+ CTL [71]. Moreover leaky Ad gene expression induces adaptive immunity, resulting in destruction of Ad-transduced hepatocytes [72,73]. In immunocompetent hosts, this response causes transient transgene expression, which lasts for less than a month. In order to improve the safety profile, second- and third-generation Ad vectors have been developed. There is only marginal improvement in the *in vivo* toxicity or duration of transgene expression in these vectors. Nevertheless, these early generation Ad vectors have been useful in proof-of-principle experiments and remain a useful vector for cancer gene therapy and vaccination.

Helper-dependent adenoviral vector (HDAd). HDAds are the latest generation Ad vectors, which have a greatly improved safety profile and allow for sustained transgene expression *in vivo* [74]. HDAds have a large cloning capacity, accommodating inserts of up to 37 kb. The HDAd lacks all viral protein-coding genes and encompasses only the ITR for replication and the packaging signal. Helper virus, an FGAd, provides the necessary viral proteins *in trans* for packaging in cultured cells. Thus, chronic hepatotoxicity seen in early generation Ads has been eliminated in purified HDAds. However, minimal acute toxicity still exists. The innate immune response to HDAds underlies this residual toxicity [75,76], which is caused by the direct interaction of viral particles with innate immune effector cells upon systemic vector administration, commonly used for hepatocyte transduction. Transient depletion of Kupffer cells is effective in reducing toxicity as well as to increase hepatic transduction by HDAds [77].

Apart from innate immune responses, HDAds have been considered to evade most of the adaptive immunity and thus sustain long-term transgene expression [76]. In animal models, HDAd-mediated hepatic gene delivery exhibits stable, long-term transgene expression associated with reduced hepatotoxicity [17,78–82]. However, both FGAd- and HDAd-transduced human dendritic cells (DCs) efficiently and stimulated the proliferation of autologous T cells, suggesting that preexisting immunity is directed primarily against the viral capsid [83]. A significant proportion of humans acquire respiratory tract infections caused by various Ads. Over 85% of human peripheral blood mononuclear cells (PBMCs) exhibited T cell response against human Ad5 [84]. Therefore, cell-mediated immunity could remain a challenge even with HDAd gene therapy.

35.2.3.3.2 RNA Viral Vectors

The Molony murine leukemia RV was the first gene transfer vector developed for gene therapy. Other RNA viral vectors include LV and FV. These RNA viral vectors integrate the transgene into the host chromosome, resulting in a sustained transgene expression.

Oncoretroviral vector (RV). RVs are single-stranded RNA viruses. The current vector is pseudotyped with the vesicular stomatitis virus glycoprotein (VSV-G). This confers a broad host range and stabilization of the vector particles, allowing the vector stock to be concentrated to high titers by ultracentrifugation. The packaging capacity of this vector is about 8 kb. Transgene expression persists due to integration into the host chromosome. However, the vector genome is integrated randomly, rendering insertional mutagenesis and oncogenesis as rare but definite possibilities. Another drawback is that RVs work only in cells that are actively dividing because they can access the nucleus only if the nuclear membrane has been broken down. RVs are mainly used in *ex vivo* gene therapy and are effective in transducing hematopoietic stem cells [49].

Lentiviral vector (LV). LVs were derived from human immunodeficiency virus (a member of the RV family) and are mostly pseudotyped with VSV-G. LV can penetrate an intact nuclear membrane and transduce nondividing cells. Thus, LV can be used in both *ex vivo* and *in vivo* applications. The deletion of most of the parental genome in the vector and in packaging constructs minimizes the possibility of generating a replication competent virus. As with RVs, most LVs now in use are self-inactivating, lacking the regulatory elements in the downstream long-terminal repeat (LTR), thus eliminating transcription of the packaging signal. Few immunological problems have been reported for both RV and LV. RV favors transgene integration near transcription start sites and shows little preference for active transcription units, while LV preferentially integrates into active genes [85,86].

Foamy viral vector (FV). FVs are the most recently developed gene transfer vectors. FVs comprise a genus of retroviruses but have distinct properties from oncoretroviruses and lentiviruses [87]. They have the largest genome size (up to 9.2 kb) of all retroviruses and are considered apathogenic in their natural animal hosts and after zoonotic transmission into humans [88]. The FV genome contains canonical retroviral *gag*, *pol*, and *env* genes, but replication is dependent on a transcriptional activator, Tas, encoded by the *bel1* gene [89]. FV has a broad tropism and infects both dividing and nondividing cells. Although they show a preference for integration near transcription sites and for CpG islands (methylated DNA), they do not integrate preferentially within genes [90]. They are effective in transducing hematopoietic stem cells of mice and humans and human embryonic stem cells [91–93].

35.3 GENE THERAPY FOR HYPERLIPIDEMIA

Over the last half century, the mortality rate of coronary heart disease (CHD) has continued to decline [94]. However, an aging population and an increasing prevalence of overweight and obese individuals (see recent trend at <http://www.cdc.gov/nccdphp/dnpa/obesity/trend/index.htm>) could reverse the gain in treatment of CHD. Inherited and acquired forms of hyperlipidemia are an independent risk factor for the development of atherosclerosis. Most of diet-related hyperlipidemia and heterozygous familial hypercholesterolemia (FH) can be

treated with lipid-lowering drugs such as statins (3-hydroxy-3-methylglutaryl-coenzyme A [HMG CoA] reductase inhibitors), bile acid binding resins, ezetimibe to inhibit cholesterol absorption in intestine, or combinations of the above.

FH is an autosomal-dominant disorder caused by mutations of the low-density lipoprotein (LDL) receptor (LDLR) gene. Close to 2000 sequence variants have been reported (www.ucl.ac.uk/fh). FH is one of most common inherited disorders that affect 1 in 500 individuals in the heterozygous form. Homozygous FH patients exhibit severe phenotype in which the plasma cholesterol levels can range from 700 to 1200 mg/dl. Many homozygous FH patients develop angina in childhood due to the aortic stenosis and coronary atheroma. MI has been reported as early as age 2 years, and most patients do not survive beyond the third decades of life if not treated [95]. A subset of heterozygous FH and the most severe forms of homozygous FH do not respond to the conventional therapy. Several other therapeutic options are liver transplantation, LDL apheresis, biliary diversion, and portacaval anastomosis [96]. The lack of conventional interventions has attracted interest for gene replacement therapy.

35.3.1 *EX VIVO* APPROACH

LDLR facilitates the uptake of LDL in the liver and disposal of cholesterol into the bile to maintain normal cholesterol level (Figure 35.3). Unregulated hepatic overexpression of LDLR has not been associated with significant adverse events in animal studies, although hepatic steatosis is a primary concern. In the Watanabe heritable hyperlipidemic (WHHL) rabbit, a model of FH, Chowdhury et al. developed an *ex vivo* LDLR replacement gene therapy method [97]. Autologous hepatocytes were harvested by a partial hepatectomy and transduced in culture with RV carrying normal LDLR. The modified hepatocytes were then transplanted via the portal vein into the liver of the animal from which the cells were originally derived. This treatment resulted in a 30%–50% reduction of plasma cholesterol, which persisted for 6.5 months. These encouraging results led to the first pilot clinical gene therapy trial for FH. A total of five patients were treated. Although the procedure was safe and feasible, it was concluded that the variable metabolic responses due to the low gene transfer precluded broad application [98,99]. This study uncovered important practical implications for human application. It required isolation of autologous hepatocytes through an invasive partial liver dissection, cell proliferation, transduction with a vector that could potentially induce genotoxicity, and handling of large number of hepatocytes.

35.3.2 *IN VIVO* APPROACH

Researchers have demonstrated efficient gene transfer to the liver by intravenous injection of Ad vector. Several groups have reported complete phenotypic correction of elevated LDL cholesterol levels in mouse and rabbit models of FH after a single intravenous injection of FGAd vector carrying

LDLR or very-low-density lipoprotein receptor (VLDLR) [100–103]. VLDLR is a multiligand apoE receptor, which is normally synthesized in LDLR-deficient mice. The effect of gene transfer with Ad was transient and associated with hepatotoxicity. However, HDAd-mediated LDLR and VLDLR gene transfer into LDLR-deficient mice conferred long-term phenotypic correction and protection against diet-induced atherosclerosis lasting up to 2 years [79,104]. LDLR was more effective, though it produced anti-LDLR antibodies at high dose. Therefore, in the context of LDLR protein deficiency, VLDLR may be preferable. Leberherz et al. treated LDLR-deficient mice with an intraportal vein injection of AAV2, AAV7, and AAV8 carrying human LDLR gene. AAV7 and AAV8 treatment normalized serum lipid for at least 21 weeks and significantly protected LDLR-deficient mice against atherosclerosis [105].

In vivo administration of RV has also been tested for the long-term reversal of hypercholesterolemia in a WHHL rabbit [106]. A 20% reduction of plasma cholesterol was observed 52 weeks after treatment. However, the requirement of both a 10% liver resection to induce cell proliferation and repeated vector injection combined with plasmid/liposome-mediated thymidine kinase gene transfer to induce cell division makes this impractical for clinical application. LV is a more efficient *in vivo* integrating vector. Kankkonen et al. treated WHHL rabbits with an intraportal vein injection of a third-generation LV carrying LDLR. The treatment reduced serum cholesterol by 34% at 2 years after the treatment without major safety issues [107]. No clinical trial for FH using this *in vivo* approach has been performed.

