PART I Delivery Systems and Therapeutic Strategies

Chapter 1 Retroviral Vectors for Cell and Gene Therapy	3
<i>Axel Schambach, Tobias Maetzig, and Christopher Baum</i>	
Chapter 2 Production of Retroviral Vectors: From the Producer Cell to the Final Product.....	17
<i>Pedro E. Cruz, Ana S. Coroadinha, Teresa Rodrigues, and Hansjörg Hauser</i>	
Chapter 3 Adenovirus Vectors for Gene Therapy.....	39
<i>Neil R. Hackett and Ronald G. Crystal</i>	
Chapter 4 Modified Adenoviruses for Gene Therapy.....	69
<i>Joel N. Glasgow, Akseli Hemminki, and David T. Curiel</i>	
Chapter 5 Helper-Dependent Adenoviral Vectors for Gene Therapy.....	87
<i>Nicola Brunetti-Pierri and Philip Ng</i>	
Chapter 6 Adeno-Associated Virus and AAV Vectors for Gene Delivery	115
<i>Barrie J. Carter, Haim Burstein, and Richard W. Peluso</i>	
Chapter 7 Therapeutic Gene Transfer with Replication-Defective Herpes Simplex Viral Vectors	159
<i>D. Wolfe, W.F. Goins, A.R. Frampton, Jr., Marina Mata, D.J. Fink, and J.C. Glorioso</i>	
Chapter 8 Oncolytic Viruses for Treatment of Cancer	193
<i>Mari Raki, Maria Rajacki, David Kirn, and Akseli Hemminki</i>	
Chapter 9 Lentiviral Vectors.....	207
<i>John M. Felder III and Richard E. Sutton</i>	
Chapter 10 Vaccinia Viral Vectors	245
<i>J. Andrea McCart and David L. Bartlett</i>	
Chapter 11 Baculovirus-Mediated Gene Transfer: An Emerging Universal Concept	263
<i>Kari J. Airene, Anssi J. Mähönen, Olli H. Laitinen, and Seppo Ylä-Herttuala</i>	

Chapter 12	Bacterial Vector in Gene Therapy.....	293
	<i>Ming-Shen Dai and Georges Vassaux</i>	
Chapter 13	Redox-Responsive Polymer-Based Gene Delivery Systems	309
	<i>David Oupický, Ye-Zi You, and Devika Soundara Manickam</i>	
Chapter 14	Polymers and Dendrimers for Gene Delivery in Gene Therapy.....	321
	<i>Ijeoma F. Uchegbu, Christine Dufès, Pei Lee Kan, and Andreas G. Schätzlein</i>	
Chapter 15	Receptor-Targeted Polyplexes for DNA and siRNA Delivery	341
	<i>Alexander Philipp and Ernst Wagner</i>	
Chapter 16	Electroporation of Plasmid-Based Vaccines and Therapeutics	363
	<i>Ruxandra Draghia-Akli and Amir S. Khan</i>	
Chapter 17	Magnetofection: Using Magnetic Particles and Magnetic Force to Enhance and to Target Nucleic Acid Delivery	379
	<i>Franz Scherer and Christian Plank</i>	
Chapter 18	Biolistic and Other Needle-Free Delivery Systems	405
	<i>Mark A.F. Kendall</i>	
Chapter 19	Optimization of Nonviral Gene Therapeutics.....	423
	<i>Nancy Smyth Templeton</i>	
Chapter 20	Photochemical Internalization: A Technology for Efficient and Site-Specific Gene Delivery	435
	<i>Anette Bonsted, Anders Høgset, and Kristian Berg</i>	
Chapter 21	Interactions in Macromolecular Complexes Used as Nonviral Vectors for Gene Delivery	443
	<i>Rudolf Podgornik, Daniel Harries, Jason DeRouchey, Hemult H. Strey, and V. Adrian Parsegian</i>	
 PART II Other Therapeutic Strategies		
Chapter 22	<i>In Vivo</i> Applications of Morpholino Oligonucleotides	487
	<i>Jeff S. Isenberg, William A. Frazier, and David D. Roberts</i>	
Chapter 23	Antisense Oligonucleotide-Based Therapeutics.....	497
	<i>C. Frank Bennett, Eric Swayze, Richard Geary, Scott Henry, Lloyd Tillman, and Greg Hardee</i>	
Chapter 24	Development of RNAi Therapeutics	523
	<i>Antonin R. de Fougères</i>	
Chapter 25	Suicide Gene Therapy	539
	<i>Nikiforos Ballian, Bert W. O'Malley Jr., and F. Charles Brunnicardi</i>	

Chapter 26 Selectable Markers for Gene Therapy..... 555
*Jean-Pierre Gillet, Chava Kimchi-Sarfaty, Shiri Shinar, Thomas Licht, Caroline Lee,
 Peter Hafkemeyer, Christine A. Hrycyna, Ira Pastan, and Michael M. Gottesman*

Chapter 27 Embryonic Stem Cells and Their Application in Regenerative Medicine and Tissue Engineering 581
Nicholas D. Evans and Julia M. Polak

Chapter 28 Polymeric Nano- and Microparticles for the Delivery of Antisense Oligonucleotides and siRNA 599
Elias Fattal and Giuseppe De Rosa

PART III Gene Expression and Detection

Chapter 29 Deliberate Regulation of Therapeutic Transgenes 619
Nuria Vilaboa and Richard Voellmy

Chapter 30 Monitoring Gene and Cell Therapies in Living Subjects with Molecular Imaging Technologies 637
Sunetra Ray, Sandip Biswal, and Sanjiv Sam Gambhir

Chapter 31 Nonviral Genome Modification Strategies for Gene Therapy: Transposon, Integrase,
 and Homologous Recombination Systems 677
Lauren E. Woodard and Michele P. Calos

PART IV Disease Targets and Therapeutic Strategies

Chapter 32 Hematopoietic Progenitor Cells 695
Kuan-Yin Karen Lin, Olga Sirin, and Margaret A. Goodell

Chapter 33 Gene Therapy for Hematopoietic Disorders 713
Elizabeth M. Kang, Mitchell E. Horwitz, and Harry L. Malech

Chapter 34 Use of Genetically Modified Stem Cells in Experimental Gene Therapies 731
Thomas P. Zwaka

Chapter 35 Cardiovascular Gene and Cell Therapy 737
Kazuhiro Oka

Chapter 36 Gene Therapy for Cancer 761
Karsten Brand

Chapter 37 Molecular Therapy for Type 1 and Type 2 Diabetes..... 801
Susan Leanne Samson, Vijay Yechoor, and Lawrence Chan

Chapter 38 Progress toward Gene Therapy for Cystic Fibrosis..... 817
Ruth S. Everett and Larry G. Johnson

viii	
Chapter 39	Gene Therapy for Neurological Diseases..... 833 <i>William J. Bowers, Suresh de Silva, and Howard J. Federoff</i>
Chapter 40	Principles of Gene Therapy for Inborn Errors of Metabolism..... 869 <i>Jon A. Wolff and Cary O. Harding</i>
Chapter 41	RNA Interference–Based Gene Therapy Strategies for the Treatment of HIV Infection 881 <i>Lisa J. Scherer and John J. Rossi</i>
Chapter 42	Cutaneous Gene Transfer: Cell and Gene Therapy of Skin and Systemic Disorders..... 889 <i>William Buitrago and Dennis R. Roop</i>
Chapter 43	Gene Therapy for Childhood Onset Blindness 913 <i>Matthew C. Canver and Jean Bennett</i>
Chapter 44	DNA Vaccines 921 <i>Jian Yan and David B. Weiner</i>
Chapter 45	Immunoisolation for CNS Cell Therapy 949 <i>Dwaine F. Emerich and Christopher G. Thanos</i>
 PART V Clinical Trials and Regulatory Issues	
Chapter 46	Cardiovascular Gene Therapy..... 975 <i>Jörn Tongers, Jerome G. Roncalli, and Douglas W. Losordo</i>
Chapter 47	Gene Therapy for the Treatment of Cancer: From Laboratory to Bedside..... 1001 <i>Gianpietro Dotti, Barbara Savoldo, Fatma Okur, Raphaël F. Rousseau, and Malcolm K. Brenner</i>
Chapter 48	p53 Tumor Suppressor Opens Gateways for Cancer Therapy..... 1019 <i>Mu-Shui Dai, Jayme R. Gallegos, and Hua Lu</i>
Chapter 49	Recombinant Adenoviral-p53 Agent for Treatment of Cancers..... 1033 <i>Zhaohui Peng, Qing Yu, and Jingya Zhu</i>
Chapter 50	Gene Marking Studies of Hematopoietic Cells..... 1057 <i>Catherine M. Bollard, Siok K. Tey, Malcolm K. Brenner, and Helen E. Heslop</i>
Chapter 51	Regulatory Aspects of Gene Therapy 1071 <i>Stephanie L. Simek and Lilia Bi</i>
Index 1087

Foreword

BIRTH AND INFANCY OF GENE THERAPY

Major and daring new developments in biomedicine and particularly in clinical studies are often circuitous and beset with the need to understand mechanisms of the inevitable setbacks to refine concepts, invent new tools, and set new directions. In the modern era of medical science, this was certainly true of indispensable modern therapeutic methods such as bone marrow transplantation, many aspects of cancer chemotherapy, the application of monoclonal antibodies to improved diagnosis and therapy, and many other fields. As these breakthroughs evolved from laboratory curiosities to effective therapies, there were long periods of setbacks and clinical failures, harm to patients so deep that at times paralyzed scientific investigation and fueled public doubts about the validity of the approaches. For instance, human clinical applications of bone marrow transplantation first appeared late in the 1950s but it was not until well into the mid-1970s that the survival rate of transplant patients with a variety of hematological diseases rose to above 1%–2%. Chemotherapy for the uniformly fatal childhood lymphocytic leukemia began in 1948 and has now achieved a cure rate of well over 80% or better. But such successes did not happen overnight, and it took more than 15 years or so before the cure rate climbed over 8%–10%. Diagnostic and therapeutic applications of monoclonal antibody methodology had a promising and even a splashy birth in the early 1970s but then virtually vanished for more than a decade because of failures and setbacks. It is only now assuming a prominent place in clinical application.

Although the concepts of human gene therapy emerged first early in the 1970s, it was not possible to apply these ideas readily to experimental testing let alone to human clinical use because of the paucity of well-developed efficient and safe methods of gene transfer. With the development of the retrovirus vectors in the early 1980s, the impetus for rapid delivery to human clinical needs became irresistible and human clinical studies began in 1989–1990. Over the next few years, to great fanfare and soaring expectations, many additional clinical studies were undertaken, many new vectors systems were developed, successes were often thought to be imminent, an entire new biotechnology industry was born, and claims were even made for clinical success.

We are all much wiser now and we realize the errors of those early days during which gene therapy was simplistically imagined to be straightforward. It was not to be, and we have learned and continue to learn the many ways in which the current tools available to us in the clinical setting for genetic attack on disease are still immature and in need of refining and a great deal of troubleshooting. But one cannot troubleshoot unless there is trouble, and of course there have been a number of very prominent adverse events in gene therapy—induction of childhood leukemia in the course of successful

treatment for childhood immunodeficiency, patient deaths in some studies, and abandoned clinical studies in the face of troubling setbacks with other disease studies. Based on the experience with transplantation methods for bone marrow and other organs, chemotherapy, monoclonal antibody technology, and many other aspects of modern medicine, we now should realize that such a history is to be expected and the expected evolution of difficult new technologies should not be interpreted to be a “failure,” as happens disturbingly often in the public media, some very influential members of which seem to have little understanding of the ways in which biomedicine progresses and apparently less of an appetite for learning and illuminating this history for the public.

Gene therapy must now be seen in historical terms to have taken a route from concept to unequivocal clinical success that is typical of new biomedicine. And there has been clinical success even with the admittedly imperfect tools so far available. Children with X-linked severe combined immunodeficiency (X-SCID) and adenosine deaminase deficiency-severe combined immunodeficiency (ADA-SCID) have received real therapy and most of these treated children, but sadly not all, are now leading normal childhood lives [1,2]. Therapy does not mean uncomplicated success in every case—no therapy promises or delivers this. Nevertheless, there is little doubt that additional clinical successes are imminent—forms of cancer, genetic and degenerative diseases of the eye, and others.

What is needed for the next phase for making gene therapy an established and broadly utilized method of treatment, not just occasional proof-of-principle clinical studies, but rather for far broader application for many more common human diseases? How can the still sparse clinical successes become treatments of choice for more of the human health scourges rather than occasional curiosities? One might begin to argue that the field has indeed achieved such a status, at least for diseases such as ADA-SCID and possibly X-SCID. But the needs are still enormous for most other target diseases. As is so thoroughly outlined in this book, a prime need is the development of ever more efficient, safe, and targeted methods of delivery of genes and other elements designed to modify expression of resident genes. We often pay lip service to the notion that there will be no magic bullet and universally useful vectors: there will be a need for many kinds of viral and nonviral vectors tailor-fit for specific clinical needs. But at the same time, we all can occasionally become so enamored with some systems even to the point of shifting developmental resources from important systems. For instance, there has recently been a palpable embrace of clinical applications of the adeno-associated virus (AAV) vector system as the most current promising one for many clinical applications. As important as that system is, resources for production and clinical application of other important delivery systems have been reduced far too much to the point of endangering important

development and early clinical trials with other vector systems. This lesson may have come all the more pertinent with the recent death of a patient in the United States who was suffering from severe but not immediately life-threatening rheumatoid arthritis and who was enrolled in a study using direct joint delivery of an AAV vector expressing an inhibitor of tumor necrosis factor alpha (TNF- α). The causes of death in this case [3] have not yet been clarified but the bulk of the current evidence points to the likelihood that the patient was already immunocompromised by other earlier and concomitant treatments, that she was thereby susceptible to the overwhelming opportunistic infection that was the immediate cause of her death, and that the AAV vector system or the transgene played little if any role in the adverse event. Although these are not yet proven, the tragic event does serve to remind us that we must not become complacent about the potential for disruption of important homeostatic systems from any gene transfer manipulation in human patients and experimental subjects and that even this vector delivery system, generally thought to be very safe, must be understood in greater detail than we presently do. And so we need better vectors.

Wide-scale gene therapy also would be greatly enhanced by a major effort to develop clinical applications for the powerful new methods for modifying endogenous gene expression with RNA interference methods, and for genetic sequence correction through zinc-finger or other site-specific recombination approaches rather than relying entirely on genome augmentation with foreign transgenes to complement aberrant functions. The recent discovery of the powerful and ubiquitous role of RNAs in regulating normal endogenous gene expression will enable many therapeutic approaches to disease treatment. These methods receive appropriately prominent discussion in this book.

Of course, possibly the most important element in making gene therapy more widely effective is the need to achieve a far deeper understanding of disease and its pathogenesis. In many cases, even for monogenic disease, we understand too little to devise the most powerful genetic means to intervene.

This book is an attempt to put together many of the technical advances in gene delivery, in new approaches to the

regulation and modification of gene expression, and in its clinical application. The underlying understanding of this volume is that the new intellectual achievement represented by gene therapy requires years and that the road toward that goal will not always be smooth. New technology is and will continue to be needed, if only it were otherwise, as in the case of Athena, the Greek goddess of so many areas of human intellect and work—wisdom, war, justice, the arts, industriousness, weaving, patroness of craftsmanship and diplomacy, inventor of the flute, and more. She had so very much to do and, amazingly, she was fully armed and prepared for all of her tasks even as she sprang at birth from the head of her father Zeus. She needed no period of learning; her tasks and her tools must have all been so clear and straightforward for her. Unfortunately, most human accomplishments are not as clearly defined and we usually require long periods of learning, errors, missteps, and relearning. Gene therapy is one such human endeavor and I am sure that Athena would have understood this and has been patient with us. Even so, we can all take great pleasure and pride in being present and even taking part in the birth and early rearing of this nascent field of medicine. Its future development will be exciting and important.

Preface

Since the publication of the first edition of this book in 2000, gene therapy and cell therapy clinical trials have yielded some remarkable successes and some disappointing failures. In many research laboratories, valuable insights have been gained that will enable us to overcome many of the difficulties encountered to date and to move these therapies toward routine use in the clinic. As with any new therapy, such as heart transplantation, many failures must be expected before treatment becomes routine. Long-term success requires that we rationally assess each failure and determine what additional knowledge is required to solve each problem we encounter. Once again, the authors of this third edition have provided thoughtful insights into the challenges that must be met for specific applications of gene and cell therapies.