Apolipoprotein (apo) E-deficient mice develop spontaneous atherosclerosis. In this mouse model, a single injection of HDAd carrying apoE gene and its liver enhancer element has been shown to reverse hypercholesterolemia for their lifetime [78]. AAV7 and AAV8 expressing apoE also have been used to prevent atherosclerosis in apoE-deficient mice [108].

There are other therapeutic genes that can be exploited to treat dyslipidemia. Apolipoprotein A-I (apoAI) is a major protein component of high-density lipoproteins (HDL). HDL cholesterol is inversely correlated with the risk of CHD. Raising HDL cholesterol by elevated apoAI has attracted an attention for prevention of atherosclerosis. Long-term hepatic expression of apoAI inhibited a progression of atherosclerosis and remodeled unstable plaques to a stable phenotype in LDLR-deficient mice [109]. Similarly, AAV-mediated apoAI expression was stable for at least 1 year [110].

Another potential target is apoB100, which is a protein component of LDL. Teng et al. used an FGAd carrying apoB mRNA editing enzyme catalytic subunit-1 (apobec-1) to induce apoB100 mRNA editing and reduced plasma cholesterol in LDLR-deficient mice [111]. This is possible because resulting apoB48 containing lipoproteins are more efficiently taken up by the liver LDLR via apoE ligand. Enjoji et al. designed a hammerhead ribozyme to cleave human apoB100 mRNA and introduced it by FGAd-mediated transfer into

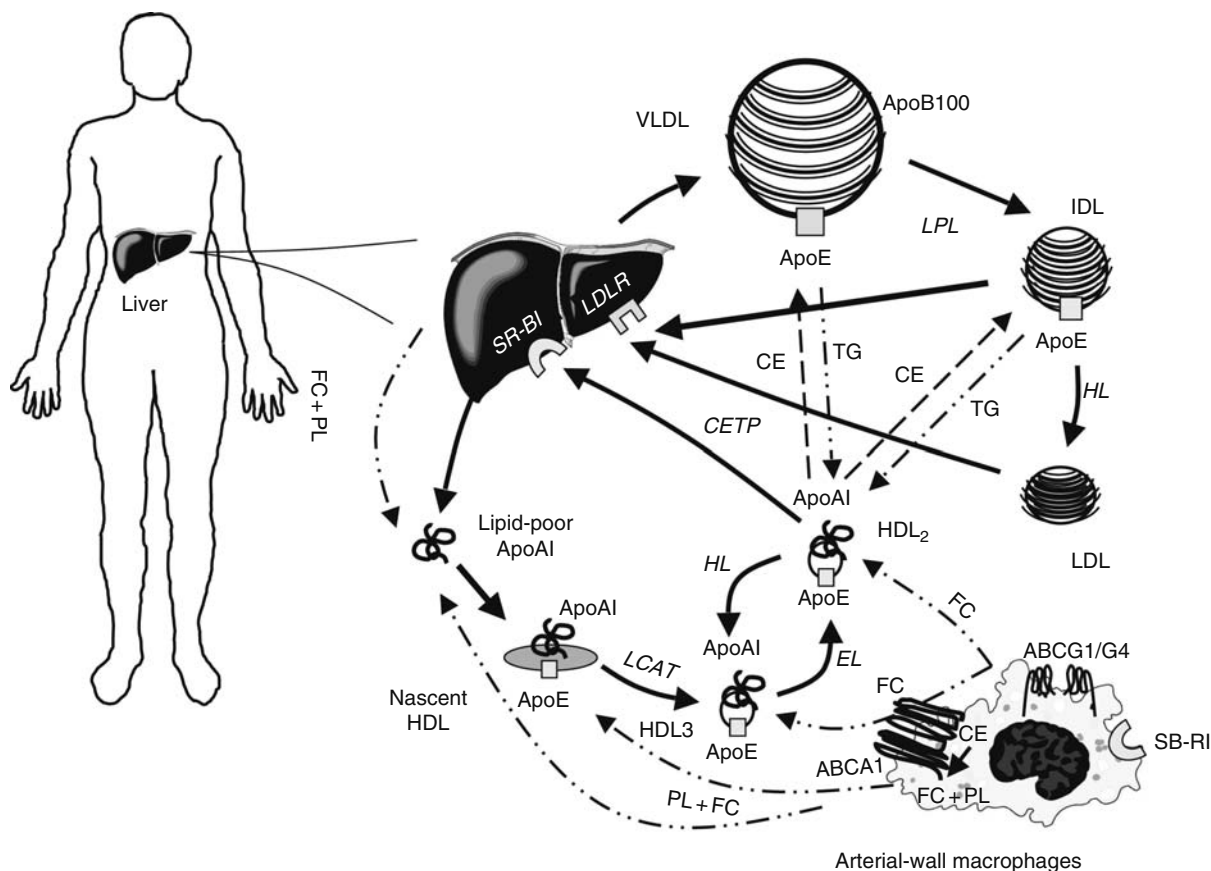

FIGURE 35.3 Overview of metabolism of liver-secreted lipoproteins and reverse cholesterol transfer via macrophages in humans. apoB100 containing triglyceride (TG)-rich VLDL is secreted from the liver. TGs on VLDL are hydrolyzed to free fatty acids and glycerol by the action of lipoprotein lipase (LPL). This process remodels VLDL to a smaller, denser, intermediate-density lipoprotein (IDL). IDL is taken up by the LDLR or other apoE receptors through an apoE ligand and is further remodeled by hepatic lipase (HL). LDL particles are taken up by LDLR through an apoB100 ligand. Lipid-free or lipid-poor apoA-I is secreted from the liver and serves as an acceptor for ATP binding cassette transporter-1 (ABCA1)-mediated lipid efflux from hepatocytes as well as macrophages. ABCA1-mediated efflux of free cholesterol (FC) and phospholipids (PL) to apoA1 forms nascent or pre- β -high-density-lipoprotein (β -HDL) which is further modified by lecithin-cholesterol acyltransferase (LCAT). In humans, the resulting large, less dense HDL₂ and smaller, more dense HDL₃ can serve as acceptors for ABC subfamily G member 1 (ABCG1)/ABCG4-mediated cholesterol efflux. This pathway is favored by the presence of apoE in HDL. HL also hydrolyzes PL in HDL₂ and, therefore, is involved in the conversion of HDL₂ to HDL₃. Endothelial lipase (EL) is considered to act on HDL-PL. HDL cholesterol is taken up by the liver and is secreted into the bile for disposal through the scavenger receptor class B type I (SR-BI). Cholesteryl ester transfer protein (CETP) transfers CE from HDL to TG rich lipoproteins in exchange for TG. LDLR-related protein (LRP) in liver is considered the receptor for diet-derived chylomicron remnants, which is not shown. There are substantial differences in lipoprotein metabolism between humans and mice. In mice, liver-secreted VLDL contains both apoB100 and apoB48 due to the presence of apoB's mRNA editing activity. TGs on apoB48-VLDL are hydrolyzed by LPL and are remodeled to smaller, denser apoB48-VLDL remnants. These particles are taken up through an interaction with apoE receptors. Mouse plasma does not have CETP activity. As a result, major cholesterol carrying lipoproteins in humans are LDL, while they are HDL in mice.

apoB100 transgenic apobec-1-deficient mice. This resulted in reduced apoB100 and plasma cholesterol [112]. Similarly, siRNA has also been used to reduce plasma cholesterol by decreasing apoB mRNAs [113,114]. Recently, antisense ODNs against apoB have been used in a small phase II double-blind randomized, placebo-controlled, dose-escalation clinical trial for mild dyslipidemia [115].

Cell-based approaches also have shown some success in modifying dyslipidemia, mostly through transplantation of genetically modified BM cells. Macrophages synthesize and secrete apoE. Transplantation of BM cells transduced

with RV- or LV-expressing apoE has been reported to protect apoE-deficient mice against atherosclerosis [116,117]. Also, apoA1 expression in macrophages has been reported to attenuate development of atherosclerosis in apoE-deficient mice [118]. This is likely through the apoA1-mediated promotion of cholesterol efflux from macrophages.

Successful gene therapy for FH requires high-level long-term stable expression of therapeutic genes and evasion of the host immune system. Progress in gene therapy for FH has been the standard to inspire treatments for other systemic acquired or genetic diseases.

35.4 GENE THERAPY FOR VASCULAR DISEASE

35.4.1 RESTENOSIS

Stenosis is the narrowing of arteries leading to decreased perfusion of tissues. Restenosis is a recurrent reduction in luminal size following intraarterial procedures including angioplasty and atherectomy because of injury to the arteries. Grüntzig pioneered the nonsurgical technique for the treatment of symptomatic coronary artery disease known as percutaneous transluminal coronary angioplasty (PTCA) [119]. This has revolutionized the treatment of acute coronary syndrome by cardiologists. However, on a cellular level, normally quiescent smooth muscle cells (SMCs) within the treated vessel can be activated to migrate and proliferate as a part of the normal wound-healing process. This has been documented following percutaneous coronary interventions (PCIs) including coronary stenting and balloon angioplasty. A post-PTCA restenosis occurs in 30%–40% of treated coronary lesions in 6–7 months. Gene therapy has been explored as a potential single long-lasting treatment. However, vascular gene therapy to prevent postangioplasty restenosis has experienced a significant challenge in the past few years. The combination of coronary stenting and aggressive antithrombotic and antiplatelet therapy and development of drug-eluting stents have significantly reduced the incidence of restenosis. Future studies using gene therapy approach for the treatment of restenosis should be combined with drug-eluting stents to further improve outcomes. Such strategies have been reported in rabbit vascular injury models [120,121].