The ongoing development of these therapies draws from many disciplines including cell biology, virology, molecular biology, medicine, genetics, immunology, biochemistry, physiology,

chemistry, biophysics, molecular imaging, microbiology, pharmacology, toxicology, and others. This book includes topics in each of these areas and has been planned to facilitate its ongoing use as a textbook for classes in gene and cell therapies and gene transfer. The chapters are written so that readers from all backgrounds including students, physicians, scientists, and other interested persons can understand the current status of gene and cell therapies and how these diverse disciplines contribute to these fields. Several contributors have broadened their introductions to facilitate use of this edition as an educational textbook and have contributed information to provide context for their focused research efforts. Hopefully, this volume will provide readers with a broad knowledge of the aspects and tools available in the evolving fields of gene therapy and cell therapy.

Nancy Smyth Templeton

Editor

Dr. Nancy Smyth Templeton obtained a PhD in molecular biology and biochemistry and had her postdoctoral stint at the National Institutes of Health, Bethesda, Maryland. Currently, she is a tenure-track assistant professor in the Department of Molecular and Cellular Biology, a member of the MCB graduate faculty, and a principal investigator. She also has a secondary appointment in the Department of Molecular Physiology and Biophysics and at the Center for Cell and Gene Therapy.

Dr. Templeton has created and patented novel liposomes for increased systemic delivery of nucleic acids at the NIH, a technology licensed by several companies, for research and for therapeutics. She has served on numerous review panels, study sections, professional committees, and also as an ad hoc reviewer for several peer-reviewed journals. She has edited two books and has 48 publications to her credit. She is a member of many professional societies and has presented over 137 seminars as an invited speaker or moderator including

national and international meetings. She is a consultant for several biotech and pharmaceutical companies and also has worked in biotech companies. She has worked through sponsored research agreements for several companies including her Baylor start-up company and has two issued patents and several patent applications submitted. Several investigators at the Baylor College of Medicine, the M.D. Anderson Cancer Center, and other institutions have been and will use Dr. Templeton's nonviral therapeutics in upcoming Phase I/Phase II clinical trials for the treatment of lung, breast, head and neck, and pancreatic cancers, and hepatitis B and C infections.

Dr. Templeton has also mentored numerous students, medical students, and postdoctoral fellows, and has taught classes for first-year medical students. She has also received two Fulbright and Jaworski Faculty Excellence awards in 2005 and in 2007 for creating enduring educational materials and for teaching and evaluation, respectively.

1.1 INTRODUCTION

Gene therapy is defined as the insertion of genes into an individual's cells and tissues, undertaken to treat or prevent a disease. Basically, gene therapy aims to reach two important goals:

1. Substitution for a defective or missing factor (e.g., factor IX or adenosine deaminase [ADA]) by introducing an intact copy of the faulty gene or ideally repairing it [1]. Instead of supplementing the missing factor (protein), gene therapy directly targets the molecular cause.
2. Introduction of a gene to modify the way a cell functions. For example, for the treatment of cancer, the therapeutic gene product can encode a potentially suicidal protein, which mediates sensitivity to a precursor substance (cytotoxic prodrug).

The simple treatment of cells with naked DNA is often not sufficient to reach efficient gene transfer. If the DNA can be introduced into a cell via a "gene shuttle," gene transfer is by far more efficient. Viruses represent naturally evolved shuttle systems for nucleic acids.

Gene transfer vehicles have been developed on the basis of retrovirus, adenovirus, adeno-associated virus, herpes virus, and many others [2]. Furthermore, various physical gene transfer systems have been established, e.g., the complexation of DNA with condensing and membrane traversing agents (liposomes and cationic polymers) [3].

However, most of these approaches mediate only temporary episomal gene maintenance and expression. The advent of episomally replicating DNA circles still has to demonstrate its potential for persisting therapeutic genetic modification of somatic cells with a high replicative potential [4,5]. In contrast retroviral vectors have the ability for stable integration into the host cell genome and allow long-term expression, so that theoretically a single administration could have a sustained, potentially even, lifelong curative effect [6].

The first clinical gene therapy study using a retroviral vector was initiated in 1990, undertaken to introduce the ADA gene into T-lymphocytes from patients with ADA deficiency [7–9]. Now in the year 2007, over 1300 clinical protocols have been approved worldwide. In close to one quarter of these studies retroviral vectors have been used (overview in <http://www.wiley.co.uk/genetherapy/clinical/>).

First trials targeting hematopoietic stem cells (HSCs) have been successfully conducted and proven clinically benefit for the patients as shown for X-linked severe combined immunodeficiency (SCID-X1), ADA-dependent SCID (SCID-ADA) [6,8,10], and chronic granulomatous disease (CGD) [11]. Promising approaches in adoptively transferred T cells are also emerging [12,13]. At the same time, evidence for dose-limiting side effects of retroviral gene delivery into HSCs has been obtained in animal models and clinical trials [11,14–18]. Previously anticipated to be a finite risk of minor importance [19], cancer induction by random insertion of vectors in the vicinity of cellular proto-oncogenes, resulting

in their upregulation, now represents a significant concern associated with retroviral gene delivery. In this somewhat heated situation, the present chapter explores basic principles of gammaretroviral vector design and avenues for future research. Gammaretroviral vector production and lentiviral vectors are covered in different chapters of this book.

1.2 RETROVIRUSES AND THEIR LIFE CYCLE

Retroviruses are lipid-enveloped viruses. Each particle's capsid harbors two copies of a linear, plus-stranded RNA genome in the size of 7–11 kb. The family *Retroviridae* contains various viruses that have shown potential utility for gene therapy, such as the mammalian and avian type C retroviruses (gammaretroviruses, e.g., murine leukemia virus [MLV]), lentiviruses (e.g., human immunodeficiency virus type 1 [HIV-1]), and spumaviruses (e.g., foamy virus) [20].

Retroviruses share significant similarities in their virion structure, genomic organization, and method of replication. For the development of retroviral gene transfer vectors, the understanding of retroviral replication was a fundamental prerequisite. Section 1.3 explains the replication of MLV (Figure 1.1).

Infection with a retrovirus starts with the recognition of a surface receptor (e.g., for ecotropic MLV this is mCAT1, a cationic amino acid transporter) allowing fusion with the cell membrane or receptor-mediated endocytosis. Entry then proceeds with the uncoating of the viral particle, a still mysterious process whose exact mechanism remains to be defined. A ribonucleoprotein (RNP) complex composed of viral and cellular proteins with yet unknown structure is released into the cytoplasm. At this or a later stage in the cytoplasmic journey, retroviral RNA may be released and subject to immediate translation. While this early release and translation of retroviral mRNA clearly represents a byproduct of the retroviral life cycle, it may nevertheless be of interest as a tool for transient cell modification [21].

The paradigmatic use of retroviral vectors, however, results from their ability to deliver integration-competent DNA into cells. This occurs as follows: Still associated with the capsid, the viral RNA is reverse transcribed into linear double-stranded DNA by the retroviral enzyme reverse transcriptase (RT). For reverse transcription to be initiated and completed, several motifs are required on the retroviral RNA. The most important ones are the primer binding site (PBS), where a cell-derived tRNA serves as the primer for the RT-polymerase,

FIGURE 1.1 Retroviral life cycle as shown for a simple gammaretrovirus. After receptor binding the virus fuses with the target cell (or may be endocytosed), and the RNP complex is released into the cytoplasm. The RT performs the synthesis of double-stranded DNA, and the arising preintegration complex (PIC) gains access to the nucleus (most efficient during mitosis). The viral integrase (IN) catalyzes the integration into the host cell genome. The integrated viral DNA is called provirus. After transcription the viral mRNA is exported to the cytoplasm. Unspliced RNAs encode for the structural proteins (gag), replication enzymes (pol), and spliced RNAs for the envelope (env) proteins. Genomic viral mRNA and the translated gag, pol, and env proteins are transported to the plasma membrane, where virus assembly and budding are initiated. The fully infectious virion is created by proteolytic rearrangements. In the right upper corner an (enlarged) mature virus with its RNA genome, nucleocapsid, RT, IN, protease, spherical capsid, matrix, and envelope proteins is shown.

and the polypurine tract (PPT) which primes synthesis of the second DNA strand by forming an RNA hairpin that is resistant to the RNaseH activity of RT. The complex steps of reverse transcription are further supported by the sequence homology of the R-region that builds both start and end (if we ignore the polyA tail) of the retroviral genomic RNA, and may involve intra- and intermolecular jumps of RT. The two strands of RNA present in the same virion may thus support recombination events. Furthermore, a mutation rate of about 1 in 10kb processed bases is a typical outcome of reverse transcription.

The product of reverse transcription remains associated with some viral proteins (most notably the IN) and various cellular proteins to form the so-called PIC. In the various steps between entry and formation of the PIC, several host factors may block retroviral replication as part of an innate immunity against retroviruses. Factors targeting capsid sequences encoded by gag (such as TRIM5 α) may be responsible for major species-specific differences in retroviral infectivity [22]. The NB-tropic MLV gag sequences are unrestricted in both rodent and human cells and used in all major MLV-based gene vector systems, allowing relatively straightforward dosing studies in the murine model.

Intracellular transport of the PIC follows the cytoskeleton along the highways of the cells, the microtubules, and is dependent on host proteins [23]. Gammaretroviral PICs cannot actively cross nuclear membranes, possibly by missing a linker molecule to the nuclear import machinery. Only breakdown of the nuclear membrane during mitosis exposes the chromosomes to the PIC [24]. Having encountered host DNA, the viral IN incorporates the linear DNA into the host cell genome. Prior to integration, circular forms of the retroviral DNA may be formed to result in so-called 2-LTR-circles and 1-LTR-circle. Having lost the ability for IN-mediated integration, these circles typically represent dead ends of the retroviral life cycle. In the context of lentiviral vectors that are able to transduce resting cells, these unintegrated circular forms become increasingly popular for sustained cell modification [25,26]. In replicating cells, the long-terminal repeat (LTR) circles are expected to be lost during mitosis because they lack the capacity for chromosomal attachment.

Integration of the retroviral DNA into cellular chromosomes is highly efficient, occurs without major structural modifications of the neighboring cellular sequences, and does not form transgene concatemers, but is untargeted. Somewhat dependent on its location in the genome and the associated chromatin context, an integrated provirus may serve as an efficient gene expression cassette. The transcriptional control elements are largely contained in the LTR. Both LTRs contain enhancer sequences that may interact with neighboring promoters. Although the LTRs are sequence identical, their role in gene expression is different. The 5'LTR typically serves as the promoter for the polymerase II complex while the 3'LTR provides transcriptional termination and polyadenylation signals. The exact mechanisms regulating the differential utilization of the promoter and termination signals remain to be elucidated. The most likely explanation is read-through

suppression of the 3' promoter by the transcript originating in the 5'LTR, and suppression of the 5'LTR-located polyadenylation signal by its proximity to the transcriptional start site (TSS) [27].

All replication-competent retroviruses have open reading frames (ORFs) that harbor the structural proteins (gag), the replication enzymes (pol), and the viral glycoproteins (env). The simple gammaretroviruses have only one primary transcript, which serves as genomic and messenger RNA (mRNA) for the viral gag and pol proteins. The viral glycoproteins are synthesized from a spliced mRNA, formed by a splice donor (SD) located shortly behind the PBS and a splice acceptor (SA) that is found in the downstream sequences of pol. The recognition of these sequences is incomplete, allowing the coexpression of unspliced and spliced RNA. Suboptimal consensus sequences and, in the case of MLV, SD suppression by a complex RNA secondary structure have been identified as the mechanisms underlying partial splicing [28,29]. The spliced intron corresponds to the gag/pol coding sequence. In gammaretroviral vectors, the intron can be reduced to the size of the packaging motif [28,30].

Gag and pol are synthesized as polyproteins from the cytosolic ribosomes. The viral env glycoproteins are translated at the rough endoplasmic reticulum, and transported and processed via the vesicular transport pathway. Gag self-assembles in close proximity to the cellular membrane. In the assembly process preferentially those mRNAs are packaged that carry the packaging signal ψ , mediated by specific interaction with the nucleocapsid domains of gag. Another nucleic acid to be incorporated to sustain the life cycle is a tRNA that matches the PBS. As mentioned above, this tRNA is a gift of the host cell, not encoded by the viral genome.

Freshly synthesized env represents a protein precursor for a bipartite transmembrane protein. The env precursor is incorporated during budding of the viral particle as part of the membrane coat. After virus release has taken place at the cell membrane, extracellular conversion to the mature, infectious virion follows. Virion maturation thus only occurs after budding and involves cleavage of the viral polyproteins into functional subunits by the viral protease (for further reading see [31]). Targeted proteolysis thus generates four distinct proteins out of gag (matrix, p12, capsid, nucleocapsid), three out of pol (protease, RT, and IN), and two out of env (surface and transmembrane part). The necessity for particle maturation in the extracellular phase of the life cycle is one principle by which self-superinfection of a retrovirally infected cell is avoided. The second principle is the saturation of the env receptor by de novo synthesized env proteins. Blocking self-infection is an important goal in the design of retroviral packaging cells, to avoid the accumulation of potentially recombined proviral vector copies [32].

1.3 RETROVIRAL VECTORS AND SPLIT PACKAGING DESIGN

To take advantage of the retroviral life cycle for vector development, one would need to include a foreign gene, if possible

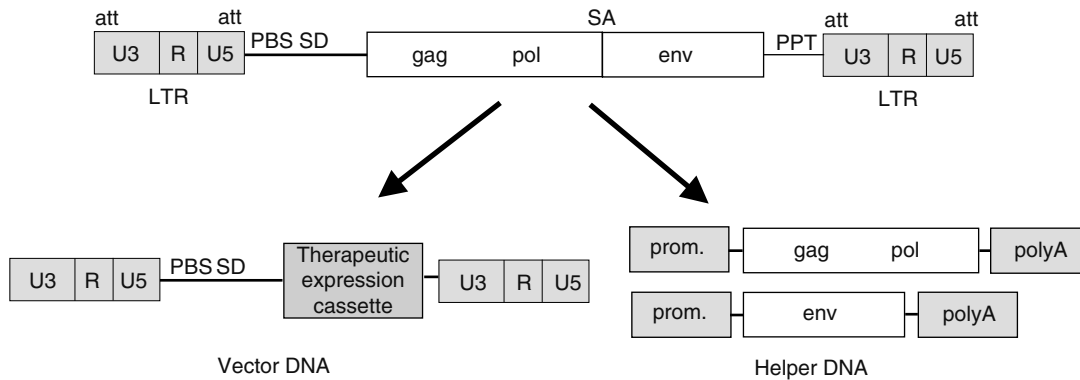

FIGURE 1.2 Split-packaging design. A strategy for engineering a virus into a vector. The general genome organization of a simple retrovirus is shown above with the LTRs (LTR, with U3, R, and U5 regions), the PBS, splice signals (SD, SA), the packaging signal ψ , the PPT, and the attachment signals of the IN (att). ORFs for the structural proteins (gag), replication enzymes (pol), and the envelope glycoproteins (env) are indicated. To construct a (replication-deficient) gene transfer tool, the cis-acting elements (LTR and leader region) and the ORFs for gag, pol, and env are divided on separate plasmids (vector DNA and helper DNA). Gag, pol, and env are encoded by helper plasmids (prom., promoter; polyA, polyA signal) that can be delivered as a single molecule or split into different DNA molecules for safety reasons. The helper DNA lacks the packaging signal (ψ) and thus cannot be packaged into a viral particle. The vector DNA contains the therapeutic expression cassette, flanked by the LTR. It harbors a packaging signal (ψ) for efficient packaging into the viral particle.

along with its regulatory sequences, into the virus genome and, at the same time, prevent viral gene expression and disable viral replication. To achieve this goal, the retroviral coding sequences have to be removed, which creates at least 6kb space for the transgene of interest. If the cis-acting sequences required for nuclear export of unspliced RNA, assembly, reverse transcription, and integration are all preserved, this operation may result in a very efficient replication-deficient vector (Figure 1.2). These cis-acting sequences comprise the R-region stem loop (RSL), the packaging signal (ψ), the PBS, the PPT, and those parts of the LTR that are essential for reverse transcription and integration (R, U5, and small “attachment” sequences located in the beginning of U3 and the end of U5) (Figure 1.3). Further enhancing vector

safety, designer PBS sequences may be incorporated that match only artificial tRNAs, which need to be expressed from transgenic sequences in packaging cells [33].

The viral structural proteins (gag) and replication enzymes (pol) as well as the envelope (env) glycoprotein are encoded on separate helper plasmids which should avoid any sequence overlap with the transfer vector. Typically gag-pol is expressed from one plasmid and env from another. In the case of MLV, this is easy to achieve as the minimal cis-elements necessary for vector construction do not overlap with the coding sequences [28,30].

This so-called split-packaging design makes recombination back to a replication-competent retrovirus a very unlikely event and thus contributes to biosafety. However, still used in

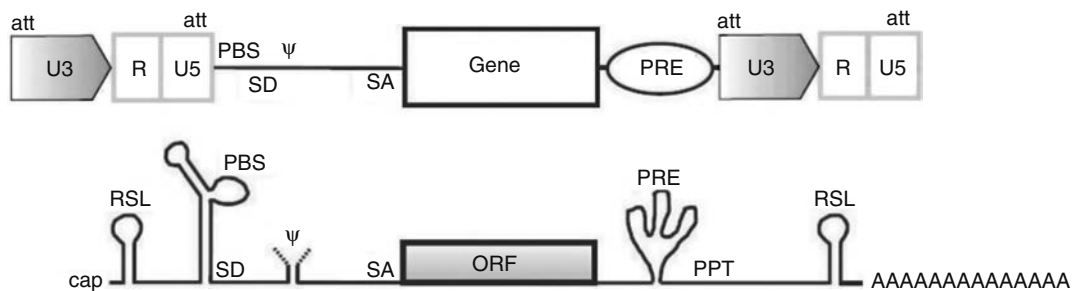

FIGURE 1.3 LTR-driven retroviral vectors. The schematic view of an LTR vector (compare Figure 1.2) and its corresponding RNA (below) is given. Several cis-acting elements and stable RNA secondary structures are depicted. Within the R-region of the LTR a stable stem-loop structure was mapped (RSL; [110]), which is thought to increase cytoplasmic RNA levels. The intron, located in the leader region (SD, SA) and surrounding the packaging signal ψ may further enhance cytoplasmic RNA levels. The PBS is embedded in another stem-loop structure originating in the U5. Furthermore, the woodchuck hepatitis virus posttranscriptional regulatory element (PRE), which is located in the 3'UTR enhances retroviral RNA levels by increasing mRNA stability, export and polyadenylation. ORF, open reading frame.

FIGURE 1.4 Production of viral particles and transduction of target cells. Production of infectious retroviral particles from a packaging cell line, transfected with a plasmid encoding the retroviral vector using the calcium phosphate method or lipofection. The packaging cell line (often derived from 293 T cells) provides the viral proteins which are either introduced via stable transfection (e.g., Phoenix cells, Nolan Lab, Stanford) or transiently cotransfected together with the retroviral vector. The vector encoded packaging signal ψ is recognized by the nucleocapsid proteins and allows the specific packaging of the retroviral RNA (including the transgene sequence). Infectious particles are released from the cell membrane (i.e., budding, left electron microscopy picture; full particles right; pictures kindly provided by Dr. G. Rutter, Hamburg). The cell culture supernatant—containing the viral particles—is harvested, filtered, and transferred onto target cells. Retroviral particles enter the target cells through interaction with a specific membrane receptor. After uncoating, the viral RNA is reverse transcribed into DNA. The DNA reaches the nucleus and is integrated into the host cell genome. Because of the lack of other viral structural proteins, no new infectious particles can be generated. Transgene expression can be monitored by standard techniques, including northern and western blot, real-time PCR, ELISA, FACS, and immunofluorescence.

many laboratories are early generations of gammaretroviral vectors that do not provide a strict separation of vector and helper sequences. When using such constructs, the occasional generation of replication-competent recombinants is an expected outcome.

Replication-incompetent viral particles can only perform a “single-round” infection of the target cell (Figure 1.4). The viral structural proteins recognize the ψ -containing vector RNA, but not the helper (ψ -deficient) nucleic acid, resulting in the packaging of the vector genome into an infectious particle. After entry of the particle into the target cell, only the vector nucleic acid is reverse transcribed and can integrate into the genome of the target cell. Since neither structural proteins nor replication enzymes are encoded by the target cell, the generation of replication-competent virus is prevented. A potential advantage of gammaretroviral vectors is that no exogenous human retrovirus has been described so far that is able to mobilize vector mRNA for infection of other cells or organisms.

Production of gammaretroviral vector particles can be achieved after transient cotransfection of the helper plasmids

with a plasmid encoding the transfer vector, or using stable packaging lines in which the transfer vector’s DNA is introduced in a transient or stable form (Figure 1.3). For more details regarding the gammaretroviral packaging technology, refer to Chapter 2 by Cruz et al.

1.4 SELF-INACTIVATING VECTOR DESIGN

Self-inactivating (SIN) retroviral vectors lack enhancer–promoter sequences in the U3 region of their LTRs and rather make use of an internal promoter to initiate transcription of the transgene cassette (Figure 1.5). This design has been first described for gammaretroviral vectors in 1986 [34] and was subsequently adopted for lentiviral and spumaviral vectors [35,36]. The SIN design has some important advantages compared to the conventional LTR design: It reduces the risk of insertional upregulation of neighboring genes by decreasing long-distance enhancer interactions or promoter activity from the 3’LTR [37,38]; it further lowers the risk of recombination to create a replication-competent retrovirus; if a cell expressing the SIN transgene is superinfected by a replicating retrovirus,

FIGURE 1.5 SIN retroviral vectors. SIN vectors are devoid of promoter/enhancer elements in the 3'U3 region and are therefore dependent on an internal promoter. Moreover, this internal promoter can be chosen according to the tissue specificity and expression strength needed for the vector application. To overcome transcriptional interference and to produce sufficient amounts of packageable genomic RNA (upper), a strong promoter should be taken to drive the genomic message (e.g., Rous sarcoma virus [RSV] promoter plus SV40 enhancer).

the SIN-vector RNA (due to the lack of genomic packageable RNA) is unlikely to be mobilized; and finally, deleting the strong retroviral enhancer–promoter sequences avoids potential interference with more cell-type specific or inducible transcriptional control systems that are introduced to express the gene(s) of interest.

A few rules have to be considered to construct efficient SIN vectors. Reverse transcription copies the 3'U3 region into the 5'LTR, so that the deletion of enhancer–promoter elements in the 3'U3 of the vector plasmid will affect both LTRs. For the same reason, modifications of the plasmid's 5'U3 region, as recommended above to achieve high titers, do not alter the nature of the vector's genomic sequences packaged in the virions, provided that the modified 5'U3 region still uses the same TSS as the original retrovirus.

For construction of SIN vectors, all the enhancer–promoter sequences, which are located behind the IN attachment site and terminate in the TATA box, should be removed from the 3'U3 region. Some earlier generations of SIN vectors still included the TATA box, which was removed later to further improve safety [39,40].

Unlike HIV-derived lentiviral SIN vectors, the first generation gammaretroviral SIN vectors were compromised by a severe drop in infectious titers. Inclusion of the PRE from woodchuck hepatitis virus (wPRE) increased infectious titers above 1×10^6 transducing units per milliliter [39]. Nevertheless, infectious titers remained substantially reduced when compared to conventional LTR-driven retroviral vectors. Of note, SIN vectors produce two types of RNA in the packaging cell line. The first is the genomic RNA harboring the packaging ψ needed for efficient packaging, the second the shorter RNA initiated by the internal promoter (Figure 1.5). Since the availability of packageable, genomic RNA is a major determinant for a productive virus titer, efforts have been initiated to enhance the production of genomic RNA from SIN vector plasmids. Incorporating promoters with a high processivity in the 5'LTR of the SIN plasmid may substantially increase the titer of SIN vectors, under optimal circumstances to those achieved with the archetypical LTR-driven vectors. Such promoters can either be constitutively active (e.g., RSV, cytomegalovirus, or combinations with additional enhancers) or inducible versions (e.g., tetracycline responsive promoters) [35,40,41].

Having deleted the enhancer–promoter sequences from the 3'U3 region of the vector plasmid creates space for the incorporation of new elements that may further improve vector performance. The U3 region typically tolerates insertions of ~500 bp of foreign sequences without a significant loss of titer. This only applies if these sequences follow the basic requirements of foreign sequences for retroviral vector genomes. Introduced sequences should be devoid of

- Recombinogenic motifs (e.g., those formed by direct or inverted sequence repeats)
- Transcriptional terminators (to avoid premature termination of the transcript in packaging cells)
- Strong splice sites
- Complicated secondary structures (that are poorly resolved during reverse transcription)
- Promoters forming significant amounts of antisense message (to avoid RNA interference during the production process)

If suitable sequences are introduced in the residual U3 region (Figure 1.6) after reverse transcription these will be present in two copies, i.e., at both ends of the vector's genome. This feature is particularly useful for the introduction of insulator elements and transcriptional termination sequences. Small expression cassettes, e.g., shRNA genes driven by polymerase III promoters [42], may also be introduced into the U3 region, resulting in “double copy vectors.” Even the R-region is amenable for such “double copy” modifications [43]. Although the latter architecture has not found many friends, it still underscores the flexibility of the gammaretroviral genome.

However, gammaretroviral sequence flexibility is not unlimited. For reasons that remain to be identified, certain expression cassettes are significantly more stable in a lentiviral vector context. The most prominent example is the β -globin gene cassette that combines large cis-regulatory sequences and introns. Due to the presence of strong cellular introns, this cassette needs to be introduced in antisense orientation to the vector's genomic mRNA. While gammaretroviral vectors fail to give good titers with this insert, lentiviral vectors could be produced to titers that allow a convincing correction of disease in

FIGURE 1.6 SIN vectors within the 3'UTR and the 3' Δ U3 region. The deletion of promoter/elements of the 3'U3 (Δ U3) creates space for the incorporation of useful features. Interestingly, these elements will be present (due to the mode of reverse transcription) in its integrated form. For RNAi applications short hairpin RNA (shRNA) expression cassettes, consisting of a Pol. I promoter and a shRNA RNA, can be introduced. In addition, chromatin insulators (e.g., cHS4) and polyadenylation enhancers (upstream polyadenylation enhancers, USE) can be incorporated here (for details see text).

preclinical animal models [44–48]. If the mechanisms for the differential performance of lentiviral and gammaretroviral globin vectors will be identified, similarly complex cassettes could potentially be adopted for gammaretroviral vectors.

1.5 TERMINATION ENHANCERS AND INSULATORS

As the retroviral termination signal is present in both LTRs, the element in the 5'LTR has to be suppressed to allow for efficient transcription of the retroviral mRNA species. Gammaretroviral and lentiviral termination signals differ in their configuration and mechanism of suppression. While in lentiviruses cross-talk with the SD is involved in suppression of the 5' termination sequence, the exact mechanism remains to be defined for gammaretroviruses [27]. Vectors derived from either retrovirus may cause significant amounts of transcriptional read-through into downstream cellular sequences. Read-through is further enhanced in the SIN design, suggesting that the wild-type U3 sequences contribute to transcriptional termination [49,50]. Cellular termination signals cannot be simply incorporated into retroviral vectors as they may trigger premature termination of the transcript in packaging cells, thus causing a severe loss of titer. Two elements have been shown to tighten termination of retroviral vector sequences while even increasing the yields of infectious particles. The first is the PRE derived from wPRE. This rather long sequence (>500 bases) forms extended secondary structures and may act at several levels of posttranscriptional gene regulation [51–55]. Evidence for a role in enhancing transcriptional termination has been obtained by us and others [54,55]. Significantly shorter sequences that may be even more potent termination enhancers than the wPRE are upstream polyadenylation enhancer elements (USE) derived from other viruses or cellular genes. These U-rich motifs facilitate the binding of crucial cellular termination factors to accomplish more efficient utilization of the retroviral polyadenylation site [56]. Using a panel of reporter assays, including assays detecting transcripts of integrated vectors, we showed that USEs can largely suppress

residual read-through of gammaretroviral and lentiviral SIN vectors [54].

Insulators are cis-elements that inhibit enhancer or silencer interactions between the integrated transgene and the neighboring chromatin [44,57–63]. These sequences are of interest to reduce the notorious position-dependent variation effects, to increase the transcriptional autonomy of the transgene and avoid silencing, thus allowing for a more homogenous transcription level in polyclonal situations. The second aim for the incorporation of insulators is to reduce long-distance effects of the integrated transgene on neighboring cellular genes (insertional mutagenesis). Several groups have provided evidence that insulators may be helpful to reach these goals, although they may not seem to act in a very dominant manner if the vector's enhancer is strong [44,57–63]. Defining more powerful insulators and analyzing their potential context-dependence are important activities of ongoing research.

1.6 COEXPRESSION STRATEGIES

Gene therapy trials performed today often make use of monocistronic vectors which allow the correction of monogenic diseases. For more complex applications such as the additional use of selection markers, different coexpression strategies (Figure 1.7) can be applied which have shown to be functional in cell and animal models, although most of them have different (dis)advantages and are yet to be tested in human trials.

In general, coexpression of at least two transgenes can be achieved either by (post)transcriptional (splicing, multiple promoters) or by translational mechanisms (IRES, 2A cleavage, fusion proteins). One of the most effective coexpression systems has been evolved by retroviruses. Every retrovirus depends on the generation of packageable genomic RNA. By controlling splicing of the genomic message a balanced ratio of subgenomic gag-pol and env molecules is obtained which is crucial for the survival of the virus. The principle of balanced splicing can also be employed for the coexpression of transgenes from retroviral vectors but it is problematic, especially in the context of the SIN design. Splicing cannot be suppressed

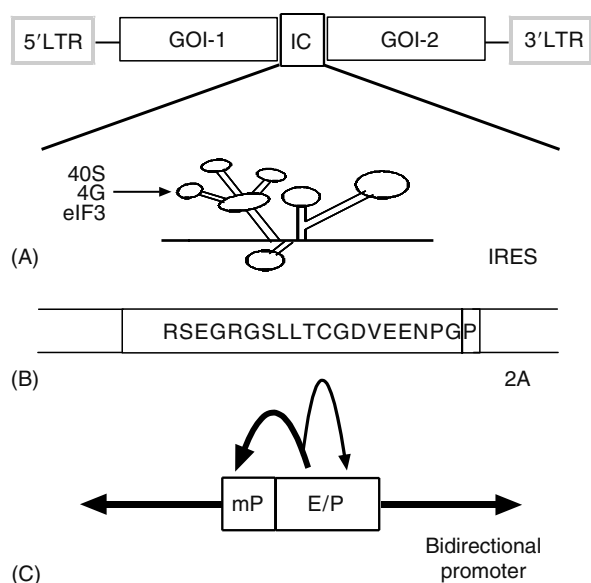

FIGURE 1.7 Coexpression strategies. Bicistronic expression can be achieved via several strategies. For efficient coexpression the internal cassette (IC) can be formed by internal ribosome entry sites, 2A “self-cleavage” sites and single or bidirectional promoters. (A) Internal ribosome entry sites recruit parts of the translation machinery (e.g., eukaryotic initiation factor 4G and eIF3 plus 40S ribosome). (B) Self-cleavage indicated for the *Thosea asigna* virus 2A-cleavage site (T2A). The peptide consists of 20 amino acids. Cleavage occurs via a co-translational ribosome skipping mechanism between the C-terminal Glycine and Proline residues, leaving the indicated amino acids attached to the end of the 5' protein and the start of the 3' protein. (C) Bidirectional promoters consist of two antisense oriented (minimal = m) promoters (P) sharing the same enhancer (E) but driving transgene expression in opposite directions.

in the packaging cell, which ultimately leads to a drop in titer and lower transduction efficiencies. In SIN vectors, the intron might be deleted prior to packaging of the genomic RNA, unless it contains the packaging signal [30,39,52].

A simpler approach can be taken by generating fusion proteins (e.g., formed by a therapeutic and a marker protein) although their biological function has to be empirically tested, because the fusion might induce misfolding or interfere with interaction partners. The most elaborate fusion partners described are GFP (and its derivatives) and luciferase which can be fused to many genes of interest at the C- or N-terminus.

Most cellular mRNAs carry a 5' m⁷G cap which protects the RNA against degradation and serves as the ribosome binding site. Translation is then initiated at the first AUG start codon detected by the scanning ribosome (cap-dependent translation). In contrast to cap-dependent translation, the IRES sequence (i.e., internal ribosomal entry site) forms a secondary structure recruiting ribosomes and all translation initiation factors (except the cap binding protein eIF4E) directly to the initiation codon of a downstream ORF. In order to achieve bicistronic gene expression, the IRES has to be located between both genes. Translation is then cap-dependent upstream but cap independent downstream of the IRES.

Several IRES sequences have been found in viral and eukaryotic genes allowing for bicistronic transgene expression. Their size ranges between 10 to 600 nt [64]. The most widely used IRES in gene therapy vectors today is derived from encephalomyocarditis virus and is ~600 nt long. Although viral vectors are routinely equipped with IRES sequences, they are not the optimal choice when equimolar amounts of both transgenes are needed since the suboptimal recognition of the IRES typically leads to a reduced expression of its 3' gene.

In contrast to IRES, almost equal expression levels can be achieved by using effective 2A “self-cleavage” sites [65,66]. Here, both transgenes are encoded as fusion proteins, with the 2A peptide interspaced. This peptide consists of ~20 amino acids with a C-terminal prolyl-glycyl-prolyl (PGIP) sequence which will cotranslationally be cleaved by a ribosomal skipping mechanism between the glycyl-prolyl residues. Thus, the beginning of the first and an additional prolyl residue to the N-terminus of the second protein. Noteworthy, never reported to impair protein functions nor to be immunogenic, antibodies have been successfully raised against the FMDV 2A tag fused to the N-terminal protein [67]. Advantages of the 2A-sequences are not only their small size (~60 nt) but also the potential to incorporate multiple 2A-sequences between multiple transgenes. In doing so, Vignali and colleagues could give rise to all four subunits of the CD3 receptor complex [68].