Targets of gene therapy. The physiological response to vascular injury is divided into four stages: (i) the early phase; (ii) the thrombogenic phase (formation of thrombi due to local hemorrhage and thrombosis); (iii) neointima hyperplasia (the proliferation and migration of medial and intimal vascular SMCs); and (iv) remodeling (an adaptive growth of a fibrocellular lesion composed of vascular SMCs and extracellular matrix with a more synthetic state). Growth factors and cytokines are believed to play a key role in the stimulation of vascular SMCs during neointima hyperplasia. It was considered that a key target for gene therapy should be to decrease growth factors, thus inhibiting the pathologic proliferation of SMCs and preventing restenosis. However, this approach was not fruitful due to redundancy in functions among growth factors.

Effective treatments to prevent restenosis are based on the knowledge of regulation of cell cycle in cancer cells [2]. Medial vascular SMCs are normally quiescent and exist in G₀ phase. In response to vascular injury or stimulation by growth factors, they progress to G₁. This transition is regulated by cyclins and cyclin-dependent kinases (CDKs). The progression of the cell cycle depends on the phosphorylation and dephosphorylation of CDKs. The CDK inhibitor, p27, plays a predominant role in the regulation of the transition from G₁ to S phase, and is an essential checkpoint in the progression through the cell cycle. Mice deficient in p27 display enhanced growth and multiorgan hyperplasia [122]. Rapamycin is a pharmacological approach to this problem since rapamycin-coated stents inhibit intimal hyperplasia by increasing p27 [123]. Using a gene therapy

approach, Ad-mediated overexpression of p21 inhibits neointima formation in a rat model of balloon angioplasty [124].

Another key regulator of cell cycle progression is the product of the retinoblastoma gene (pRB), a tumor suppressor. Inactivation of RB is lethal in mice, causing multiple defects in hematopoiesis and neurogenesis [125] while overexpression of the RB gene in transgenic mice causes dwarfism [126]. pRB is a nuclear phosphoprotein that arrests cell cycle at the G₁ phase by repressing genes required for transition to the S phase. This is accomplished through formation of a complex with the transcription factor E2F. This complex formation prevents E2F's activation. As CDKs activity increases, pRB becomes phosphorylated and dissociates from E2F, activating the S phase genes. Transcription decoys bearing the E2F consensus-binding sequence inhibit E2F effects on its target genes [127]. In the ITALICS trial (Randomized Investigation by the Thoraxcenter of Antisense DNA using local delivery and IVUS after Coronary Stenting), proto-oncogene c-myc was targeted by ODNs. Phosphorothioate-modified 15-mer antisense ODNs were delivered into the coronary arteries after stent implantation. Unfortunately, the treatment did not reduce neointimal volume obstruction or restenosis [128].

35.4.2 VEIN GRAFT FAILURE

In contrast to gene therapy for postangioplasty stenosis, vein graft stenosis may be a more amenable target for gene therapy because of direct access to the vein during surgery. The vein graft can be manipulated *ex vivo* prior to implantation [129]. Matrix metalloproteinases (MMPs) play a role in extracellular matrix degradation, allowing SMC migration during neointima formation. MMPs are inhibited by endogenous inhibitors called TIMPs (the “tissue inhibitors for MMP”). Studies have shown the expression of TIMP 1–3 in human saphenous vein (SV) cultures inhibits migration of SMCs. Ultrasound exposure of vein grafts in the presence of microbubbles complexed with plasmid DNA expressing TIMP-3 inhibited neointimal formation in a pig model [130]. *Ex vivo* approaches have proven successful in animal models of neointimal hyperplasia: Ad-mediated expression of the carboxyl terminus of the β -adrenergic (β -AR) receptor kinase in a aortocoronary SV graft in a canine model [131] and Ad expression of antisense transforming growth factor β 1 (TGF β 1), a chemotactic and mitogenic factor, to inhibit SMC migration, endothelial cell proliferation, and extracellular matrix synthesis in rats [132].

Nitric oxide (NO) plays a key role in maintaining vascular homeostasis by regulation of platelet adhesion and aggregation, vascular SMC migration, and proliferation, as well as inhibition of endothelial activation and inflammation [133]. West et al. have shown that exposure to Ad, expressing nitric oxide synthase (NOS), during jugular-carotid bypass surgery in rabbits improved endothelial cell function, blocked SMC proliferation, and reduced vascular superoxide production [134]. Endothelial NOS (eNOS) was more effective in preventing intimal hyperplasia, suggesting the potential of this approach for prevention of restenosis [135]. In another study, the expression of the tumor suppressor gene p53 caused apoptosis of SMCs, thereby blocking their migration and inhibiting neointimal formation in

human SV coronary artery grafts [136]. Similarly, Ad-mediated p53 gene transfer into the luminal surface of porcine SV grafts prior to grafting resulted in increased lumen size and inhibition of neointimal formation [137]. Although most studies have used Ads, the treatment for vein graft stenosis may require long-term therapeutic gene expression and AAV may have more utility in this approach [138].

Despite early reports suggesting that an E2F decoy can block cellular proliferation in vein grafts [139], this treatment was ineffective in preventing graft failure in two large multi-center randomized double-blind placebo-controlled studies of 2400 [140] and 1404 patients [141]. Perhaps, siRNA technology could be more effective than decoys to silence harmful factors in vein grafts. Midkine is a heparin-binding growth factor and deficient mice exhibit a reduction in neointima formation in a restenosis model. ShRNA to midkine was mixed with atelocollagen and was shown to reduce intimal hyperplasia up to 90% in jugular vein-to-carotid artery interposition vein grafts in rabbits 4 weeks after treatment [142].

35.4.3 THERAPEUTIC ANGIOGENESIS FOR ISCHEMIA

A study by Folkman et al. suggested that angiogenic growth factors are required for induction of new blood vessel formation and tumor growth [143]. The growth of blood vessels is essential for organ growth and repair. Development of the vascular system occurs via vasculogenesis (angioblast mobilization), angiogenesis (sprouting), and arteriogenesis (maturation) (Figure 35.4) [144].

Angiogenesis. Angiogenesis is the sprouting of new capillaries from postcapillary venules. In adults, it is stimulated mainly by tissue hypoxia via activation of hypoxia-induced factor (HIF)-1 α expression. Among many genes induced by HIF-1 α , angiogenesis-specific genes include the vascular endothelial growth factor (VEGF) family, angiopoietins (Ang), and inducible nitric oxide synthase (iNOS). The VEGF family is composed of five closely related genes: VEGF-A, -B, -C, -D, and PlGF. There are several isoforms of VEGF-A that differ by their amino acid length and their ability to bind