Instead of employing translation dependent coexpression mechanisms it is also possible to rely on elements regulating transcription, namely promoters, which can be arranged in different settings. The simplest setting consists of an LTR-driven vector with an additional internal promoter, in this way controlling two ORFs. This can also be achieved by two internal promoters in a SIN-vector configuration. Since the message initiated from the first promoters runs over the transcription factor binding sites of the downstream promoter, it might be silenced by transcriptional suppression. Additionally, promoter interference might hamper efficient gene expression which makes empirical tests for all promoter-transgene combinations essential. A more elegant approach using a bidirectional promoter was recently published by Amendola and colleagues [69]. This approach uses two antisense oriented internal core promoters sharing the same enhancer, as previously introduced by Bujard et al. for the simultaneous regulation of two genes from the same tetracycline-inducible promoter [70]. Although bidirectional promoters are a sophisticated coexpression alternative, these constructs generally suffer from reduced titers, since the generated antisense message interferes with packageable genomic RNA production.

1.7 TARGETING INTEGRATION

IN has been identified as the most important determinant of the semi-random integration pattern of retroviruses [71]. HIV-1 and MLV differ in their propensity to integrate in the 5 kb neighborhood of a gene's TSS (twofold higher risk for MLV), next to DNaseI hypersensitive sites (10-fold elevated for

MLV) and within transcribed sequences (twofold elevated for HIV) [71]. Other retroviral INs are less biased in their preference for actively transcribed genes. However, even avian sarcoma leukosis virus which has the least bias for active genes and no TSS preference [72] is still a potent insertional mutagen *in vivo* [73], possibly because of its strong enhancer/promoter sequences within the U3 [74]. Irrespective of the IN used, it thus seems wise to restrict the number of insertion events when modifying cell types that have an increased risk of malignant transformation, such as HSCs.

The strictest approach to overcome the issue of insertional mutagenesis would be the generation of a retroviral IN that acts in a site-specific manner. As IN is organized in distinct subdomains, the DNA-recognition site has been altered to adopt site-specific modules. Proof-of-principle for modified target specificity has been achieved *in vitro*, but so far no highly specific system has been described for targeted gene insertion in mammalian cells that works with similar efficiency as unmodified retroviral vectors [75]. To reach this important goal, the field follows various approaches. One of the most promising is the cotransduction of cells with IN-deficient lentiviral vectors that provide LTR circles as a template for homologous recombination, triggered by site-specific DNA double-strand breaks that can be introduced using transiently expressed endonucleases [76,77]. Determining residual off-target effects and increasing the efficiency in primary cells represent challenges for future research.

1.8 PSEUDOTYPING

Gammaretroviral vectors are pretty flexible in their choice of potential envelope proteins. A variety of foreign glycoproteins has been successfully incorporated into vector particles. The most widely used envelope proteins are the murine ecotropic envelope (which restricts infection to rodent cells) [78], the amphotropic envelope (which transduces both human and rodent cells) [79], the envelope derived from gibbon ape leukemia virus [80], or the one from feline retrovirus RD114 [81] (both of which transduce human cells much more efficiently than mouse cells). Examples for virtually ubiquitously infectious glycoproteins are those derived from vesicular stomatitis virus (VSV) [82] or the lymphocytic choriomeningitis virus [83]. Approaches to obtain retargeted designer envelope proteins are reviewed elsewhere [84]. One of the challenges in envelope retargeting is to preserve the ability for fusion of the viral particle with the target cell following recognition of the surface structure.

The choice of the envelope protein will primarily depend upon the receptor status of the target cell and the ability to concentrate vector stocks. Very stable preparations that allow repeated concentration by ultracentrifugation can be obtained when using the VSV glycoprotein. However, cytotoxic effects and contamination of vector preparation with cellular microvesicles limit the enthusiasm for this pseudotype [85].

1.9 APPLICATIONS

For a long time, key applications of gammaretroviral vectors have been the expression of oncogenes in cancer research, and the creation of potentially therapeutic vectors for the genetic engineering of HSCs and T-lymphocytes. For the study of oncogenes or other sequences that may have an impact on cell survival, researchers typically use LTR-driven gammaretroviral vectors that coexpress a fluorescent protein as part of a bicistronic message, the fluorescent protein typically being under control of an internal ribosomal entry site. If such vectors trigger malignant transformation of cells, it may be a good idea to investigate the insertion site for potential evidence of collaborating cellular sequences that may have been selected based on the survival advantage mediated by insertional mutagenesis in the given experimental system [86–89].

For the therapeutic use of gammaretroviral LTR-driven vectors, there is increasing evidence for insertional mutagenesis as a dose-limiting toxicity. This is particularly relevant for the genetic modification of HSCs [11,14–18]. Future attempts to use gammaretroviral vectors in this setting should be based upon carefully redesigned vectors (if possible a SIN design without strong enhancers that are active in HSCs) and a proactive validation of residual genotoxicity in emerging preclinical models [37,38,62]. The use of earlier generations of LTR-driven vectors may have to be restricted to conditions for which an appropriate safety profile is established or to a situation of an imminent medical need when alternative vectors are not yet available. Importantly, insertional side effects are highly context-dependent and vary for yet unknown reasons even in different clinical studies targeting HSCs [90–92]. In contrast to the situation encountered in HSCs, no insertional side effects have been detected to date in recipients of gammaretrovirally transduced human T cells, although infused cell numbers are usually much higher than in the trials targeting HSCs [93].

A still hot topic in basic research is the propensity of gammaretroviral LTR vectors to be epigenetically silenced in embryonic stem cells (ESCs). This feature, most prominent for Moloney MLV, has actually been very welcome in the literally revolutionary creation of “induced pluripotent cells” by retroviral transduction of differentiated somatic cells with a cocktail of transcription factor sequences [94,95]. In this context, robust silencing of the transduced sequences, some of which are clearly oncogenic, may have represented a major advantage of the vectors used.

Modifications of the gammaretroviral LTR enhancers and the PBS—which overlaps with the binding site for a still ill-defined repressor—have resulted in vectors that increase the chance of transgene expression in ESCs [96]. Similarly designed vectors also showed better long-term expression in HSCs, where the repressor targeting the PBS sequences also operates [97–100]. However, if transduced ESCs were induced to differentiate, these modified LTR-driven vectors were still silenced with a very high probability [101], in contrast to lentiviral vectors with a SIN design and a cellular promoter [102].

Initial reports suggested that lentiviral vectors are generally more resistant to silencing than gammaretroviral vectors. However, carefully designed studies have found no clear evidence for this hypothesis [103]. Vector architecture and content thus seem to play a major role in determining the susceptibility of retrovirally transduced sequences to silencing in stem cells and their differentiated progeny [103,104]. For modification of ESCs and the generation of transgenic animals using viral vectors, lentiviral SIN vectors with internal cellular promoters currently represent the state of the art [102,105]. The side-by-side evaluation of gammaretroviral and lentiviral vectors will play an important role in the elucidation of the underlying mechanisms.

1.10 OUTLOOK

In the era of lentiviral vectors that are able to transduce quiescent cells and appear to be more robust than gammaretroviral vectors in the incorporation of complex transgene cassettes, one may wonder which interesting features remain to be offered by gammaretroviral vectors.

The first nice feature is their simplicity. The gammaretroviral technology can easily be adapted in every laboratory that has experience with cell culture, plasmid cloning, and transfection. Unless very complex cassettes are introduced, infectious titers are robust and most target cells that replicate in culture are readily transduced when using an appropriate envelope protein. Of note, the generation of lentiviral vectors can be similarly efficient and simple. If wanted, both lentiviral and gammaretroviral vectors can be restricted to biosafety level 1, when using the ecotropic envelope for pseudotyping [106,107]. The second feature and currently a real advantage that is of interest for clinical use is the availability of stable gammaretroviral packaging conditions that are suitable for upscaling to clinical grade vector production. Lentiviral packaging systems are still struggling to reach this important goal, although promising advances have been reported [108,109]. The third point of interest is the relatively low concern of vector genome mobilization and the absence of preexisting immunity to gammaretroviral particle-dependent antigens. This may be of particular relevance in gene therapy for patients suffering from HIV infection. The fourth potential advantage is the advent of SIN vectors with reduced long-distance enhancer activity. Using such vectors, the insertion profile of gammaretroviral vectors may not be as problematic as it is in the context of either LTR-driven vectors or SIN vectors containing a strong internal enhancer [37,38]. Envisaging the availability of a fully insulated SIN vector, the gammaretroviral insertion pattern may even be superior to the lentiviral one, as it may reduce the residual risk of gene disruption. The fifth argument for the continued use of gammaretroviral vectors is their established safety record in applications other than HSCs. Finally, as the diversity of human gene therapy increases and patients may need to be treated more than once with viral vectors or vector-modified cells, adaptive immunity may recognize vector-associated antigens that can be present for several days in transduced cells. It will thus be important to have access to

a variety of alternative vector systems, such as lentiviral, foamy-viral, and gammaretroviral when considering systems for stable genetic modification. These points may suffice to illustrate that gammaretroviral technology, as many other vector systems, is very potent when applied to a suitable cell type but under a high pressure for innovations to further increase efficiency and biosafety. Considering the above, the flexibility and simplicity of the gammaretroviral life cycle creates a fertile ground for basic and translational vectorology.

2.1 INTRODUCTION

Retroviral vectors have become an important tool for gene transfer, murine leukemia virus (MLV)-based retroviral vectors have been used over 25 years in gene therapy clinical

trials. Application of these vectors leads to integration of the transgene into the host-cell chromosome resulting in prolonged transgene expression; thus, they are particularly suited for diseases where long-term expression of the therapeutic gene is desirable. Traditionally, retroviruses have been the

vectors of choice for *ex vivo* transduction of hematopoietic stem cells (Table 2.1). The first clinical trial where retroviral vectors were applied occurred in 1990 to correct adenosine deaminase (ADA) deficiency (Blaese et al., 1995). White blood cells isolated from two children with severe combined immunodeficiency (ADA-SCID) were transduced *ex vivo* with an MLV-based vector expressing ADA and a neomycin marker. Neomycin resistant cells were isolated and introduced into the patients. The treatment improved the physical conditions of the patients and the ADA-containing provirus was stable in the blood for several years. It was concluded that gene therapy could be an effective addition to the treatment for some patients with this severe immunodeficiency disease. Since these first studies, gene therapy has become the focus of a continuously expanding research activity. The demonstration of the full correction of the SCID-X1 phenotype in infants and the recent treatment of CGD further demonstrated the efficacy of retroviral vectors (Cavazzana-Calvo et al., 2000; Ott et al., 2006). Retroviral vectors have been used for the treatment of other monogenic disorders *ex vivo*, the Gaucher disease, by transferring the glucocerebrosidase gene into hematopoietic cells (Dunbar et al., 1998) and hypercholesterolemia, by transferring the low-density lipoprotein receptor into hepatocytes (Grossman et al., 1994).

Retroviruses have also shown some promising results in cancer therapy and bone marrow transplantation. In tumor therapy, retroviral vectors have been mainly applied *ex vivo* to transduce immunomodulatory molecules (IL-2 and IFN-γ) into neoplastic cells and tumor infiltrating lymphocytes (Tan et al., 1996; Nemunaitis et al., 1998; Palmer et al., 1999). In other cases, retroviral vectors were applied *in vivo* for the treatment of melanoma, glioblastoma, ovarian, breast, prostate, and lung cancers (Roth and Cristiano, 1997). The introduction of the *thymidine kinase* suicide gene and the administration of ganciclovir showed that the treatment of graft-versus-host disease was efficient (Bonini et al., 1997).

Clinical trials to treat HIV-1 infection with therapeutic retroviral vectors were also performed. One of the strategies was the *ex vivo* modification of syngenic lymphocytes using retroviral vectors to suppress the expression of HIV genes (Nabel

et al., 1994; Morgan and Walker, 1996; Wong-Staal et al., 1998). A second strategy involves the modification of autologous fibroblasts to express a part of the HIV envelope gene so that a host immune response could be elicited (Nabel et al., 1994; Morgan and Walker, 1996; Wong-Staal et al., 1998).

2.2 BIOLOGY OF RETROVIRUSES

2.2.1 VIRAL PARTICLE

Retroviruses are complex enveloped particles with a lipid bilayer surrounding a nucleocapsid (NC) containing the genetic material and the enzymes necessary for replication (Coffin et al., 1997). They belong to the RNA family of enveloped viruses with the ability to “reverse transcribe” their genome from RNA to DNA (Weiss, 1998). Virions measure around 120 nm in diameter and contain two identical copies of positive strand RNA genome, forming a dimer, complexed with nucleocapsid proteins. The enzymes reverse transcriptase (RT), integrase (IN), and protease (PR) are also contained in the nucleocapsid, the inner portion of the virus (Palu et al., 2000). A protein shell, formed by capsid proteins (CA), encloses the NC, the inner portion of the viral core (Jones and Morikawa, 1998). The matrix (MA) proteins form a layer outside the core and interact with the envelope, this consists of a lipid bilayer derived from the cellular membrane, which surrounds the viral core particle (Coffin et al., 1997). Anchored on the membrane envelope the viral envelope glycoproteins are responsible for virus interaction with specific receptors on the host cell. The envelope is a protein complex formed by two protein subunits: transmembrane (TM) and surface (SU) connected by disulfide linkage, the latter binding to the cellular receptor and the former participating in the fusion of the viral and cellular membranes (Opstelten et al., 1998; Lavillette et al., 2000) (Figure 2.1).

2.2.2 RETROVIRUS GENOME AND VIRAL REPLICATION

On the basis of their genome structure, retroviruses can be classified into simple (e.g., MLV) or complex retroviruses (e.g., HIV) (Coffin et al., 1997). Both encode four gene

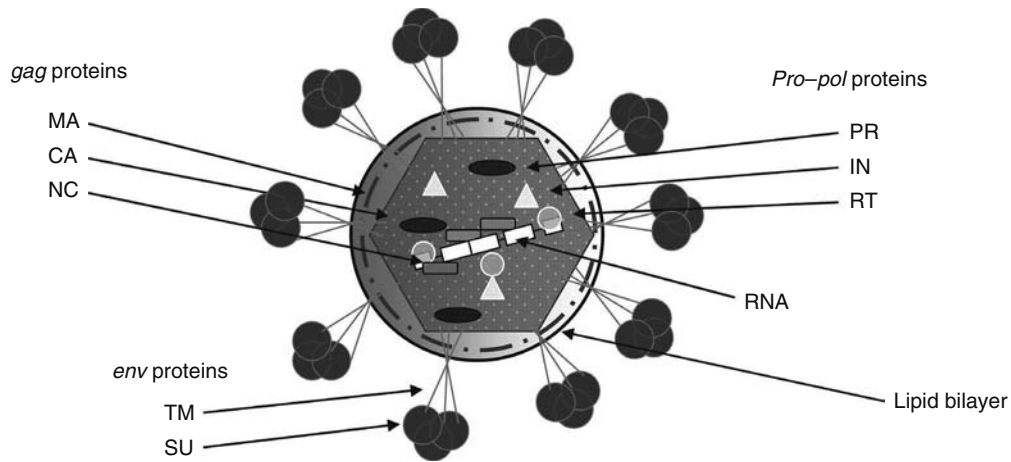

FIGURE 2.1 Structure of a retrovirus particle.

families, *gag* (group specific antigen), *pro* (PR), *pol* (polymerase), and *env* (envelope) (Figure 2.2). The *gag* sequence codes for the three main structural proteins: MA, CA, and NC (additionally also codes for p12 which assists in the virion assembly). The *pro* gene, allocated between *gag* and *pol*, encodes PRs responsible for Gag and Gag-Pol cleavage and viral particle maturation during budding. The *pol* sequences encode the enzymes RT and IN, the former being responsible for transcription of viral RNA to DNA during the infection process and the latter catalyzing the integration of the proviral DNA into the host genome. The *env* sequence encodes the two subunits of the envelope glycoprotein, SU and TM (Figures 2.1 and 2.2).

Efficient gene transduction and integration depends on a number of *cis*-acting sequences present in the retroviral genome: two long-terminal repeats (LTRs), a viral packaging signal (ψ), signals for reverse transcription such as the primer binding site (PBS), and the polypurine tract (PPT). The LTRs contain elements required to drive expression, reverse transcription and integration into the host chromosome (Hu and Pathak, 2000). The packaging signal (ψ) is the sequence that interacts with the viral proteins allowing the specific packaging of the viral RNA. PBS and PPT are required for reverse transcription.

The full-length RNA transcript produced by the integrated provirus encodes the precursor proteins for *gag*, *pro*, and *pol*

but in the unspliced form serves as the viral genome. It is assembled into progeny virions at the cell membrane. A portion of the full-length RNA is also spliced to form *env* mRNA which encodes a precursor for the virion membrane protein complex. Thus, the full-length RNA serves three essential functions: as genomic RNA, as mRNA for *gag*, *pro*, and *pol* proteins, and as pre-RNA for *env* mRNA.

The envelope proteins suffer posttranslation modifications in the Golgi, the addition of N-linked carbohydrate side chains. The cleavage of the precursors occurs also in the Golgi apparatus into the SU and TM peptides. They are transported, associated to each other, to the cell membrane where assembly of the virus occurs (Hunter and Swanstrom, 1990; Hansen et al., 1993).

Hence, the retrovirus replication cycle can be summarized in three main steps: (1) interaction and fusion of the viral particles with the cell surface, (2) uncoating of the virus, reverse transcription and integration of the viral genome, and (3) synthesis, assembly, and budding of newly formed virus. In step (1) the viral envelope glycoproteins bind to specific receptor complexes on the host-cell surface, leading to membrane fusion of the virus to the cell, and to subsequent internalization of the virus. Subsequently in step (2) the virus core is released into the cytoplasm where it is partially degraded to form a large nucleoprotein (pre-integration complex) that is transported to the nucleus (Palu et al., 2000). For MLV the entry in the nucleus is mitose-dependent (Roe et al., 1993; Lewis and Emerman, 1994). Oncoretroviruses are not able to pass through the pores of the nuclear membrane and only gain access to it when the nuclear membrane is disassembled during mitosis. The double-stranded proviral DNA synthesized by RT in the cytoplasm is integrated in the host's genome by viral enzymes. In step (3) the integrated provirus is transcribed into new viral genomic RNA and into viral proteins, all of this making use of cellular enzymes and machineries. Subsequently assembling of virions occurs, forming new viruses that bud out of the host cell (Coffin et al., 1997).

2.3 CONVERTING A VIRUS INTO A VECTOR: REPLICATION-DEFECTIVE RETROVIRAL VECTORS

In most gene therapy applications it is not desirable to deliver replication-competent retroviruses (RCRs) because they may spread beyond the target tissue and cause adverse effects. Therefore, most recombinant retroviral systems designed for gene delivery are divided into a vector, expressing the therapeutic gene and a helper construct that encodes the viral proteins, but limiting the ability of the virus to replicate (Miller et al., 1986). The helper or packaging functions are provided by a helper virus, as co-transfected plasmids, but mostly in a packaging cell format. The latter has the advantage of generating higher virus titers, reproducible batches, and higher safety. Helper or packaging cells are therefore more suitable for clinical applications and thus the following chapters will only focus on this application.

2.3.1 HELPER OR PACKAGING CELLS

Several packaging cell lines producing retroviral vectors have been generated; in these, the sequences expressing the viral genes, *gag*, *pro*, *pol*, and *env* (packaging functions) are supplied in *trans* using molecular constructs which cannot be packaged into retroviral particles. The therapeutic gene is supplied into a genetic vector that mimics the structure of the viral genome by containing minimal *cis*-acting sequences, which allow its efficient incorporation into viral particles, its reverse transcription, integration, and expression in the target cells (Palu et al., 2000).

Retroviral vectors have been derived from several viruses, namely avian, simian, or feline retroviruses. However, the most common and widely used is derived from a murine retrovirus, the MLV. In the design of retroviral packaging cell lines, the problem of spontaneous formation of RCRs has been addressed and this led to different types of helper cell lines that can be divided into “generations.” The

first generation of packaging cells was produced by providing the packaging functions with a retroviral genome where the packaging signal was deleted from the 5' untranslated region, thus preventing the incorporation of the packaging functions into the viral particles (Cone and Mulligan, 1984). However, one recombination event between the vector and the packaging genome could easily lead to the creation of recombinant helper free viruses (Miller et al., 1986). Further modifications were introduced in the second generation packaging cells where the 3'LTR and the second strand initiation site were replaced with the polyadenylation site of SV40. Additionally, the 5' end of the 5'LTR was deleted. Two recombination events would now be required to restore a replication-competent virus. The well-known PA317 cell line was constructed in this way (Table 2.2). The third generation further separates the constructs that express, *gag-pol* and *env*. In the case of ψ -CRIP and ψ -CRE cells, *gag-pro-pol* and *env* were cloned in separate constructs (Figure 2.3) (Danos and Mulligan, 1988). The resulting system requires three independent recombination events to generate replication-competent virus, which is statistically very improbable. Nevertheless, replication-competent viruses can still occur in third generation cell lines (Chong and Vile, 1996; Chong et al., 1998). This was reduced by decreasing the homology in the vector construct, using different LTR species to those used in the packaging functions (Cosset et al., 1995) or alternatively, using heterologous promoters such as CMV (Soneoka et al., 1995; Rigg et al., 1996). The majority of the cell lines developed for stable production of retroviral vectors are derived from murine NIH/3T3 cells but have been slowly substituted by human cell lines such as HT1080 or HEK 293 (Rigg et al., 1996) (see Section 4.4).

2.3.2 ENVELOPE PROTEINS AND VECTOR TROPISM

The separation of the three retroviral components, *gag-pol*, viral genome, and envelope, in different constructs in the packaging cell line allowed recombinant retroviral vectors to be

pseudotyped with SU proteins from different viruses. This technique can be useful to determine the tropism of a virus that can be either expanded to an ensemble of target cells or restricted to a specific cell type. A wide range of packaging cell lines with different pseudotypes is currently available (Table 2.2).

Four subgroups of naturally occurring MLVs were identified based on their receptor recognition in mouse cells. Accordingly, their envelope proteins are commonly referred to: ecotropic, amphotropic, polytropic, and xenotropic. For example, the most commonly used envelope to pseudotype retroviral vectors are the amphotropic MLV envelopes 4070A or 10A1, which can transduce nearly all mammalian cells (Miller and Chen, 1996). Other retroviral helper cells produce pseudotyped viruses that are derived from surface glycoproteins from different retrovirus species or of different virus families. Pseudotyping with the glycoprotein from GaLV (gibbon ape leukemia virus) has come into practice as it transduces hematopoietic cells more efficiently than the same retroviral vectors with amphotropic pseudotype (Miller et al., 1991). The glycoprotein from the cat endogenous virus RD114 allows efficient transduction of human cells and, in addition, confers partial resistance to human serum (Takeuchi et al., 1994). The HIV-1 envelope targets specific CD4 positive cells and can be incorporated in MLV particles (Schnierle et al., 1996; Lodge et al., 1998). SU proteins of less related virus have also been successfully incorporated into retroviral vectors. This is the case with VSV-G (vesicular stomatitis virus G protein) that allows efficient infection of a broad range of target cells. VSV-G pseudotyped viral vectors have the advantage of resisting ultracentrifugation due to the monomeric structure of VSV-G. Unfortunately, this protein can be toxic to cells which constrains its constitutive expression in stable packaging cell lines (Burns et al., 1993; Yee et al., 1994a,b).

Genetically or chemically modified envelope glycoproteins have also been developed for cell or tissue specific targeting. Retroviral envelope proteins can tolerate a variety of genetically encoded modifications. Polypeptides can be fused to N-terminally truncated envelope glycoproteins, thereby changing the SU portion of the envelope to interact with other cell surface molecules. This is often achieved by deletion of a part of the coding region of SU and replacing it with regions of other proteins such as erythropoietin, heregulin, insulin-like growth factor I, and single chain variable fragment antibodies against various proteins (Chu et al., 1994; Kasahara et al., 1994; Chu and Dornburg, 1995; Han et al., 1995; Somia et al., 1995; Jiang et al., 1998; Konishi et al., 1998; Chadwick et al., 1999; Jiang and Dornburg, 1999).

Another pseudotyping strategy makes use of bifunctional adaptor molecules to redirect retrovirus attachment. The adaptor works as a molecular bridge between the viral envelope and a receptor molecule on the cell surface. Multivalent antibody linkers or biotin streptavidin bridges are examples of such. However, efficient transduction was generally impaired by the lack of proper envelope–receptor interaction (Goud et al., 1988; Etienne-Julan et al., 1992). The earliest example of a chemical modification of the binding characteristics was the modification of ecotropic MLV particles by the addition of lactose to their surface in order to target the asialoglycoprotein receptor on human hepatocytes (Neda et al., 1991).

2.3.3 DESIGN OF VIRAL GENOME AND THERAPEUTIC TRANSGENE

The simplest approach to generate a viral vector is to use the retroviral LTR promoter to control the expression of the desired cDNA or protein of interest. The minimal *cis*-acting sequences needed are the following regions initially identified as essential for the correct function of the vector: two LTRs, the PBS, the packaging signal extending into the 5' of the *gag* sequence and, the downstream untranslated region containing the PPT.

The design of the vector genome can be modified in order to include several genetic elements that render it more efficient in specific treatments and also in order to increase the vector safety. Alternative internal promoters and IRES (internal ribosomal entry site) elements can be used to drive the expression of one or more proteins. Selectable markers (e.g., neomycin, thymidine kinase, hypoxanthine–guanine phosphoribosyl transferase) can be used to facilitate selection of transduced cells.

To increase vector safety, the regulatory sequences in the LTRs can be deleted as in self-inactivating or self-deleting vectors (Yu et al., 1986). The viral vector genome design and safety will be thoroughly discussed in another chapter.

2.3.4 RCRs: ACCIDENTAL FORMATION OF NEWLY RECOMBINED VIRUSES

Depending on the construction of helper cell lines retrovirus-mediated gene transfer can give rise to newly recombined

viruses (Bosselman et al., 1987; Scarpa et al., 1991; Otto et al., 1994). As a consequence, infected cells obtain undesired properties or even become producer cells themselves, a process which renders the transfer uncontrollable.

There are two predominant mechanisms that are responsible for alteration of the properties of infectants: recombination and retrofection. Homologous recombination is a frequent process. The efficiency depends on the degree of homology between the retroviral vector and the helper function. As a result of a recombination event immobilized helper functions regain their capacity to replicate autonomously and thus RCRs spread through the culture. The RCRs represent the main safety problem accompanying the retrovirus-mediated gene transfer; amphotropic RCRs obtained from recombination events in MLV-based packaging cells were shown to replicate in nonhuman primates and to induce lymphoma (Donahue et al., 1992; Vanin et al., 1994).

Apart from the frequent recombination during transfection of cells (extrachromosomal DNA recombination), during cultivation of retroviral helper cells two additional recombination pathways have to be considered. Generally, recombination may occur within transfected packaging cells at the DNA level or during reverse transcription at the RNA level. While DNA recombination is a purely cellular process performed by the cellular repair machinery, RNA recombination is coupled with the retroviral life cycle and mediated by a viral enzyme, RT.

A prerequisite for RNA-based recombination is the co-packaging of the vector and the RNA into the same virus particle. Although the RNA lacks the ψ packaging signal it may be packaged at a low rate. It was shown that the deletion of the ψ packaging signal may reduce the rate of packaging only about 10^3 – 10^4 fold (Mann and Baltimore, 1985; Stuhlmann et al., 1990). Therefore, packaging cell lines producing 10^6 virus particles per milliliter release a significant number of virions carrying the helper RNA. These helper RNAs may recombine and thereby give rise to the formation of RCRs.

To increase the level of safety much effort was spent to decrease the risk of recombination in packaging cells. The subdivision of the helper genome in two independent transcription units resulted in helper cells in which more than one recombination event is required for the formation of RCRs. In addition, the extent of homology between vector and helper genes was significantly reduced. In these packaging cells (e.g., Ω E cells [Morgenstern and Land, 1990]) the frequency of RCR formation is significantly reduced.

Further investigations showed that even cellular RNAs without any retroviral elements may be packaged to a low extent, a process which was termed retrofection (Linial, 1987; Linial and Miller, 1990). In MLV-based packaging cells the rate of retrofection is reduced 10^6 – 10^8 fold if compared to functional retroviral vectors (Stuhlmann et al., 1990). The risk arising from the packaging of cellular genes is probably low as their RNAs may not compensate for any viral function and thus could not contribute to the formation of RCRs. However, it cannot be excluded that certain cellular RNAs may form a structure that is similar to the retroviral ψ sequence

and are preferentially transmitted. A safety problem arises if these RNAs are able to change the properties of infected cells, as for example the oncogenes do.

Another potential problem using the retrovirus-mediated gene transfer arises from endogenous retroviral elements that are naturally present in the cells, such as endogenous retroviruses with the vector helper functions. In particular, rodent cells carry a huge amount of endogenous retroviral elements. Usually, they are not able to form infectious viruses themselves; however, they are potential candidates for recombination events both at DNA and RNA level and thus may contribute to the formation and release of new, autonomously replicating retroviruses. Initially the majority of the cell lines developed for stable production of retroviral vectors are derived from NIH/3T3 cells (Danos and Mulligan, 1988; Morgenstern and Land, 1990; Miller et al., 1991) which were found to express endogenous MLV sequences (Irving et al., 1993). These can be packaged and participate in recombination to form replication-competent viruses (Scadden et al., 1990; Cosset et al., 1993; Vanin et al., 1994). Thus, non-rodent cells (e.g., human cells) were introduced and are nowadays preferred. Recently constructed packaging cell lines are derived from human cell lines 293 that do not have MLV-related endogenous sequences (Rigg et al., 1996; Patience et al., 1998).

2.4 STATE OF THE ART STABLE RETROVIRAL VECTOR PRODUCER CELL LINES

One of the major disadvantages of retroviral vectors concerns the difficulty in manufacturing. The retroviral vector productions yield relatively low titers as a result of low producer cell line productivity and short vector half-life (Wikstrom et al., 2004). However, gene transfer clinical protocols often require large amounts of biologically active recombinant retrovirus (Table 2.1). Thus, the successful implementation of retroviral vectors in such trials depends to a great extent on the existence of high titer stable producer cells.

2.4.1 CLASSICAL RETROVIRAL PRODUCER CELL LINES

Historically, most packaging cell lines used to produce recombinant retrovirus have been derived from murine cell lines, e.g., NIH/3T3. These are being replaced by human cell lines. This is not only due to the possibility of packaging endogenous retroviral sequences and recombination of these with the vector as mentioned above, but also because of the glycosylation pattern of the murine cell lines that render the virus sensitive to human complement. It is generally considered that the presence of galactosyl(α 1–3)galactose carbohydrate moieties produced by murine cells in the retroviral vector envelope is rapidly detected by antibodies and inactivated by the human complement system (Cosset et al., 1995; Pensiero et al., 1996; Takeuchi et al., 1996; Takeuchi et al., 1997), although other translational modifications might also play a role (Mason et al., 1999). The murine packaging cell lines also have the disadvantage of producing lower retroviral infectious titers

(Naviaux et al., 1996; Davis et al., 1997). Producer cell lines based on human cell lines were therefore developed being able to produce retroviral vectors resistant to complement inactivation (Cosset et al., 1995). The human embryonic kidney cell line HEK 293 has been shown to produce virus that yields higher transduction efficiencies (Finer et al., 1994; Rigg et al., 1996) as compared to murine ψ -CRIP-based producer cells (Davis et al., 1997). Table 2.2 is a partial list of some of the available retroviral producer cell lines.

2.4.2 NOVEL RETROVIRAL VECTOR PRODUCER CELL LINES

The viral titer produced by packaging cells limits the use of retroviral vectors in gene therapy. The titer depends on a number of items and their interplay, including the nature of the cell line, the expression of the vector and the helper functions, the balance of helper function expression, and on the cultivation conditions. It seems that a maximal expression of the viral vector construct genome, which expresses the transgene, is one of the limiting conditions. The need for screening for appropriate expression levels of the viral vector indicates that this parameter is critical for virus production. This is supported by previous work indicating that optimal virus production depends on a high retroviral vector transgene transcription and balanced expression of the retroviral helper genes encoding *gag-pol* and *env* (Yap et al., 2000).

In addition, the expression of the helper functions must be sufficient to allow packaging of the transcribed viral RNA. Thus, in the development of helper cell lines, the maximization of helper function expression was an important issue. Improvement was achieved by different means. Extensive screenings have to be undertaken in order to identify clones that lead to a high-titer virus production with stability for the time of production.