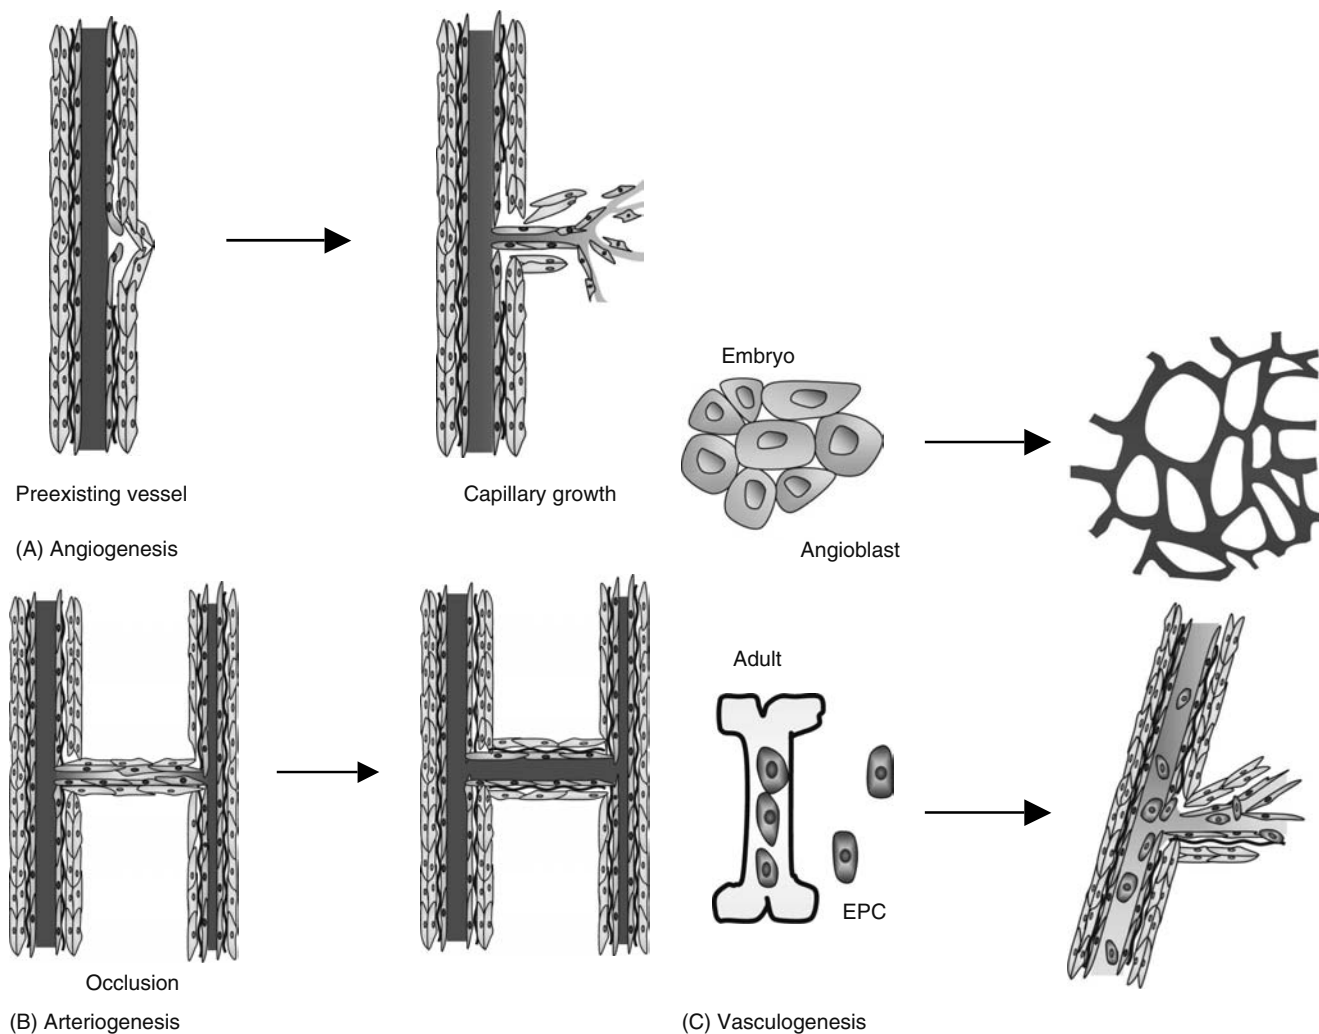

FIGURE 35.4 Vascular growth. (A) Angiogenesis is the process by which preexisting vascular structures sprout to new capillary network, operated by the in situ proliferation and migration of preexisting endothelial cells. (B) Arteriogenesis is maturation or de novo growth of collateral conduits. It occurs frequently outside the area of ischemia in response to local change in shear stress. (C) Vasculogenesis. In embryo, angioblasts (EPCs) assemble in a primitive network. In adults, bone marrow derived EPCs are activated in response to vascular trauma, home to the site of neovascularization and are incorporated into blood and lymphatic vessels.

to heparan sulfate. The long isoforms, VEGF₂₀₄ and VEGF₁₈₆, bind to heparan sulfate tightly and do not diffuse through extracellular matrix. In contrast, a short isoform, VEGF₁₂₁, lacks binding to heparan sulfate and shows wide diffusibility. VEGF₁₆₅ preserves both properties and thus possesses increased ability to stimulate VEGF receptors [145]. This isoform is the most promising for promotion of vascular growth [146]. Placenta growth factor (PlGF) is a unique member of the VEGF family. Its arteriogenic effects and ability to release EPCs from the BM have been reported [147,148]. Angs is a family of four genes involved in the regulation of vessel stability and remodeling. Ang-1 counteracts the VEGF-induced angiogenesis that causes the vessels to be more permeable and tightens the permeability barrier by enhancing the interaction between endothelial cells, pericytes, and the surrounding matrix [149].

Arteriogenesis. Arteriogenesis occurs frequently outside the area of ischemia in response to local accumulation of blood-derived mononuclear cells at the sites of arterial stenosis, where shear-stress is increased [150]. Angiographic studies in rodent hind limb ischemic models have demonstrated remodeling of preexisting vessels [151]. However, it remains a hotly debated issue whether arteriogenesis occurs de novo or represents enlargement of preexisting vascular structures. Both angiogenesis and arteriogenesis increase blood flow, which has attracted attention as a potential treatment for CHD and peripheral arterial disease (PAD). Fibroblast growth factors (FGFs) are the best-studied family of arteriogenic growth factors and are potent inducers of cell growth and migration through their interaction with four tyrosine kinase receptors and syndecan-4. Those with the most pronounced angiogenic activity include FGF-1, -2, -4, and -5 [152]. However, FGF activity is regulated mainly at the level of FGF receptor expression in target tissues [153]. Other contributors to arteriogenic response include PDGF and hepatocyte growth factors [146].

Vasculogenesis. Circulating BM-derived EPCs are activated in response to stimuli such as cytokines or tissue ischemia. They home to sites of neovascularization and are incorporated into the foci [154]. This phenomenon of vasculogenesis was originally described for embryonic neovascularization but also has been found in adults [6,155]. BM-derived EPCs functionally contribute to vasculogenesis during wound healing [156], limb ischemia [6,157], post-myocardial infarction [158], endothelialization, and microvessel formation from vascular grafts [159,160], and physiological and pathological neovascularization [157].

Therapeutic myocardial angiogenesis is an attractive treatment option for patients with end-stage coronary disease who have failed angioplasty and surgical methods of revascularization. Many potential genes have been identified in proof-of-principle experiments using small or large animals. The most popular model for therapeutic angiogenesis has been the hind limb ischemia in rodents, rabbits, or pigs [161–164]. Direct injection of naked DNA or viral vectors expressing VEGF has been reported to be effective

in inducing collateralization and improving perfusion [165–167]. Most studies of gene therapy for ischemic disease have used *in vivo* delivery of single genes, usually growth factors, which initiate a cascade of angiogenesis. Kondoh et al. have tested an *ex vivo* approach with dual gene expression. In a rabbit model of hind limb ischemia, autologous fibroblasts were infected with Ad expressing VEGF or basic FGF, alone or combination, and injected via the left internal iliac artery. In the combination group, collateral conductance showed synergistic effects while additive effects were found *in vivo* blood flow and SMC-positive vessel density [168].

Other approaches include the use of multiple active genes or transcription factors that impact on the angiogenesis pathways. The injection of skeletal myoblasts infected with Ad bicistronic vector expressing VEGF₁₆₅ and Ang-1 stimulated functional neovascularization of hind limb [169]. Whitlock et al. used Ad expression of a VEGF cDNA/genomic hybrid that allows the expression of three major VEGF isoforms 121, 165, and 189 for greater restoration of blood flow [170]. Another approach has been to upregulate endogenous VEGF expression by engineering ZFP transcription factors. Ad-expressing VEGF-activating ZFP was delivered to the adductor muscle of the ischemic hind limb in a mouse model. The treatment improved blood flow and limb salvage, demonstrating the feasibility of designing ZFPs to therapeutically regulate gene expression [171].

Despite encouraging results in early small open-labeled trials, randomized controlled trials employing angiogenic gene therapy have not shown a clinical benefit [1,172]. In one phase II study, patients with lower limb ischemia were recruited for treatment with Ad-VEGF₁₆₅ or plasmid-VEGF₁₆₅. The primary endpoint was increased vascularity measured by angiography at 3 months; this was significantly improved but the restenosis rate was not [173]. In a small double-blinded placebo-controlled study, patients with critical limb ischemia received intramuscular injection of plasmid-carrying VEGF₁₆₅. Although significant improvement in pressure indices (ankle-to-brachial index, toe-to-brachial index) and clinical improvement (skin, pain, and quality of life score) were detected, the amputation rate was not reduced [174]. In the regional angiogenesis with vascular endothelial growth factor (RAVE) trial, 105 patients with intermittent claudication were treated with intramuscular injection of low- or high-dose Ad-VEGF₁₂₁ or placebo. Unfortunately, the treatment did not improve exercise performance or quality of life so the results did not support local delivery of Ad-VEGF₁₂₁ as a treatment for patients with intermittent claudication. In fact, it was noted that the Ad-VEGF₁₂₁ administration was associated with increased peripheral edema [175]. However, in another phase II randomized controlled trial of Ad-VEGF₁₂₁ (REVASC), there was improvement in exercise-induced ischemia at 26 weeks in patients who received intramyocardial delivery of Ad-VEGF₁₂₁ [176]. Therapeutic angiogenesis was also tested for patients with a previous MI or angina. Ad-mediated transfer of VEGF₁₆₅ or FGF-4 has been reported to be effective in

increasing myocardial perfusion [177,178] while the treatment with plasmid-carrying VEGF₁₆₅ was ineffective [179].

35.4.4 HYPERTENSION

High blood pressure (BP) is associated with an increased risk of mortality and morbidity from stroke, CHD, congestive heart failure (CHF), and end-stage renal disease. Worldwide prevalence is estimated to be approximately 1 billion individuals [180]. More than 75 antihypertensive agents in nine classes are available. Much progress has been made in recent years in the prevention, detection, and treatment of high BP. More emphasis is now placed on lifestyle/behavior modification (obesity, high dietary intake of fat and sodium, physical activity, smoking, excessive alcohol intake, low dietary potassium intake) to control BP as well as to improve the efficacy of pharmacologic treatment of high BP. Also, new classes of antihypertensive agents along with new compounds in established drug classes are widening the repertoire that physicians have to combat hypertension. Some examples include aldosterone receptor blockers, direct renin inhibitors, endothelin receptor antagonists, and dual endopeptidase inhibitors [181]. Although these pharmacologic solutions make gene therapy out to be an unlikely treatment option, part of the challenge in controlling BP is patient noncompliance. Patients with hypertension tend to have low compliance rate because this disorder is asymptomatic. The conventional antihypertensive therapies do not cure the problem and some patients find it difficult to continue with lifestyle modifications. Thus, long-acting gene therapy could be an unexpected treatment option.

RNAi- and antisense ODN-based strategies may be useful for the control of hypertension. Targeting of the renin-angiotensin system appears to be a viable strategy [182]. A single intracardiac administration of RV-containing angiotensin II type I receptor antisense gene resulted in prolonged BP lowering and prevention of cardiac hypertrophy in hypertensive rodent models. However, this treatment did not attenuate endothelial dysfunction [183,184]. Tyrosine hydroxylase (TH) is a rate-limiting enzyme for catecholamine synthesis. Inhibition of TH may have similar effects to that of β -AR receptor blockers. Tail vein injection of antisense ODNs against TH caused hypotensive effects in SHR with a concomitant reduction of TH activity, epinephrine, and norepinephrine levels in the adrenal medulla [185].

Increased levels of reactive oxygen species have been shown in blood vessels and in tissues in experimental models of hypertension [186]. Increased superoxide may contribute to hypertension by inactivation of vascular NO that induces vascular relaxation [187]. Thus, gene transfer of extracellular superoxide dismutase (ecSOD) may reduce arterial pressure. Intravenous injection of Ad-expressing ecSOD but not ecSOD lacking the heparin-binding domain reduced BP and cumulative sodium balance in SHR [188].

Other vasodilatory approaches may be viable as well. Atrial natriuretic peptide (ANP) is a 27 amino acid peptide with potent vasodilatory, natriuretic, and diuretic effects [189].

Prolonged infusion of synthetic ANP to humans with essential hypertension causes a reduction in BP and enhanced natriuresis [190]. Similar results have been reported by injection of naked ANP plasmid into SHR or Ad expressing ANP into Dahl salt-sensitive rats [191,192]. Interestingly, the treatment also reduced stroke-induced mortality in Dahl salt-sensitive rats signifying that the important cardiovascular outcomes could be affected [192]. To achieve long-term ANP expression, Schillinger et al. have used HDAd-mediated mifepristone-inducible ANP gene transfer into the BHP/2 mouse model, and demonstrated decreased BP, increased urinary cGMP output, and decreases in heart weight [193]. Other therapeutic genes that might decrease BP by inducing vasodilation are kallikrein, adrenomedullin, and eNOS [194,195].

Primary pulmonary hypertension is a rare but life-threatening disease characterized by progressive pulmonary hypertension, leading to right ventricular failure and premature death [196]. Prostacyclin is a potent vasodilator that inhibits platelet adhesion and cell growth. Impaired prostacyclin production has been linked to the development of pulmonary hypertension [197]. Intratracheal transfer of cDNA coding for human prostacyclin synthase into the lungs of monocrotaline (MCT)-induced pulmonary hypertensive rats has been reported to attenuate pulmonary arterial pressure and pulmonary resistance and improve survival of rats [198].

Factors that inhibit SMC proliferation and induce apoptosis also are potential therapeutic genes. Survivin is an inhibitor of apoptosis found primarily in cancer cells. It has been reported that balloon-mediated arterial injury in rabbits results in expression of survivin in vascular cells where it is involved in pathological vessel-wall remodeling [199]. Survivin is also expressed in pulmonary arteries of patients with pulmonary hypertension and rats with MCT-induced pulmonary hypertension. Inhibition of survivin by inhaled Ad expressing the dominant negative mutant reversed MCT-induced pulmonary arterial hypertension and prolonged survival by 25% in rats [200].

35.4.5 THROMBOSIS

Deep vein thrombosis is a common condition, affecting 1% to 2% of the population. More than 200,000 new cases occur in the United States annually. Of these, 30% of patients die within 30 days of the event and one-fifth will suffer sudden death due to pulmonary embolism [201]. Drug treatment strategies to prevent thrombosis include antiplatelet and systemic anticoagulation. Vascular cyclooxygenase-1 (COX-1) is the rate-limiting enzyme in prostacyclin synthesis. Injection of Ad-expressing COX-1 into angioplasty-injured porcine carotid arteries was able to inhibit thrombus formation [202]. Other genes tested for their utility are tissue plasminogen activator [203], thrombomodulin [204], tissue factor pathway inhibitor [205], C-type natriuretic peptide [206], and ectonucleoside triphosphate diphosphohydrolase [207]. Direct injection of plasmid-expressing VEGF into thrombus also was shown to improve thrombus recanalization [208].

35.5 GENE THERAPY FOR HEART FAILURE

Heart failure remains one of major causes of morbidity and mortality in industrial societies, worsening as the population ages. The anatomical structure of the heart and advances in percutaneous methods to access the heart make it possible to target this organ for local gene or cell therapy. The failed heart may contain both nondiseased and dysfunctional cardiomyocytes and the goal of gene therapy is to improve the contractile function of cardiomyocytes. Cell therapy attempts to replace lost cardiomyocytes.

The main targets of gene therapy for heart failure are enhancement of contractility via intracellular calcium and β -AR pathways, inhibition of cardiac hypertrophy, remodeling and fibrosis, and prevention of arrhythmias. Enhancement of contractility of cardiac myocytes can be achieved through manipulation of intracellular calcium levels. The sarcoplasmic reticulum (SR) plays a central role in the regulation of intracellular calcium in cardiac muscles during excitation-contraction coupling. The SR ATPase pump is responsible for most of the Ca^{2+} removal during relaxation, and relaxation abnormalities related to deficient SR Ca^{2+} uptake have been documented in heart failure [209]. The catheter-based direct injection of Ad-expressing SR Ca^{2+} -ATPase into left ventricle has been reported to improve left-ventricular function in a rat model of heart failure [210]. Other genes tested to sequester calcium include parvalbumin [211], a mutant of phospholamban, which is a key regulator of cardiac SR Ca^{2+} cycling [212], and Ca^{2+} -binding protein S100A1 [213].

The β -AR system mediates the inotropic and chronotropic effects of epinephrine and norepinephrine and therefore plays a crucial role in the regulation of cardiac function. Intracoronary delivery of Ad expressing β 2-AR has been reported to increase contractility in rabbits [214]. Because of our rapidly progressing understanding of cardiomyocyte signal transduction, new potential targets have been emerged. The protein kinase C (PKC) family is involved in hypertrophy, dilated cardiomyopathy, ischemic injury, and mitogen stimulation [215]. Inhibition of PKC α by expression of a dominant-negative mutant or overexpression of p38 kinase have been reported to enhance cardiac contractility, restore pump function, and increase cell survival in a rat model of postinfarction cardiomyopathy [216,217]. However, a more direct approach to rescue failing cardiac myocytes may be to inhibit apoptosis through a blockade of caspase activation [218]. Ischemia and oxidative stress are the major mechanisms of tissue injury. The heme oxygenase system is a regulator of endothelial cell (EC) integrity and oxidative stress. Direct delivery of the cytoprotective heme oxygenase gene into the rat myocardium using AAV has been reported to protect the myocardium from ischemia/reperfusion injury in rat [219]. Myocardial ischemia is the most common cause of CHF and enhancement of myocardial perfusion could improve myocardial dysfunction. Ad-VEGF₁₂₁ treatment has been reported to enhance myocardial function in a swine model of pacing-induced heart failure [220].

An interesting development in treatment of heart failure is the use of biological pacemakers. Although electronic pacemakers have been used to manage symptomatic bradycardia, implantable devices are associated with multiple complications. In recent years, gene and cell therapy approaches have been explored to replace or complement electronic devices with biological pacemakers to treat sick sinus syndrome or atrioventricular conduction block [221]. There are three strategies: gene transfer to existing cardiomyocytes; cellular transplantation; and delivery of genetically modified cells to the heart. The normal cardiac rhythm originates in the sinoatrial node in the right atrium. Proper pacemaker function is encoded by the hyperpolarized-activated cyclic nucleotide-gated channel (HCN) gene family, whose gene products generate the current. Ad-mediated gene transfer of synthetic HCN into the left ventricular myocardium has been reported to induce pacemaker activity with spontaneous action potential oscillations in myocardium [222–224]. Long-term studies with AAV or integrating viral vectors are clearly needed to evaluate its effectiveness. Much remains to be learned at the preclinical level and fine tuning of this approach is necessary before clinical trials are designed.

35.6 CELL THERAPY FOR MYOCARDIAL INFARCTION

Prolonged interruption of myocardial blood flow initiates events that lead to the cumulative loss of cardiac myocytes. MI, ischemic cardiomyopathy, and CHF remain the predominant causes of morbidity and mortality throughout the world. Currently, no medication or procedure has shown efficacy in replacing damaged myocardium. Therefore, reports suggesting that the transfer of BM cells could regenerate infarcted myocardium and improve cardiac function by neovascularization have generated tremendous excitement [7,8]. All studies of cell transfer into damaged cardiac tissues in small animal models have reported beneficial effects. However, how those transplanted cells repair the damage has not been fully determined [225]. The initial suggestion for trans-differentiation of donor BM cells into myocardium [7] has been supported by evidence of phenotypic conversion of progenitor cells [226–228], while others failed to demonstrate this phenomenon [229–231].

In contrast, cell fusion is a well-recognized phenomenon in several tissues [232–234]. Another potential mechanism for repair of damaged cardiac muscle is cell integration, which refers to the ability of certain cell types to integrate into the cardiac syncytium without transdifferentiation into cardiomyocytes [232,235]. Whether there is true functional integration or a paracrine effect by transplanted cells requires further study. Transplanted cells may secrete various cytokines, chemokines, and growth factors, which could indirectly promote survival of cardiomyocytes, mobilization of endogenous progenitor cells, or neovascularization [236–240]. Although the prospect of regeneration of cardiac tissues is exciting, so far animal studies have challenged the idea that BM cells can

generate cardiomyocytes efficiently [229,231] and clinical studies have shown that only a small fraction of infused BM cells are retained in the heart [241].