The inserting of selectable markers in the packaging constructs downstream of the viral genes, so they are translated from the same transcript after ribosomal reinitiation, assuring maximal expression of the viral genes revealed to be an elegant and efficient method (Cosset et al., 1995). Therefore, to facilitate screening for efficient vector expression many viral vectors contain a (selectable) marker gene. This marker gene allows screening for stable integration and high level, long-term expression. This approach is often needed in settings where the therapeutic transgene itself does not support high throughput screenings. However, such marker genes can impose significant problems in therapeutic settings. One concern is that an immune response against the foreign gene(s) is provoked. This can result in the elimination of transduced cells, thereby limiting or excluding the therapeutic success. Another concern is raised since insertional leukemogenesis was observed in a mouse model due to the transduction of a marker gene that was considered before to be biologically inert (Li et al., 2002; Baum et al., 2003). Thus, it is now state of the art to exclude any coding sequences apart from the therapeutic gene. Several approaches have addressed this point. One strategy is to express the resistance marker from an independent expression cassette outside the retroviral

vector cassette (Xu et al., 2004). Alternatively, a loxP flanked marker gene is integrated into the retroviral vector to be excised upon Cre-mediated recombination (Wildner et al., 1998; Loew et al., 2004). While the latter approach allows efficient selection of producer clones it is not compatible with large size therapeutic vectors.

Once having isolated a cell clone with a favorable titer, it has to be optimized with respect to large-scale culture conditions, including the adaptation to production media (Merten, 2004). This is time consuming and this work has to be performed for each producer cell clone independently. For clinical applications, production under GMP conditions has to be established. This requires a detailed safety testing including an accurate and precise characterization of the producer cell and the stability of recombinant virus production. In total, the process starting from transfection of a packaging cell line to a suitable clone usually takes 6 months or more (Sinn et al., 2005).

The use of helper cell lines described so far requires the establishment of the vector into the chromosomal DNA of the packaging cell. This is accompanied by random integration. The properties of cell clones generated in this way and in particular the titer is largely determined by the nature of the integration site and the influence of neighboring chromosomal elements. Based on the work of Karreman et al. (1996), Schucht et al. (2006) and Coroadinha et al. (2006a) developed a new strategy that provides well-defined high-titer retroviral producer cells at high speed. This strategy excludes random integration of the vector DNA into the host's chromosomal DNA. Instead, it relies on the reuse of prescreened favorable retroviral vector integration sites. These integration loci that are tagged with Flp-recombinase recognition sites confer stable, high-level expression. These integration loci were identified by extensive screening for high and stable expression of the retroviral vector transgene. In subsequent steps, the expression constructs for *gag-pol* and *env* were introduced and cell clones were screened for maximal expression of these genes.

Different retroviral vectors were specifically integrated into the preselected loci via Flp-mediated recombination (Figure 2.4). All isolated clones showed correct integration and identical titers for each of the vectors. Up to 2.5×10^7 infectious particles (IPs) per 10^6 cells in 24h were obtained within 3 weeks. Also, high-titer producer cells for a 8.9 kb collagen VII therapeutic vector were obtained (Schucht et al., 2006). These data provide evidence that the precise integration of viral vectors into defined chromosomal loci leads to highly predictable virus production (Schucht et al., 2006; Coroadinha et al., 2006a). The method speeds up the time to clinical or research application and supports marker free viral vector production. It further provides a tool for evaluation of different retroviral vector designs under identical conditions.

Site specific integration of retroviral vectors into pre-defined loci is further characterized by (1) high speed, (2) safety due to the defined integration of the vector within the packaging cell line, and (3) favorable production conditions by preadaptation of the packaging cell line to culture conditions and media.

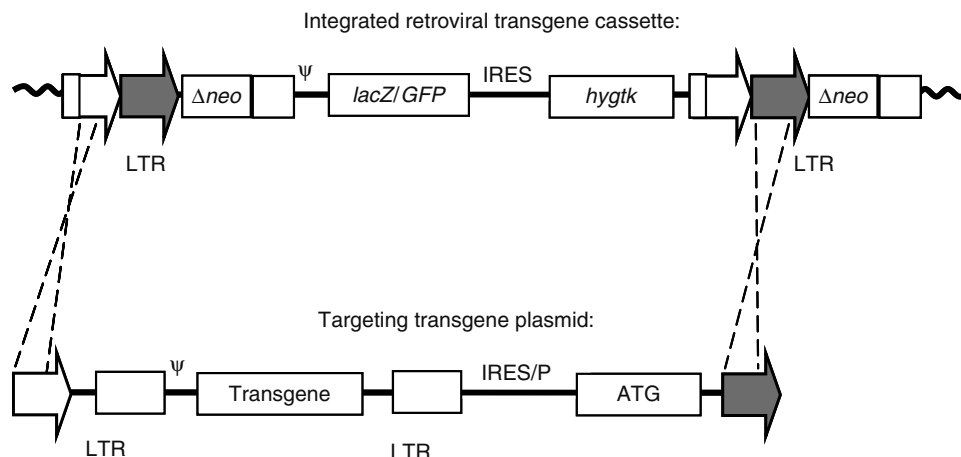

FIGURE 2.4 Tag and target methodology for the cassette exchange by Flp-mediated recombination in Flp293A and 293 Flex retroviral producer cell lines. The tagging retroviral plasmid contains a reporter gene, *lacZ* or *GFP*, *hygk* positive and negative selection markers, two FRT sites, and a defective *neo* gene. The targeting plasmid contains the two FRT sequences flanking the gene of interest and an ATG sequence that will restore the *neo* gene in the tagged clone after Flp-mediated recombination.

2.5 PRODUCTION OF RETROVIRAL VECTORS

The production of clinical grade retroviral vectors has to be compliant with the stringent regulatory requirements imposed by the FDA and the EMEA. Biological safety and compliance with the guidelines for good manufacturing practices (cGMP) must be assured whenever clinical trials are envisaged. To avoid potential immunological problems during clinical trials all production activities have to be performed in an aseptic environment and all potentially unsafe contaminants have to be removed. Raw materials used in the production will have to be free from adventitious viruses, as these will not be removed during purification (specially enveloped viruses) due to their similarity with retroviral vectors. For this purpose several actions must be taken from the beginning, including the selection of producer cell, production system, and culture conditions.

After the construction of the producer cell line it is necessary to establish a master cell bank (MCB) consisting of frozen cell stocks derived from a single-cloned cell, a working cell bank (WCB) derived from the MCB and maximum end of production cells (MEPC) comprising cells having undergone a number of population doublings beyond the end of the production process. The creation of the MCB involves a number of steps starting with the choice of the best producer clone. Table 2.3 below provides a timetable for MCB generation and vector production and certification.

To initiate a production run typically one to two vials of cells from the MCB are thawed and cells are expanded in tissue culture flasks. The cell culture is then scaled-up by increasing the number of flasks until sufficient cells are finally obtained to inoculate the appropriate number of cell factories or roller bottles to produce the clinical batch. The inoculum density ranges from 1 to 2×10^4 cells/cm² for cell factories and the cell cube in reported GMP production runs (Eckert et al., 2000; Wikstrom et al., 2004).

2.5.1 CURRENT PRODUCTION SYSTEMS

The ongoing landmark clinical trials presented in Table 2.1 suggest the use of 10^8 – 10^9 transduced cells per patient. With an average transduction efficiency of 25% and for a multiplicity of infection of 5, one should expect a need of 10^9 – 10^{10} retroviral vectors per patient. At the current production titer of 10^6 IPs per milliliter this represents a need for 1–10 L per patient.

Since only four patients are recruited for initial studies, the production systems used to date are considered for small

TABLE 2.3
Timeline for MCB Generation and Vector Production

Step	Time
Transfection of packaging cells	1 week
Population supernatant screening for titer	1 week
Clone isolation	3 weeks
Clone screening for high titer producers	2 weeks
Candidate clones expansion	2 weeks
Evaluation of candidate clones for titer and function	4 weeks minimum
Preparation of the MCB (100–200 vials)	3 weeks
Evaluation of the MCB for titer and function	3 weeks minimum
Production run—generation of 20 L per run	4 weeks
Confirmation of titer and function	2 weeks minimum
Certification of the MCB and clinical supernatant	14 weeks
Preparation of product release records to include QA audit	2 weeks

scale, preferably disposable systems. These include cell factories, large T-flasks, and roller bottles as the first choice.

Although these systems can be considered as not being the state of the art for mass production, they fit perfectly the current needs for the production of clinical batches of retroviral vectors. In fact, the use of these systems is widespread being the choice of the National Gene Vector Laboratory (Indianapolis, IN) in over 30 production runs since 1995 (Cornetta et al., 2005). Even today, roller bottles, the cell cube, and cell factories are being used for the production of clinical grade material (Eckert et al., 2000; Wikstrom et al., 2004; Przybylowski et al., 2006). In these systems, the vector production under GMP conditions ranges from 10 to 40L, again in line with the needs for clinical trials. For example, both the cell cube (25 stack) and the 20 roller bottle system are able to provide total yields in the order of 10^{10} – 10^{11} IPs using Phoenix Frape-1 cells (Wikstrom et al., 2004).

This somewhat conservative approach to retroviral vector production derives from a number of facts. First, when going from a small flask to a number of larger flasks, the scale-up is linear, with roller bottles being the typical example. This reduces uncertainty as the medium volume and cell numbers are increased proportionally to the growth area, similar titers are normally obtained. This makes validation of the production process relatively easy and a preferred option remains for sporadic low supernatant volume demands. A second argument relates to the fact that all large-scale systems utilize at least some non-disposable parts that need to be cleaned and sterilized before reuse, thus leading to the performance of extensive validation studies.

Finally, for most phase I or II applications full optimization of the production process is often not financially justifiable. The focus is thus put on to the consistency of the harvested material, the compliance with the quality specifications, and the attainment of a titer that is acceptable for the intended application.

There are, nonetheless, a number of alternative culture systems for retroviral vector production (Merten, 2004). These include a number of systems of greater scalability such as fixed bed bioreactors and stirred tanks that allow improving the titers by 10 to 100-fold reaching more than 10^7 IPs per milliliter.

In spite of the relatively large number of cells that grow attached to surfaces (including PA317, ψ -CRIP, and PG13 cells, among others), some cells can be grown as suspension cultures after adaptation. These include the recent HEK 293-based packaging cells. In this case, suspension cultures may be the only option. Thus, stirred tanks would be more appropriate and all the advantages referred above for these bioreactors can be used to increase both cell concentration and retrovirus titer (Garnier et al., 1994). Nevertheless, even in the cases where retroviruses may represent a viable solution for other diseases with higher incidence such as cancer (Lenz et al., 2002; Braybrooke et al., 2005), given the validation issues the trend will probably continue to be the use of disposable bioreactors such as the stirred tanks from Hyclone/Thermo and the Wave bioreactor.

2.5.2 CULTURE CONDITIONS

As with all other animal cells, mammalian cells used for the production of retrovirus are also affected by nutrient limitation (oxygen and glucose) and accumulation of byproducts such as ammonia and lactate. As a consequence, producer cell metabolism has been studied in order to better understand the factors influencing both vector productivity and vector stability (Coroadinha et al., 2006b). In addition, both osmotic pressure and the carbon source affect the specific retrovirus productivity and vector stability (Coroadinha et al., 2006c; Coroadinha et al., 2006d), thus creating a challenge for the definition of new medium formulations.

Culture temperature has been shown to affect the final retrovirus titer in the large majority of the reports. In fact, culture temperature assumes a particularly important role as it influences both the rates of retrovirus production and degradation (Cruz et al., 2000). According to Le Doux et al. (1999) an optimal temperature exists because the rate of retrovirus degradation has a higher increase with temperature than the rate of retrovirus production in the range between 28°C and 37°C. In fact, there are several retroviral vector clinical batches currently being produced at 32°C (Lamers et al., 2006a; Lamers et al., 2006b).

2.5.3 OPERATION MODE

Although the production of retroviral vectors is usually performed as a batch culture, due to the low stability of these vectors at 37°C (Le Doux et al., 1999; Pizzato et al., 2001; Beer et al., 2003; Carmo et al., 2006), several harvests should be performed. The use of this stepwise perfusion mode has the advantage of recovering retroviruses from the culture broth at shorter residence times with visible benefits upon retrovirus quality, derived from reduced degradation and increased final IP number per batch. The collection of culture supernatants in cell factories can be performed every 24 h up to 4 days (Eckert et al., 2000). The same time interval can be used in continuous perfusion mode in the cell cube with equivalent gains in total IP yields per batch (Wikstrom et al., 2004). The several harvests are then stored at –80°C after clarification before they are thawed and pooled for quality control and release.

Medium exchange is not common in large scale production of recombinant proteins and monoclonal antibodies in suspension cultures. However, when using adherent cells in cell factories, roller bottles, cell cube, or fixed bed bioreactors at the 10–40L scale, this does not pose relevant challenges. In fact, since the current production protocols use medium containing 10% serum during cell expansion phase and serum-free medium during the production phase, the ability to perform medium exchange is practically a prerequisite to the system (Eckert et al., 2000).

2.5.4 CULTURE MEDIUM

The production of retroviral vectors strongly affects vector downstream processing particularly in what concerns the

producer cells and culture medium used. Producer cell-contaminant proteins and DNA as well as some media additives, like serum, need to be removed to meet regulatory agencies quality standards. The development of production processes that use serum-free media is an important step towards prevention of immunological responses to viral preparations and simplification of the downstream strategy. Retroviral vectors are usually produced by adherent cell lines that secrete variable quantities of extracellular MA proteins, partially consisting of proteoglycans (Merten, 2004). These macromolecules are negatively charged and influence the transduction efficiency of retroviral vectors (Le Doux et al., 1996; Le Doux et al., 1998). Cell lines grown in suspension are known to produce less extracellular MA (Merten, 2004) and, combined with higher process scalability potential, they offer attractive advantages in larger scale retroviral vectors production.

2.6 PURIFICATION OF RETROVIRAL VECTORS

Purification of retroviral vectors from cell culture derived contaminants (e.g., producer cells, DNA, proteins from culture media or released by the producer cells) is mandatory to prevent toxicity, inflammation, or immune response in the individuals undergoing therapy (Tuschong et al., 2002). Till recently, downstream processing (i.e., the process by which the retroviral vectors are separated from contaminants) of retroviral vectors for phase I clinical trials has been only based on the separation of producer cells and debris which is insufficient regarding the increasingly stringent quality standards set by the regulatory agencies (FDA and EMEA). The removal of the contaminants requires the use of separation technology, usually based on chromatography and membrane processes (Segura et al., 2006a; Rodrigues et al., 2007a). Nevertheless, the special properties of these complex products require technological improvement of the existing purification processes and development of specific technology to increase productivity and throughput, while maintaining biological activity of the final product.

2.6.1 TECHNOLOGICAL CHALLENGES

The purification of retroviral vectors, like other macromolecular assemblies, still remains a challenge due to their large particle size, low diffusion rates, and complex molecular surfaces (Lozinsky et al., 2003). Most of the problems are associated with the low-titer production systems (usually between 10^5 and 10^7 IP per milliliter) (Merten, 2004), the inherent instability of retroviral vectors (Layne et al., 1992), the presence of transduction inhibitors (Le Doux et al., 1996), and intrinsic contaminants such as noninfectious vectors. Downstream processing of retroviral vectors needs to be fast, with few purification steps, and efficient in the removal of the contaminants as well as in the maintenance of viral infectivity. Different applications for the retroviral vectors may also require different levels of quality and biological potency of the therapeutic preparations. Thus, the definition of the purification process is also dependent on the final application; retroviral

vectors purified for *in vivo* therapy will need to fulfill more strict quality demands.

2.6.2 PROPERTIES OF RETROVIRAL VECTORS CRITICAL IN DOWNSTREAM PROCESSING

The development of a purification process demands a deep knowledge on the physical, chemical, and biological properties of retroviral vectors. Retroviral vectors are enveloped viruses with a complex macromolecular structure of 80–150 nm diameter (Salmeen et al., 1976; Coffin et al., 1997) (Figure 2.1). Due to their large size they have low diffusivity (10^{-8} cm²/s) and their density is 1.15–1.16 g/cm³ (Coffin et al., 1997). Mature and infectious retroviral vectors have a morphology with a round or sometimes slightly angular core, centered in the middle of the particles (Yeager et al., 1998). They are composed by 60%–70% protein, 30%–40% lipid (derived from the plasma membrane of the producer cell line), 2%–4% carbohydrate, and 1% RNA (Andreadis et al., 1999). The lipid membrane of retroviral vectors is studded with glycoprotein projections, between 100 and 300 per particle, the envelope proteins (Andreadis et al., 1999). Approximately three quarters of the total retroviral vectors protein corresponds to the Gag proteins; the rest includes the viral envelope glycoproteins and, to a lesser extent, the viral enzymes RT, IN, and PR (Coffin et al., 1997). Some cytoplasmic and membrane cellular proteins are also known to be incorporated during vector assembly and budding (Ott, 1997). The lipid composition of the retroviral particle is derived from the producer cell plasma membrane during budding, but is enriched in sphingomyelin and cholesterol (Quigley et al., 1971; Aloia et al., 1993; Beer et al., 2003).

The isoelectric point of Moloney MLV occurs at very low pH values thus, viral particles are negatively charged at physiological pH (Rimai et al., 1975).