Strauer et al. used catheter-based intracoronary administration of autologous BM cells in patients with acute MI [242]. The results of this study and other small studies using similar methods were encouraging [243–245]. In the REPAIR-AMI (Reinfusion of Enriched Progenitor Cells and Infarct Remodeling in Acute Myocardial Infarction) trial, Schächinger et al. reported a significant improvement of left ventricular ejection fraction (LVEF) 4 months after cell infusion by angiography. The benefit was greatest in patients with the worst LVEF at baseline [245]. However, three randomized trials in LVEF have been disappointing [246–248]. The bone marrow transfer to enhanced ST-elevation infarct regeneration (BOOST) trial reported that the improvement in LVEF seen at 6 months after cell infusion was no longer significant at 18 months [247]. Lunde et al. also did not find a significant improvement in LVEF 6 months after infarction [248]. In the TOPCARE-CHD trial (transplantation of progenitor cells and recovery of LV function in patients with chronic ischemic heart disease), Assmus et al. evaluated the transplantation of progenitor cells derived from BM cells or circulating progenitor cells (CPC) in patients with chronic ventricular dysfunction and reported a significant improvement in LVEF 3 months after treatment. Patients received BM cells had significantly greater effects than those who received CPC, but the benefit was modest [249].

35.7 CONCLUSION

Research in gene and cell therapy for cardiovascular disease has exploded in the last several years. Our knowledge of vascular biology and pathogenesis of cardiovascular diseases has identified many therapeutic targets. Despite encouraging proof-of-concept experiments and small-scale clinical trials, the early promise of efficacy has not been confirmed in large-scale double-blinded randomized clinical trials. Some of this failure is due to limitations seen in all gene therapy approaches. For gene therapy, the challenges remain to include vector systems, route of administration, pharmacokinetics, and immunity against both the vector and therapeutic gene. In cell therapy, sufficient understanding of biological processes leading to the disease may be lacking. Some key issues that must be addressed are cell types to be used, optimum dosing and timing, routes of administration, and suitable patient population. Our ultimate success or failure will rest on the clinical efficacy and the effects of treatment on mortality and morbidity.

36.1 INTRODUCTION

Gene therapy for cancer has generated great interest for nearly two decades and intensive experimental and clinical investigations are under way. In general, it comprises different technologies to deliver a cDNA of choice to cancer cells or to normal tissue for a variety of diagnostic and therapeutic applications. Based on the complex nature of cancer, these technologies are very heterogeneous, as demonstrated by a variety of concepts such as immunomodulation, the “suicide strategy” (i.e., transfer of the cDNA of a prodrug converting enzyme); gene replacement strategies like transfer of a tumor

suppressor or an antioncogene; viral oncolysis; antiangiogenic and antiproteolytic gene therapy; or the delivery of drug resistance genes into hematopoietic precursor cells. Many experimental approaches are now in clinical evaluation and more than 1280 trials have been published or initiated or are pending. More than two-thirds of these trials are directed against cancer. In the first part of this contribution, I have tried to summarize the current state of the art of the gene therapeutic vectors now available and review gene therapy principles strictly from the point of view of cancer therapy. In the second part, I have described experimental and clinical approaches for several types of cancer. The peculiarities of

the respective cancer types allow or require customized gene therapeutic approaches, particularly in a clinical setting.

This contribution cannot give a complete picture of all current gene therapy approaches and I apologize for any omissions. Cross-references to literature reviews and to the corresponding chapters in this book are given. Helpful tools for getting an overview of gene therapy trials are found at <http://www.wiley.co.uk/genetherapy/clinical/> at the Genetic Medicine Clinical Trials Database and at <http://www4.od.nih.gov/oba/RAC/GeMCRIS/GeMCRIS.htm>, a Web site provided by the NIH, Office of Biotechnology.

36.2 THERAPEUTIC PRINCIPLES

36.2.1 IMMUNOMODULATION

It has long been recognized that tumors exhibit to a certain extent of immunogenicity (Ottgen 1991). As demonstrated by several studies, the human immune system seems to respond to this immunogenicity by recognizing specific tumor antigens and, consequently, by mounting humoral and cellular responses. However, during cancer development, this response is only of limited intensity and duration (Pardoll 1994; Sahin et al. 1995). As the mechanisms that cancer cells use to escape detection by the immune system have been elucidated, many strategies have been developed to reconstitute an effective antitumor immune response. The tremendous increase in the knowledge of the immunobiology of cancer has made immunological approaches, e.g., immunomodulation, the most dominant strategy in cancer gene therapy during recent years (Blankenstein et al. 1996). In general, immunomodulation studies can be categorized according to (a) the target cells (tumor cells, host cells, T-cells, or antigen-presenting cells such as dendritic cells [DCs] or other cells); (b) the mode of gene delivery (which vector, *in vitro*, *ex vivo*, *in vivo*); or (c) the transferred transgenes (cytokines, costimulatory molecules, tumor-associated antigens). Four examples from the multiplicity of these approaches will be described in more detail.

One of the most attractive target cell types for genetic modification is T-lymphocytes. The application of cytokine-transduced tumor-infiltrating T-lymphocytes (TILs) (Rosenberg et al. 1990; Friedmann 1991; Merrouche et al. 1995; Riddell and Greenberg 1995) was among the earliest clinical protocols for gene therapy. More recently, T-lymphocytes have been the target for *ex vivo* genetic modification by cytokine gene transfer and for redirection by tumor antigen-specific T-cell receptors or chimeric receptor genes (extracellular domain: antigen binding, intracellular domain: cell signaling). They have also been isolated from genetically modified tumors or their draining lymph nodes (Greenberg 1991; Yee et al. 1996; Rosenberg 1997). Other approaches enhance T-cell reactivity with antibodies that are targeted directly at the respective receptors on T-cells (Leach et al. 1996; Melero et al. 1997). These approaches are complemented by different methods to enhance antigen recognition on the surface of tumor cells.

Another immunologic approach to generate a local inflammatory response is the use of short-range communications

between immune and nonimmune cells. Cytokine-transfected tumor cells or fibroblasts are transferred, which are then supposed to directly activate specific as well as nonspecific immune cells. In this context, the continuous local release of cytokines has been shown to increase the therapeutic index. Additionally or alternatively, costimulatory molecules can be transferred. In tumor cells where major histocompatibility complex (MHC) class I or class II molecules or costimulatory molecules such as HLA-B7 are downregulated, the transfer of the corresponding wild-type cDNA can reactivate antigen recognition on the surface of the transduced tumor cells.

During the last decade, many tumor-derived antigens have been defined. These became a very interesting target for gene transfer approaches (van der Bruggen et al. 1991). In addition to applications of the corresponding peptides, some of these antigens have been transferred by viral vectors or as naked DNA either directly to the tumors or via DCs, evoking an immune response against the tumor. Detection of new tumor antigens with new powerful methods, such as serological analysis of tumor antigens by recombinant expression (SEREX) cloning (Sahin et al. 1995, 1997) or methods for detection of differential gene expression such as microarray technologies, hold great promise for the future.

Finally, antibody-based immunotherapy should be mentioned in this context (Riethmuller et al. 1994), particularly since recombinant antibodies have finally shown marked clinical benefit. The underlying concept of this strategy is to raise monoclonal antibodies against soluble tumor antigens or against antigens that are expressed on the surface of the malignant cells or on the tumor stroma. A cancer gene therapeutic use of antibody genes is probably only a matter of time.

36.2.2 PRODRUG CONVERTING ENZYMES (SUICIDE STRATEGY)

The suicide strategy in oncology combines classical cytotoxic chemotherapy with gene transfer technology. The underlying concept is to limit the action of a known cytotoxic drug to the local area of the tumor lesion. To this end, the cDNA of a prodrug converting enzyme is delivered into the tumor by a vector system of choice. This is followed by regional or systemic application of the corresponding nontoxic prodrug. Once the prodrug reaches the tumor and is taken up by the tumor cells, which express the prodrug converting enzyme, it is converted into the cytotoxic drug. In conventional chemotherapy, toxic and myeloablative side effects can be dose-limiting. In contrast, when using the suicide gene concept, the cytotoxic effects of the converted drug are mainly restricted to the area of tumor infiltration and the time of action is limited to the presence of the cancer cells expressing the prodrug-converting enzyme. In addition, the efficacy of the suicide strategy is enhanced by the "bystander effect." This molecular mechanism allows the killing of even uninfected tumor cells in the neighborhood of infected cells due to intercellular communication mediated by gap junctions (for example). However, this mechanism is still not fully understood. There are many different prodrug-converting enzymes under experimental or clinical

investigation. For a more detailed overview of the application of the suicide strategy in cancer gene therapy, please see *Gene and Cell Therapy* (Chapter 25).