Retroviral vectors are known to be sensitive to environmental conditions and to lose infectivity relatively fast; thus the knowledge of optimal conditions for maintenance of retroviral stability is critical in downstream processing. During production retroviral vectors bud from the producer cell line and start to lose infectivity due to their labile nature at 37°C, with a half-life of about 8 h at this temperature (Higashikawa and Chang, 2001; Beer et al., 2003). As a consequence, few of the particles in a preparation are infectious, the ratio of total to IPs being typically above 100:1 (Higashikawa and Chang, 2001). Retroviral vectors are more stable at low temperatures, with half-lives higher than 100 h at 4°C (Le Doux et al., 1999; Beer et al., 2003). Besides temperature, retroviral vectors are also sensitive to acidic or basic pH, having a bell shaped pH profile with an optimum pH between 5.5 and 8.0 (Ye et al., 2004). High salt concentrations have also been reported to affect retroviral stability (Segura et al., 2005).

As mentioned above, the stability of retroviral vectors also depends on a number of producer cell and production process related variables such as the producer cell line type, viral membrane cholesterol levels, pseudotyping, production

medium osmolarity, and production temperature (Beer et al., 2003; Carmo et al., 2006; Coroadinha et al., 2006a; Coroadinha et al., 2006d). Thus, each type of vector will also have different tolerance to environmental factors.

2.6.3 TARGET CONTAMINANTS

2.6.3.1 PROTEINS

Protein impurities are the most abundant contaminants in retroviral vectors supernatants. They arise from the serum usually used to supplement cell growth media or are secreted by the producer cells. Serum albumin is the most abundant protein contaminant that comes from serum, followed by immunoglobulins (Anderson and Anderson, 2002). Evaluation of protein contamination is usually performed by SDS-PAGE with silver staining analysis and Western-blot directed to protein contaminants or vector proteins, usually aids gel interpretation (Figure 2.5) (Segura et al., 2006). Other techniques to determine and quantify protein contamination include HPLC analysis (Transfiguracion et al., 2003) and ELISA quantitation of BSA (Richieri et al., 1998; Schonely et al., 2003).

2.6.3.2 DNA

The major source of contaminating DNA are the host producer cells but, if transient transfection is used in the production of retroviral vectors, plasmid contamination can also

occur (Chen et al., 2001; Sastry et al., 2004). Concern about nucleic acid contamination arises from the possibility of cellular transformation events in the patient. Contaminant DNA limits are usually dependent on product and application and set for approval to the regulatory authorities. FDA recommends a limit of 10 ng DNA/dose (O'Keeffe et al., 1999).

2.6.3.3 Transduction Inhibitors

Transduction inhibitors interfere with the ability of the retroviral vectors to infect target cells. Thus, they decrease the efficacy of the vector preparations and increase the necessary dose to achieve desired potency. Several types of transduction inhibitors have been identified, including noninfectious particles (Seppen et al., 2000; Transfiguracion et al., 2003), free envelope proteins (Landazuri and Le Doux, 2006), and negatively charged proteoglycans (Le Doux et al., 1996).

2.6.4 PURIFICATION OF RETROVIRAL VECTORS

The first protocols used for the purification of retroviral vectors were similar to those performed for the native viruses and based on their size and density, using methods such as ultracentrifugation and density gradients (Faff et al., 1993; Andreadis et al., 1999; Reiser, 2000). According to these protocols, retroviral vectors are first separated from cell debris by low-speed centrifugation or filtration through 0.45 μm membranes, and afterwards pelleted by ultracentrifugation and separated from the extracellular medium. The resulting pellet is resuspended in buffer and the retroviral vectors sedimented to equilibrium by ultracentrifugation, usually in a sucrose gradient. Recovery of infectious vectors is usually very low after ultracentrifugation (<1%) due to the degradation of the viral vectors (Burns et al., 1993; Powell et al., 2000). Moreover, these methods are time-consuming, difficult to scale-up and allow for coprecipitation of impurities that have a similar density to the virus, like membrane vesicles from host cells (Bess et al., 1997; Seppen et al., 2000). Therefore, they are not suitable for clinical applications. Other purification processes, well established for protein therapeutics, are wiser options.

2.6.4.1 Membrane Separation Processes

Membrane filtration is defined as the separation of two or more components from a fluid suspension stream using membranes, based primarily on size differences. The membrane acts as a selective barrier as it permits the passage of components smaller than the pore size and retains larger components.

As retroviral vectors are nanoscale particles, membrane separation can be applied for clarification (cells and cellular debris are retained by the large pore membranes while the viral particles are allowed to pass), concentration, and partial purification of retroviral supernatants (the smaller pore membranes retain retroviral vectors while small proteins cross the membrane barrier). Strategies for clarification and concentration

FIGURE 2.5 Western blot analysis of proteins from an amphotropic retroviral vector using different types of primary antibodies: A, molecular weight markers; B, rat monoclonal antibody against p30 Gag protein of MLV (produced by hybridoma cell line R187, ATCC no CRL-1912); C, rat monoclonal antibody against p69/70 envelope proteins (83A25) (Evans et al., 1990); D, swine polyclonal anti-amphoteric MLV antibody (Cat# 77S000445, Viomed, USA).

of viral stocks using membrane technology include microfiltration and ultrafiltration (UF), correspondingly.

Traditionally, separation of cells from produced stocks is performed using microfiltration membranes with 0.45 μm pores. However, blockage of the membrane pores with cells and debris often hinders the passage of retroviral vectors resulting in lower recoveries (Reeves and Cornetta, 2000; Rodrigues et al., 2007). To circumvent this problem, step filtration with decreasing pore size can be used allowing a significant increase in retroviral vectors recovery (Reeves and Cornetta, 2000; Rodrigues et al., 2007). Other factors might also impact the recovery after microfiltration, including the membrane characteristics and retroviral vectors stability.

UF is an attractive process with a number of important advantages: it is fast, robust, flexible, and useful for concentrating and washing feed streams (change the pH,

salt concentration, and solute conditions of the retained product) prior to chromatography. UF has been applied with success in the concentration and partial purification of retroviral vectors, mostly at laboratory scale, using centrifugation dependent modules (Saha et al., 1994; Miller et al., 1996; Parente and Wolfe, 1996; Reiser, 2000; Yamada et al., 2003) or stirred vessels (Miller et al., 1996; Cruz et al., 2000; Transfiguracion et al., 2003). Retroviral supernatants can be ultra/diafiltered using various pore sizes, ranging from conventional 20 to 500 kDa molecular weight cut-off membranes (Table 2.4) up to 35 and 75 nm pore microfiltration membranes (Makino et al., 1994). The use of UF membranes with high cut-off pores is advantageous as it should, in principle, result in higher permeate fluxes (decreased process time) and higher purification factors due to removal of both large and low molecular weight proteins. Nevertheless, lower recoveries might

occur if the vector and membranes pore size are within the same order of magnitude (Makino et al., 1994).

Several membrane geometries use tangential flow filtration (TFF), which is easily scalable. This geometry minimizes build-up of solids on the membrane thus, decreased fouling. The most often reported TFF geometries for retroviral vectors concentration and clarification are flat sheet cassettes or hollow-fibers (Segura et al., 2006; Rodrigues et al., 2007). Together with some developments in the field of disposable downstream technology, TFF constitutes an interesting option for the production of retroviral vectors for clinical use (Table 2.4, Figure 2.6).

Although competing with ultracentrifugation in terms of achievable concentration and volume reduction factors, the advantages of UF in terms of throughput, scalability, and maintenance of vector biological activity and integrity are indisputable.

2.6.4.2 Chromatographic Methods

Chromatography is the predominant technology used for purification of biomolecules and can often be operated both as fixed or fluidized/expanded bed and also in membrane configurations. Due to the labile nature of retroviral vectors, conditions for chromatographic purification are quite restricted, limiting the range of chromatographic media and buffers that can be used. An initial screening of conditions is advisable (Rodrigues et al., 2006). Besides having high binding capacity for adsorption and elution of retroviral vectors in non-denaturing conditions, the adsorbents need also to separate retroviral vectors from contaminants derived from host-cell

material and cell culture medium. Several properties of retroviral vectors have been explored for selective adsorption/desorption to chromatographic media, including charge, size, and specific interaction with SU protein domains or unique ligand binding sites (Segura et al., 2006; Rodrigues et al., 2007).

Several affinity chromatography strategies have been evaluated for the purification of retroviral vectors, namely heparin affinity (Segura et al., 2005), streptavidin–biotin affinity (Hughes et al., 2001; Williams et al., 2005), and immobilized metal affinity (IMAC) (Ye et al., 2004). Retroviral vectors purification through interaction with heparin matrices results in high IP recoveries, approximately 60% (Segura et al., 2005). Nevertheless, many cellular and serum contaminant proteins have also affinity to heparin; thus, another purification step is necessary to remove such contaminants (Segura et al., 2005). Although the implementation of purification strategies including streptavidin–biotin affinity and IMAC is possible, the use of technologies that require modification of the vectors will pose obstacles for regulatory approval. Additionally, the desorption reagents used to elute the retroviral vectors impair their biological activity (Rodrigues et al., 2007).

Anion-exchange chromatography (AEXc) involves the adsorption of negatively charged retroviral vectors to positively charged chromatographic resins (Richieri et al., 1998; Kuiper et al., 2002; Rodrigues et al., 2006). Retroviral vectors bind strongly to AEX matrices thus, desorption is usually accomplished at salt concentrations around 1 M NaCl. AEXc has been successfully used for the purification of both retroviruses and lentiviruses allowing IP recoveries of up to 70%

(Rodrigues et al., 2007). Diethylaminoethyl ligands were considered the best anion-exchangers for capture/elution of retroviral vectors and in combination with tentacle MA technology they offer the highest recoveries of IPs after elution (Rodrigues et al., 2006). AEX chromatography offers milder conditions and also higher purification factors without the need for modification of the vector itself (Rodrigues et al., 2007). Moreover, it has been used in the preparation of other types of viruses for conventional vaccine and gene therapy trials (Konz et al., 2005; Tancevski et al., 2006), hence presents itself as a good candidate for retroviral vector purification.

Retroviral vectors can also be efficiently separated from cellular and medium contaminants by size exclusion chromatography (SEC) usually with recoveries above 70% (McGrath et al., 1978; Slepshkin et al., 2003; Transfiguracion et al., 2003). SEC is a powerful separation tool but it is difficult to scale-up, has very low throughput and works with low linear flow rates, thus increasing process time. Also it does not offer advantages in terms of final purity when combined with AEXc, thus it is not advantageous in terms of clinical application (Rodrigues et al., 2007).

The introduction of disposable membrane chromatography, already available with several chemistries in the development of purification processes for retroviral vectors (Figure 2.6) will be very beneficial in terms of clinical application, due to higher process flexibility and lower validation costs (Ghosh, 2002; Thommes and Etzel, 2007).

2.6.5 STORAGE OF RETROVIRAL VECTORS

The efficacy of retroviruses as gene delivery agents depends on the assurance of efficient and stable transfer of the transgene into the target tissue. Therefore, the maintenance of viral vectors potency until administration is of germane importance for the success of the clinical application.

Downstream processing, final product formulation, and storage temperature are determinants of the half-life of retroviral vectors. Due to this fact, reported vector half-lives range from 19 days to 18 months for retroviral vectors stored at -80°C (Wikstrom et al., 2004; Carmo et al., 2006). Historically, long-term storage of viral preparations requires cryopreservation where small volume aliquots of viral stocks are stored at -80°C until use or, alternatively, kept in a lyophilized form at 4°C (Harris, 1954).

Although little is known regarding the degradation and stabilization mechanisms of retroviral vectors, it has been shown that the addition of cryoprotectants (e.g., sucrose and trehalose) decreases the loss of infectivity of viral vectors and enhances their stability during long-term storage (Bieganski et al., 1998; Cruz et al., 2006). The need for such formulations creates an important challenge as purified vectors seem to be more sensitive than those from clarified supernatants that constitute today's common practice (Carmo et al., 2006).

Furthermore, the relevance of this point is strengthened by the fact that the vector production under GMP conditions, the necessary safety and potency testing and the subsequent

final product release for clinical application may take 6 to 12 months. Along with the time necessary to obtain the approval of the clinical protocol by the regulatory agencies, the maintenance of the potency has to be assured for at least 1 to 2 years.

2.7 QUALITY ASSESSMENT

Several orthogonal methods are necessary to assess quality of retroviral preparations due to the complexity of the product and also due to its final clinical application. Thus, the quality of a purified retroviral vectors preparation is described by appropriate dose, potency, purity, and safety standards (safety of retroviral vectors preparations is addressed in a different chapter). These quality tools aid the downstream process development and provide reassurance that preliminary *in vitro* studies are conducted with material that will be representative of that to be used in clinical trials.

2.7.1 DOSE AND POTENCY

Dose and potency are important characteristics of a retroviral preparation and are closely related. Potency can be defined as a measure of the capacity of the target cells, transduced by retroviral vectors preparations, to express the transgene product. For potency either *in vitro* or *in vivo* tests, or both, have been specifically designed for the transgene and target cells in question (Slepshkin et al., 2003). This is an important parameter to measure during clinical application. Parameters that usually define the dose of a purified retroviral vectors preparation to be used in clinical trials are the biological activity, which constitutes a measure of the IP content, the total particles, and the total protein content (Table 2.5). There is no accurate method to measure infectious and total particles due to the complexity of the target. Nevertheless, combinations of the orthogonal methods presented in Table 2.5 provide satisfactory and quantitative answers that aid process development.

2.7.2 PURITY

Being complex macromolecular assemblies of proteins, lipids, and RNA evaluation of retroviral vectors purity is cumbersome. Most of the difficulty arises from the unavailability of a well characterized standard of biologically active and pure retroviral vectors. Moreover, retroviral vectors incorporate components of the producer cells, mostly proteins, during the budding process, both within the lipid bilayer and inside the viral particle (Ott, 1997). All these characteristics greatly increase the difficulty in the determination of which sample components come from the vector and which are indeed contaminants. Due to the complexity of retroviral vector products, demonstration of product purity needs to be performed using wide range of methods, including physicochemical and immunological techniques (Table 2.5).

TABLE 2.5
Summary of the More Relevant Quality Assays Used for Retroviral Vectors

Test	Target	Assays	References		
Dose	Particle number	RT-PCR	Carmo et al., 2004		
		HPLC	Transfiguracion et al., 2004		
		Electron microscopy	Higashikawa and Chang, 2001		
		RT activity	Kwon et al., 2003

		PCR			
RCR		Amplification in a suitable cell line followed by: PG-4 S ⁺ L ⁻ assay, PCR, PERT	Printz et al., 1995; Forestell et al., 1996; Martineau et al., 1997		

2.7.3 SAFETY

Contamination with RCRs constitutes a primary safety concern regarding clinical application. Being structurally similar to non-replicative vectors, their separation during downstream processing is virtually impossible. Thus, procedures for testing the master, WCBs, and vector containing supernatants are critically important during the entire manufacture process development (CBER, 2000; Anson, 2004). Sensitive assays for the screening of RCR are required as these recombination events occur at low frequency and high levels of replication incompetent particles can interfere with the detection methods (Forestell et al., 1996). Most of the methods currently used to detect RCR in preparations for use in clinical trials are based on a combination of biologic assays and molecular detection (Table 2.5).

The elimination of adventitious viruses from vector preparations is another safety concern. Usually strategies are implemented at the end of the downstream process to eliminate such contaminants. However, they result in the inactivation of the retroviral vectors which is undesirable. Therefore, probable contamination sources (e.g., producer cell line and reagents from animal sources) should be shown free of adventitious virus contamination (EMEA, 1997). Finally the end-product must be tested for the presence of other microorganisms,

namely mycoplasma, bacteria, and fungi and also for the presence of endotoxins and pyrogens (Table 2.5).

2.8 CONCLUDING REMARKS

Retroviral vectors continue to be one of the preferential vehicles for gene therapy as they offer several advantages relative to other vectors. Current *ex vivo* gene therapy applications use clinical grade retroviral culture supernatants produced in sub-optimal conditions regarding maximum viral infectivity, purification, and maintenance of stability. In clinical settings, phase I and II trials are slowly moving to phase III, as safety concerns are being solved. This drives research to a more technological level since larger retroviral preparation volumes will require better producer cells, more sophisticated production methods, and postharvest processing. Future *in vivo* gene therapy applications of retroviral vectors will require concentrated and purified vector preparations. The generation of such purified retrovirus clinical batches with assured long-term storage is still an important challenge. The loss of viral infectivity during downstream processing represents a limitation and is still an issue. Consequently, further developments in retroviral vector production directed to increase productivity, stability, and recovery after purification and storage are mandatory to ensure the vector titers and quality required for clinical applications.