The prodrug-converting enzyme most often used for clinical purposes is the herpes simplex virus thymidine kinase gene (HSV tk). The enzyme tk phosphorylates the prodrug ganciclovir (GCV) to GCV-monophosphate, which is then further phosphorylated to toxic GCV-triphosphate. Inhibition of the DNA polymerase by GCV-triphosphate finally leads to cell death. As demonstrated in various studies, tumor eradication has been achieved even if only 10% of the tumor mass is transduced (Moolten et al. 1990). This effect is probably due to a very potent bystander effect. In preclinical animal experiments, a vector carrying the HSV tk gene is usually applied intratumorally. In several reports using immunocompromised animals, a reduction of tumor volume of more than 50% of the controls was achieved in various experimental settings and even complete remissions were frequently observed. In addition to these experimental studies in immunocompromised animals, reports in immunocompetent animals suggest that the immune system may play a supportive role in the efficacy of this approach (Barba et al. 1994). Promising results of tumor growth inhibition are not without side effects induced by the HSV tk system. Using an *in vivo* model of adenovirus-mediated gene transfer to the liver of mice and rats, liver toxicity was observed due to unwanted transduction of normal tissue (Brand et al. 1997). This can be eliminated either by targeted vectors or tissue-specific gene expression (Brand et al. 1997, 1998).

As in other gene therapy strategies, the capability of the suicide strategy to kill cancer cells in experimental and clinical studies is limited by overall low efficacy of gene transfer *in vivo*. This is probably the main reason for the overall limited clinical efficacy of the suicide strategy in several phase I, II, and III clinical trials for several types of cancer. Even with the most efficient vector systems, direct intratumoral vector application only leads to a partial transduction of tumors with a nonhomogenous intratumoral vector distribution. Consequently, low antitumor efficacy is seen, particularly in humans who present much larger tumor burdens than rodents in a typical laboratory situation. Vector distribution could, however, be improved by changing the anatomical route of vector application (intravesical, intraperitoneal, intrathecal, intraventricular, repeated, and bulk flow); through the use of conditionally replication competent vectors (see *Gene and Cell Therapy* (Chapter 8)); by enhancing the bystander effect through the transfer of connexins, which increase the number of gap junctions; and by receptor targeting (see *Gene and Cell Therapy* (Chapter 4)).

36.2.3 TUMOR SUPPRESSOR GENES AND ANTI-ONCOGENES

During the last decade, an increasing number of genes has been identified, which become dysregulated during carcinogenesis. During a complex and multifactorial process leading ultimately to the macroscopic presence of cancer, genes

become dysregulated by different molecular mechanisms including gene deletion, mutation, or promotor silencing. At the end of these processes of genetic alteration, which result in activation or inactivation of multiple genes, the cancer cell proliferates in an uncontrolled fashion. It is not able to go into apoptosis and achieves invasive potential. Genes promoting these processes, like oncogenes, become activated. Genes suppressing the processes, like tumor-suppressor genes, become inactivated.

Current approaches in this area include the inactivation of overexpressed oncogenes by antisense molecules or dominant negative mutants or, alternatively, the reconstitution of cells with tumor suppressor genes, which have been lost or have mutated. The rationale is not so much the reversion of tumor cells back into normal cells. This task would be difficult to solve because more than one mutation is usually acquired by the tumor cell during the transformation process. The aim is rather to define the weak point in the cell's regulatory balance and consequently to identify the gene or combination of genes, which would have the highest impact on the exertion of cell cycle arrest or better apoptosis. To this end, it is of crucial importance to acquire a sufficient understanding of the cell's balance with respect to signal transduction, cell cycle regulation, and finally susceptibility to apoptosis. The targeting of the genes known to be dysfunctional in the respective tumor is usually the most efficient procedure. In some cases, a combination of several genes could increase specificity and efficacy. The main obstacle to this therapeutic approach is the need for a particularly high gene transfer efficacy. Although a mild bystander effect has been reported in the context of p53 gene transfer (Bouvet et al. 1998), a high-transfer efficacy is usually necessary for eradication of tumors—at least in those cases where the immune system as an adjuvant is not dramatically activated. Such high-transfer efficacies are the exception with current vectors. Therefore, a breakthrough for this highly tumor-specific approach particularly depends on future vector development. Among several tumor suppressor genes, which have shown *in vivo* efficacy, p53 has made it into the clinic and is discussed in more detail (e.g., in Section 36.4.8). Besides proapoptotic bax (Bargou et al. 1996) and bcl-x_s (Ealovega et al. 1996), caspases (Shinoura, Saito et al. 2000), PTEN and BRCA1, those genes involved in the regulation of the G1 phase of the cell cycle have been evaluated particularly closely in animal experiments. Tumor growth could be inhibited by transfer of wild-type and truncated pRb (Riley et al. 1996; Xu et al. 1996), which in its active form binds E2F-1 and prevents entry into S-phase, as well as by the cdk/cyclin inhibitors p16 (Jin et al. 1995; Sandig et al. 1997) and p21 (Yang et al. 1995), which mainly keep pRb in its hypophosphorylated, active state. It remains to be shown whether cell cycle arrest is sufficient for therapy of established tumors or whether a strong induction of apoptosis as sometimes seen by transfer of p16 and p27 (Jin et al. 1995) is required. Undoubtedly, restoration of tumor cells with p53 or p21 can increase the sensitivity of cells to radiation (Gallardo et al. 1996; Spitz et al. 1996; Chang 1997) and chemotherapy (Fujiwara et al. 1994; Li et al. 1997; Skladanowski and Larsen 1997; Blagosklonny and El-Deiry

1998). Also, combinations of tumor suppressor genes could prove to have overadditive tumoricidal effects as has been shown for the combination of p53 and p16 (Sandig et al. 1997).

Gene therapy—directed against oncogenes or apoptosis suppressors like bcl-2 or bcl-x₁ has targeted several types of cancer and several clinical trials are under way. These are discussed in more detail in Section 36.4 and in Chapter 42. The antioncogene approach is in principle supported by the recent success of small-molecular inhibitors of oncogenes: inhibitors of the epidermal growth factor (EGF) receptor, the Rat sarcoma (RAS) pathway, and the ABL gene (Gleevec). Gene therapy has the potential to compete with small molecules because small molecules still efficiently target only enzymes and receptors whereas transdominant antioncogenes, antisense oligonucleotides, and (recently) the very promising RNA-interfering nucleotides (Borkhardt 2002; Brummelkamp et al. 2002) can inhibit virtually any oncogene of relevance.

36.2.4 TUMOR LYSIS BY RECOMBINANT VIRUSES

Since its early beginnings, cancer therapy by viral oncolysis has been one of the most challenging strategies to treat human malignancies (Kovesdi et al. 1997). The idea that viruses may be used as selective anticancer agents dates back almost a century (Dock 1904). In 1957, four years after the discovery of replicating adenoviruses, they were used in cancer therapy. Of patients with advanced cervical carcinoma receiving intratumoral or intra-arterial injections of wild-type human adenoviruses, 65% had a marked to moderate local tumor response and only three patients on steroids out of 30 patients had a viral syndrome of short duration (Smith 1956). The underlying concept of this strategy is to inject the virus directly into the tumor, leading to the transduction of a certain number of cells in which viral replication takes place. Consequently, the infected cells are finally disrupted and viral progeny are released, allowing the spread of the infection and an increase in transfer efficacy. Interest and research in this area of molecular biology has exploded, and the available virus production techniques and purification techniques have been markedly improved. Thus, much larger amounts of adenovirus can now be applied. However, one of the major concerns has been how to limit the viral replication to the site of the tumor. One strategy to confer tumor-specific replication has been developed which utilizes the dependence of the replicating adenovirus on the genetic status of p53 in the infected host cell. Like many DNA viruses, adenoviruses have also developed specific gene products that seem to counteract apoptosis-inducing molecules like p53. Among the adenoviral genes, the E1B 55 kD gene blocks p53, the best known inducer of apoptosis and indirect inducer of cell cycle arrest. In an intriguing approach (Bischoff et al. 1996), the E1B gene was deleted from the adenoviral genome, allowing viral replication only in p53-negative tumor cells but creating apoptosis upon viral infection in p53-positive normal cells (Bischoff et al. 1996; Heise et al. 1997). Since more than 50% of common solid tumors lack functional p53, this approach was thought to be widely

applicable. In the mean time, both the lack of replication in all p53-positive cells and the potent replication in all p53-negative cells (Hall et al. 1998; McCormick 2001) have been questioned. It seems that defects further down the p53 pathway, as well as functions of E1B55K independent from inactivation of p53, need to be taken into account. They may perhaps moderately limit the applicability of the approach. Independent of the outcome of this debate, this concept has already stimulated virologists and cancer biologists to develop further generations of conditionally replication-competent adenoviruses. Adenoviral E1A inactivates pRB, the well-known tumor suppressor and inducer of cell cycle arrest, and facilitates adenoviral replication by allowing cellular replication. In an approach similar to the one described above, E1A was mutated so as to no longer bind and inactivate pRb; this should lead to viral replication only in tumor cells, which typically have defects in the pRb pathway. This concept has been successfully applied *in vitro* and *in vivo* (Doronin et al. 2000; Fueyo et al. 2000; Heise et al. 2000).

Another way to achieve cancer-specific replication is through the use of tissue-specific or tumor-specific gene expression. The adenoviral E1A region, which controls viral replication through several mechanisms, was placed under the control of a tissue- or cancer-specific promoter instead of the E1A promoter. This approach allowed specific replication in the respective cancer cells and tumors when prostate-specific antigen (PSA) or probasin promoters (Rodriguez et al. 1997; Yu et al. 2001); TCF-responsive elements, which are preferentially activated in colon cancer; or the MUC1 promoter (which is active in breast carcinoma, Kurihara et al. 2000) were used to drive the E1A gene (Brunori et al. 2001).

Besides adenoviruses, other oncolytic viruses have been tested in animal models. Like adenoviruses, HSV, a neurotrophic DNA virus, directly lyses cells during viral shedding. First-generation HSV contains a 360 bp deletion in the tk gene; this seems to prevent replication in quiescent cells but allows replication in rapidly proliferating cells (Martuza et al. 1991; Jia et al. 1994). Second-generation viruses with additional mutations have been generated to increase tumor specific replication and reduce neurovirulence (Kirn 1999). Newcastle disease virus (NDV) is a chicken paramyxovirus associated with minimal disease in humans. Cytotoxicity for numerous human tumor cell lines and resistance of several human fibroblast lines have been reported (Reichard et al. 1992). The mechanism that causes tumor selectivity is not fully resolved but a failure to mount a protective interferon response may be causally involved. Tumor cell killing may involve virus replication and direct cell lysis or induction of tumor necrosis factor (TNF) secretion as well as increased sensitivity of tumor cells to TNF-mediated killing (Cassel and Garrett 1965; Lorence et al. 1988). Recently, a clinical trial of intravenous injection of NDV into 67 patients with solid tumors was published. Objective responses occurred at higher doses (Pecora et al. 2002).

Autonomous parvoviruses are DNA viruses with small genomes, which depend on helper viruses or specific cellular functions for replication. Their cytopathic effect seems to be dependent on DNA replication as well as on the expression of

nonstructural gene products and enhanced sensitivity to their effects (Kirn 1999).

In the future, the tremendous increase in knowledge in the field of tumor and virus biology can be used to create appropriate vectors. Several factors that potentially influence clinical efficacy have already been defined. Among these are (a) characteristics of the viruses, such as the size, the time between infection and lysis, as well as the number of virions produced or the induction of a humoral or cellular immune response and (b) characteristics of the tumor such as distribution of the vasculature or physical barriers to virus spread such as fibrosis. An example for how to surmount such a natural barrier is the demonstration that inactivation of particular adenoviral serotypes by preformed antibodies can be circumvented if other serotypes are used (Kass-Eisler et al. 1996).

36.2.5 ANTIANGIOGENIC AND ANTIPROTEOLYTIC GENE THERAPY

These types of gene therapies differ markedly from the majority of the other nonimmunologic gene cancer therapeutic approaches because the products of the delivered genes act extracellularly. This fact obviates the need to transduce the majority of tumor cells and even allows one to target normal tissue, which maybe easier to transduce than the tumor. In addition, these approaches are usually appropriate for long-term treatments. Therefore, the conventional demands of cancer gene therapy—high efficacy of gene transfer, acceptance of immunogenicity, and sufficiency of short duration of gene expression—are replaced by requirements more typical for the treatment of monogenetic disease. These include low immunogenicity of vector and transgene, long-duration gene expression, and achievement of at least threshold levels of gene product in the target tissue or in the blood.

Inhibition of angiogenesis has become a very promising target for cancer therapy. Advantages of targeting the growth of new blood vessels as opposed to other types of therapy include the avoidance of tumor cell resistance mechanisms, the broad and generally applicable mechanism, and easy access to targets within the vasculature. More than 20 endogenous inhibitors of angiogenesis and nearly as many stimulators, which can serve as targets for small inhibitory molecules, have been characterized (Scappaticci 2002). Interestingly, several standard chemotherapeutic drugs have been found to exert their antitumor effect in part through inhibition of angiogenesis.

There are over 80 antiangiogenic agents (proteins as well as small molecules) in clinical trials. In general, antitumor efficacy has been observed, although overall success rates have not lived up to expectations. One important reason is perhaps the choice of disease stage. Although antiangiogenic therapy will most likely be of highest efficacy at the early stages of tumor growth or metastasis, patients with excessive tumor burdens have been mostly treated so far.

Antiangiogenic gene therapy has not yet been tested in patients, but several preclinical experiments have shown promise (Scappaticci 2002). Among the first genes examined were the genes for the soluble form of endothelial cell receptor proteins, Tie2 and FLT-1. These proteins interact with the

angiogenetic factors angiopoietin-1 and vascular endothelial growth factor (VEGF), respectively. These genes were transferred *in vivo* or *ex vivo* and resulted in significant inhibition of tumor growth (Folkman 1998; Goldman et al. 1998; Lin et al. 1998). Other strategies include the transfer of antiangiogenic proteolytic fragments like angiostatin or endostatin, immunomodulatory genes with antiangiogenic properties like interferons and IL-12, or other molecules better known for other functions in the body like tissue inhibitor of metalloproteinases (TIMPs), p53, or p16.

There are several advantages of molecular therapy over direct application of the effector substance. Firstly, the use of targeted vectors allows increased intratumoral concentrations of antiangiogenic factors without the risk of potential side effects on wound healing, endometrial maturation, or embryo growth (Klauber et al. 1997). Secondly, the cost of gene delivery may be lower than prolonged protein therapy. Thirdly, experimental data suggest that effective antiangiogenic therapy requires the continuous presence of the inhibitor in the blood, which may perhaps be more efficiently achieved by gene therapy than by bolus protein therapy.

Antiangiogenic therapy itself is only in its infancy and the future development of this treatment modality will obviously have a large impact on the corresponding gene therapy approach. Because of its mainly tumorstatic nature, it seems likely that this form of therapy will have its main impact before or after surgery with a view to facilitating surgery and preventing recurrence of distant metastases, as well as in combination with conventional chemotherapy, radiotherapy, or immunotherapy.

Excessive degradation and remodeling of the extracellular matrix (ECM) is one of the hallmarks of cancer progression at nearly every step from the first breakdown of the basal membrane of a primary tumor up to the extended growth of established metastases. There are four known classes of proteases implicated in ECM turn over: matrix metalloproteinases (MMPs), serine proteinases, ADAMs, and the BMP1 family. The naturally occurring inhibitors of the MMPs, the four known TIMPs, and the inhibitors of serine proteases the PAIs have been preclinically evaluated for antitumor efficacy and are the most prominent examples of antiproteolytic gene therapy. Intratumoral injection of first-generation TIMP-2 adenovirus into subcutaneously growing tumors of mammary, colorectal, and bronchial origin reduced tumor size by 60%–80% as compared to the controls, and the incidence of lung metastases was reduced by 90% (Li et al. 2001). A similar efficacy was achieved by adenovirus-mediated transfer of TIMP-3 into subcutaneously growing melanomas (Ahonen et al. 2002). Systemic delivery of TIMP-2 by adenovirus application into the tail vein of immunocompetent mice bearing orthotopically implanted breast tumors resulted in 50% growth inhibition (Hajitou et al. 2001), and the intraperitoneal injection of TIMP-2-carrying liposomes for the treatment of spontaneously arising breast tumors allowed for a 40% size reduction and a dramatic reduction of the incidence of lung metastases (Sacco et al. 2001). An intraperitoneal approach was taken to treat peritoneally disseminated pancreatic cancer and adenoviral delivery of either TIMP-1 or TIMP-2

resulted in a 75%–85% reduction of tumor loads and a significant prolongation of survival (Rigg and Lemoine 2001).

A prevention of colorectal liver metastasis of up to 95% was achieved if Ad-TIMP-2 was injected into the tail vein of mice, leading to a preferential transduction of the liver with the antitumor gene (Brand et al. 2000). Administration of TIMP-2 vector to mice bearing established liver metastases resulted in a 77% growth inhibition. When this same concept of gene transfer into the host tissue was applied for the treatment of lymphatic liver metastases, adenoviral transfer of TIMP-1 reduced metastatic deposits by 93% (Elezkurtaj 2004). The peculiarity of this approach is the transfer of anticancer defense genes into the normal noncancerous tissue, which was termed the “impregnation” approach.

In contrast to these findings of a marked antitumor efficacy of TIMP-1, -2, and -3 with three different types of animal models and modes of vector administration, systemic transfer of TIMP-4 by intramuscular electro-adjuvated injection of naked plasmid for the prevention of orthotopically growing breast tumors resulted in a threefold increase in size and up to sevenfold increase in the incidence of primary tumors (Jiang et al. 2001). None of the cited papers has reported any TIMP-related toxicity. Mild and probably vector-related toxicity to the liver was occasionally seen when first-generation adenovirus was delivered systemically.

Transfection of tumor cells with PAI-1, an inhibitor of serine proteases, reduced metastasis. Treatment with adenovirus-mediated PAI-1 gene transfer reduced the growth of uveal primary tumors as well as the incidence of metastases (Andreasen et al. 2000). Similarly, gene transfer of PAI-2 had unequivocal antitumoral effects (Andreasen et al. 2000). In contrast and unexpectedly, transgenic mice overexpressing PAI-1 developed pulmonary metastases at the same rate as wild-type mice in a melanoma model (Ma et al. 1997). Even more paradoxically, PAI-1 knock-out mice displayed a dramatically reduced local invasion and tumor vascularization of transplanted malignant keratinocytes and administration of PAI-1 by adenoviral gene transfer restored invasion and associated angiogenesis (Bajou et al. 1998). These data indicate that anti-proteolytic therapy with PAIs, and to a lesser extent with TIMPs, can have dramatic antitumor efficacy but that paradoxical tumor-promoting effects can occur. Similar to the MMPs and TIMPs, the PAs and PAIs have been shown to display effects independent from the degradation of the ECM (Chapman 1997), which may be partly responsible for the unexpected findings. Therefore, increased knowledge of either protease/inhibitor system may help us to better understand the underlying mechanisms, resolve some unexpected findings, and to draw conclusions with therapeutic relevance.

36.2.6 DRUG RESISTANCE GENES