3.1 INTRODUCTION

The emergence of recombinant DNA as a tool to study medicine quickly promulgated the concept of cloned genes as therapeutics. As originally conceived, the concept of gene therapy was simply to introduce a wild-type copy of a deficient gene into cells to restore function *in trans* [1–4]. Viewed in this way, the technical challenge was to efficiently deliver the gene to the appropriate cell and have it expressed for sufficient time, or readminister as often as needed, for the therapeutic application. Adenovirus (Ad) gene transfer vectors offer one strategy to achieve this. The focus on Ad for gene transfer was based on basic research establishing the biology of Ad, and the knowledge that Ad efficiently delivers the viral genome to the target cells. Importantly, Ad is not oncogenic in humans, the genomes of common Ad are completely defined, the Ad genome can be easily modified, and recombinant Ad can be

readily produced in large quantities and highly concentrated without modifying the ability of the virus to infect cells.

In retrospect, the original goal of using Ad as simple delivery systems to permanently complement genetic defects seems naive. Whereas Ad gene transfer vectors can achieve robust expression of the transgene in many target organs, expression of the transgene is limited in time, resulting from a complex combination of innate and adaptive immune host defenses against the virus [5,6]. In this context, Ad vectors in their present form are most useful in applications where transient (days to weeks) expression is sufficient to have the desired therapeutic effect. For applications where persistent expression is required to achieve a therapeutic goal, there are still many challenges before and if Ad vectors will be successful. In this chapter we summarize the biology of Ad, the construction and use of first generation Ad vectors, the current status of advanced forms of Ad vectors, clinical applications of

Ad vectors, and the future prospects of using Ad in gene transfer applications.

3.2 BIOLOGY OF Ads

Adenoviruses are a group of double-stranded DNA viruses which infect a variety of vertebrate hosts including rodents, chickens, and primates. Human Ad has been isolated from several sources including the upper respiratory tracts of military recruits with respiratory infections, adenoids, conjunctiva, and the stool of infants with diarrhea [7]. As with other viruses, there is an immune response to Ad infection which includes the production of neutralizing antibodies, defined as antibodies which prevent Ad infection *in vitro*. Neutralizing sera have been used to distinguish >50 different Ad serotypes which are divided into subgroups A through E [8]. The presence of antibodies against one serotype generally protects against reinfection by the same serotype. In the context of gene therapy, serotypes 5 and 2 of the subgroup C have been used most because their structure and biology is well described and there are convenient biologic reagents available to produce recombinant subgroup C Ad gene transfer vectors in large quantities. Ads of subgroups C cause various respiratory infections either as outbreaks in confined groups (such as military recruits) or in children, sometimes associated with conjunctival infections [9]. The known predilection of subgroup C in the respiratory tract led to the initial uses of Ad gene therapy for the treatment of cystic fibrosis (CF), and thus the focus on serotypes 2 and 5.

3.2.1 STRUCTURE

Adenovirus consists of an icosahedral protein capsid of approximately 70–100 nm diameter and, within that capsid, a single copy of a double-stranded DNA molecule of length approximately 36,000 bp (Figure 3.1, reviewed in Ref. [10]). In the context of gene therapy, the fiber, penton base, and hexon are the most important capsid proteins. The 20 triangular faces of the viral capsid are built from hexon, the major capsid protein. The 240 hexon capsomeres in the capsid are each trimers comprising three copies of the 105 kDa hexon subunit with each trimer interacting with six others in a pseudo-equivalent fashion. The three-dimensional structure of hexon shows that the homotrimer has loops which project out from the capsid surface [11]. Capsid proteins VI, VIII, and IX are associated with hexon and their role is to stabilize the capsid structure. The 12 capsid vertices are made up of the penton capsomere, a complex of five copies of the penton base and three copies of fiber. Each penton capsomere interacts with five hexon capsomeres, one from each of the five faces that converge at the vertex. The fiber protein projects outward from the penton base. The DNA is wrapped in the histone-like core protein VII and there is a terminal protein attached to the 5' end of each strand of the DNA.

Neutralizing antibodies are directed primarily against epitopes located on the loops of the hexon. This is expected, as the loops project from the surface of the virus where they

FIGURE 3.1 Structure of the Ad capsid. Shown (left) is a three-dimensional representation and (right) a simplified cross-section of the capsid showing the deployment of the capsid proteins and Ad genome. The capsid is an icosahedron with 20 faces and 12 vertices. The faces are composed of hexons, each comprised of trimers of the hexon protein. The hexons are trapezoid shaped, with three loops on top, extending from the face of the capsid. The loops represent the variable regions that differ among serotypes and are the major epitopes for neutralizing antibodies. Proteins IX and VIII are associated with the hexon and are thought to stabilize the capsid. The vertices are composed of a fiber and penton base. The fiber has three domains, the base which interacts with penton, the shaft, and the knob. The knob interacts with a high affinity receptor on the target cell, and the shaft holds the virus away from the surface of the cell, depending on the length of the shaft. The penton base interacts with the hexon and the fiber and contains epitopes that interact with integrins on the cell surface. The 36 kb double-stranded DNA genome is wrapped around capsid core protein VII and the terminal protein is attached to the two 5' ends of the Ad genome. (Adapted from Shenk T., *Fields Virology*, Lippincott-Raven Publishers, Inc., Philadelphia, 1996.)

are accessible to antibodies. When the primary structures of the capsids of different serotypes are compared, related Ad differs most in these loops, suggesting the selective pressures applied by the immune system result in the emergence of mutations in the external hexon loops [12].

The fiber protein is a trimer consisting of three domains, base, shaft, and knob. The N-terminal base domain interacts with the penton base. The shaft includes an extended domain consisting of variable numbers of a 15 amino acid pseudo-repeats. The number of repeats, and therefore the length of the shaft, varies between 23 copies for the subgroup A viruses and 6 copies for the subgroup B viruses. The distal C-terminal domain of the fiber protein, referred to as the “knob,” interacts with the high affinity receptor on the surface of the target cell. The high affinity receptor for Ads except those of subgroup B is referred to as “CAR” (coxsackie and adenovirus receptor), reflecting the fact that the coxsackie B viruses and most serotypes of Ad share the same receptor [13,14]. CAR is a single membrane-spanning protein with two extracellular immunoglobulin-like domains. Apart from acting as a virus receptor, the function of CAR is unknown.

A sequence motif on the penton base is involved in internalization of the virus after high affinity CAR–fiber interaction. In serotypes 2 and 5 the amino acid motif arginine–glycine–aspartate (RGD) interacts with $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins of the cell surface and this interaction is essential for efficient internalization [15].

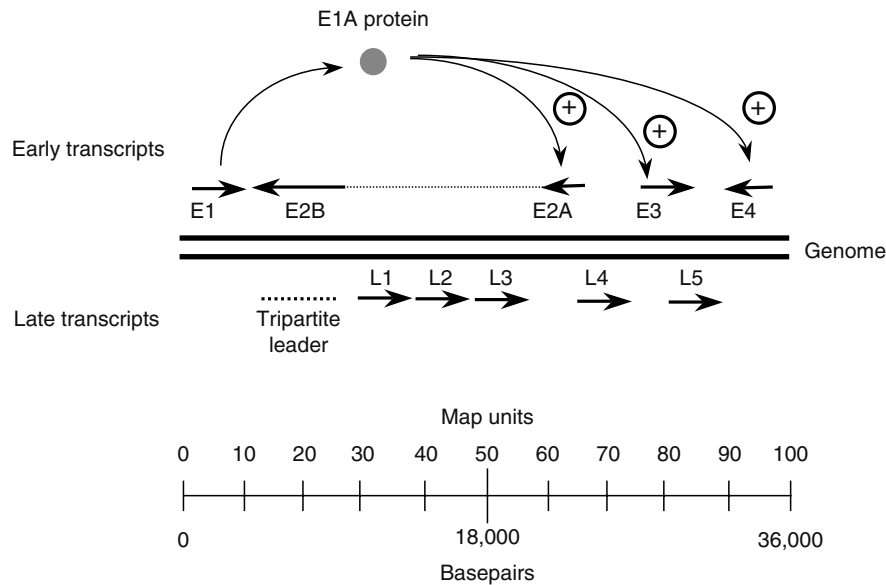

FIGURE 3.2 Structure and transcription of the major genes of the Ad type 5 genome. Schematic summary of the transcription of Ad during lytic infection. The genome is represented as two parallel lines and is divided by the scale shown underneath into 100 map units (1 map unit = 360 bp). There are nine major complex transcription units divided into early (above the genome) and late transcripts (below). The four early transcripts are produced before the commencement of DNA replication and specify regulatory proteins and proteins required for DNA replication. Upon initial infection of a cell, the E1A protein is produced from transcripts in the E1 region. E1A is a major regulatory factor required for transcription of E1B, E2, E3, and E4. In replication-deficient Ad vectors, the E1 region is deleted. Proteins coded by the E2 and E4 regions are required for late gene transcription. The E3 region codes for proteins that help the virus evade host defenses. All late transcripts rightwards originate at the same point and are produced by alternate splicing. The tripartite leader sequence is present at the 5' end of all late transcripts. The L3 region specifies hexon, the L5 region specifies fiber, and the L2 region specifies penton.

For Ad type 5, the most commonly used Ad for gene transfer vectors, the complete 35,935 bp DNA sequence is known. For convenient reference, the genome is divided into 100 equally sized map units. A detailed transcription map at various time points postinfection is used to divide the genome into interspersed early (E) and late (L) regions (Figure 3.2, reviewed in Ref. [10]). There is considerable transcriptional overlap among the genes, making manipulation of some areas of the genome difficult. Each of the five early genes is comprised of a complex transcription unit with alternative sites for transcription initiation, termination, and splicing. The E1A and E1B genes are transcribed rightwards at the left hand end of the genome close to the DNA replication origin and DNA packaging signal. The E4 region is transcribed leftward at the right hand end of the genome. Distal to the E1 and E4 regions are the termini of the DNA which are inverted copies of the same sequence. Replication of the ends of the DNA is achieved by the attachment of terminal protein to the 5' end of the DNA which acts as a primer to initiate unidirectional replication. This terminal protein is one of the components of the E2 transcriptional unit which is transcribed leftward commencing at map unit 75. The remaining early transcription unit is the E3 gene which is transcribed rightward commencing at map unit 77.

The five late genes are expressed after the beginning of DNA replication and encode the viral structural proteins. These late transcripts are all transcribed rightwards originating from map unit 17 and contain the same three part

leader sequence before alternate splicing generates different mature mRNAs.

3.2.2 VIRAL REPLICATION

The Ad viral life cycle is understood best for subgroup C, which is another factor in the choice of Ad5 and Ad2 as gene therapy vectors (Figure 3.3). The knob of the fiber protein binds to the CAR receptor [13] followed by an interaction of the RGD sequence in the penton base with cell surface $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrins [15]. Excess soluble integrins inhibit Ad internalization but not binding, suggesting that penton base-integrin interaction is instrumental in internalization [16]. Ad modified with deletion of the RGD motif replicates effectively *in vitro* so the penton base-integrin interaction is likely related to efficiency of Ad infection, but is not essential [17]. The Ad enters the cell by endocytosis into clathrin coated pits, a process that can be blocked by dynamin inhibitors [18]. After endocytosis, Ad is rapidly released into the cytoplasm prior to extensive endosome fusion. The virus proceeds rapidly to the nucleus, probably actively transported on microtubules using the dynein motor [19], and then binds to the surface of the nucleus near the nuclear pore [20]. Using fluorescent viruses, this process has been shown to be efficient and rapid, with >90% of Ad5 delivered to the nucleus within 1 h [21]. At the nuclear membrane, the DNA and terminal protein are internalized by an unknown mechanism and are assembled into the nuclear scaffold for active transcription.

FIGURE 3.3 Trafficking of Ad from membrane to nucleus. The initial contact between the virus and cell is mediated by the knob of fiber and the CAR. This allows the secondary interaction between the penton and $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrins which is required for internalization. The initial internalization is via coated pits which give rise to coated vesicles. After a very short interval, prior to fusion of early endosomes into sorting endosomes, a conformational change in the viral capsid allows escape of the virus into the cytoplasm. Microtubules carry the virus towards the nucleus. The whole capsid attaches to the outside of the nucleus but only the DNA and terminal protein are inserted into the nucleus itself, where they are assembled onto the nuclear matrix to allow transcription. (Courtesy of P. Leopold, Weill Medical College of Cornell University. With permission.)

With wild-type Ad, the viral E1A gene is transcribed immediately after infection [10]. After alternate splicing, the E1 mRNAs are translated into the two E1A proteins essential for transcription of other early viral mRNAs. E1A proteins promote the expression of cellular genes needed for DNA replication by interacting with the retinoblastoma susceptibility protein (Rb) which normally suppress entry into S phase of the cell cycle by complexing with the host transcription factor E2F. E1A also interacts with a number of cellular transcriptional factors to promote the assembly of complexes that promote transcription of other early adenoviral genes. Among the important downstream products induced by E1A is the product of the E1B gene, which blocks the apoptotic pathway through interaction with p53 long enough for a productive viral infection. The E1B 55 kDa protein also complexes with the ORF6 protein from the E4 region to modulate expression of the viral late genes which begin to be expressed around 6 h postinfection. At that time, DNA replication begins and the transcription of late genes commences, providing the capsid components that assemble into mature virions [10]. The new virions are assembled in the nucleus, necessitating transport of capsid proteins into the nucleus. As the viral infection proceeds, the integrity and viability of the cells decreases, but the mechanism of viral release from the cell is not understood.

In the context of gene therapy, the E3 region is important as it encodes immunosuppressive functions that work through two mechanisms [22]. The E3 gp 19 kDa protein prevents major histocompatibility complex class I-mediated antigen presentation on the cell surface, thereby inhibiting the differentiation of cytotoxic T lymphocytes directed against viral antigens [22]. The E3 14.7 and E3 10.4 kDa proteins inhibit apoptosis of infected cells initiated by fas/fas ligand or tumor necrosis factor (TNF) [23]. The promoter for the E3 region requires E1 products, and thus in E1⁻ deleted Ad vectors, the presence or absence of the E3 region is not relevant (see Section 3.4.3).

Transcripts from the E2 region specify the three nonhost proteins directly involved in DNA replication: The DNA polymerase, the single-stranded DNA binding protein (ssDBP), and the preterminal protein [10]. Like other viruses, Ad has developed a specific strategy for the faithful replication of the DNA ends. The last 103 nt at both ends of the genome consist of inverted copies of the identical sequence. The terminal protein binds covalently to the 5' end and acts as a primer for DNA synthesis by the adenoviral DNA polymerase of the leading strand starting at either end. DNA polymerase proceeds by a strand displacement mechanism creating a duplex and a displaced strand, which is sequestered by the ssDBP and has terminal protein attached to one end. Base pairing of the ends of the single strand creates a panhandle structure with ends identical to those of the duplex. Reformation of duplex from the single stranded form occurs by the same mechanism with the Ad polymerase initiating at the terminal protein and displacing the ssDBP. Interestingly, the viral genomes undergoing replication are at a different location from those being transcribed [24]. DNA is packaged into capsids as directed by a DNA sequence close to the left hand end of the virus. The efficiency of packaging depends on the length of DNA; genomes greater than 105% or less than 95% of the normal length propagate much less efficiently [25,26].

The E4 region plays important roles in the viral life cycle by promoting the selective expression of viral genes at the expense of cellular genes. For example, the E4-ORF3 and ORF6 proteins inhibit the transport of transcripts of cellular genes from nucleus to cytoplasm while promoting the transport of late viral transcripts [10]. The E4 region is therefore essential for viral gene expression and subsequent viral replication.

3.3 CONSTRUCTION AND USE OF FIRST-GENERATION Ad VECTORS

3.3.1 CONSTRUCTION

Although the pathology associated with wild-type Ad infections is generally mild, there is a potential risk of using fully replication-competent Ad (RCA) for gene transfer in that the inflammatory host responses to Ad infection may alter organ function [9]. There is also the possibility of overwhelming infection if Ad replication is allowed to progress when there are deficiencies in the host defense system. Since the E1A

products are essential for expression of other early and late genes and DNA replication, the most direct approach to eliminating replication is to delete the E1A genes. To produce E1⁻ Ad vectors, the classic approach is to transfect the recombinant E1⁻ Ad vector genome into the human embryonic kidney cell line 293, a cell line originally established by transforming primary cells with Ad5 [27,28]. The 293 cells contain approximately 11 map units of the Ad5 genome, originating at the left hand end [29].

One example of a so-called first-generation Ad vector expresses the human CF transmembrane conductance regulator (CFTR) cDNA under control of the constitutively highly active cytomegalovirus immediate/early promoter (CMV, Figure 3.4, [30]). A polyadenylation site is located following the cDNA and the whole expression cassette in a left to right orientation replaces the E1A and part of the E1B genes. Since the expression cassette is 5601 bp in length while the E1 deletion is 3062 bp, it is necessary to delete part of the E3 region

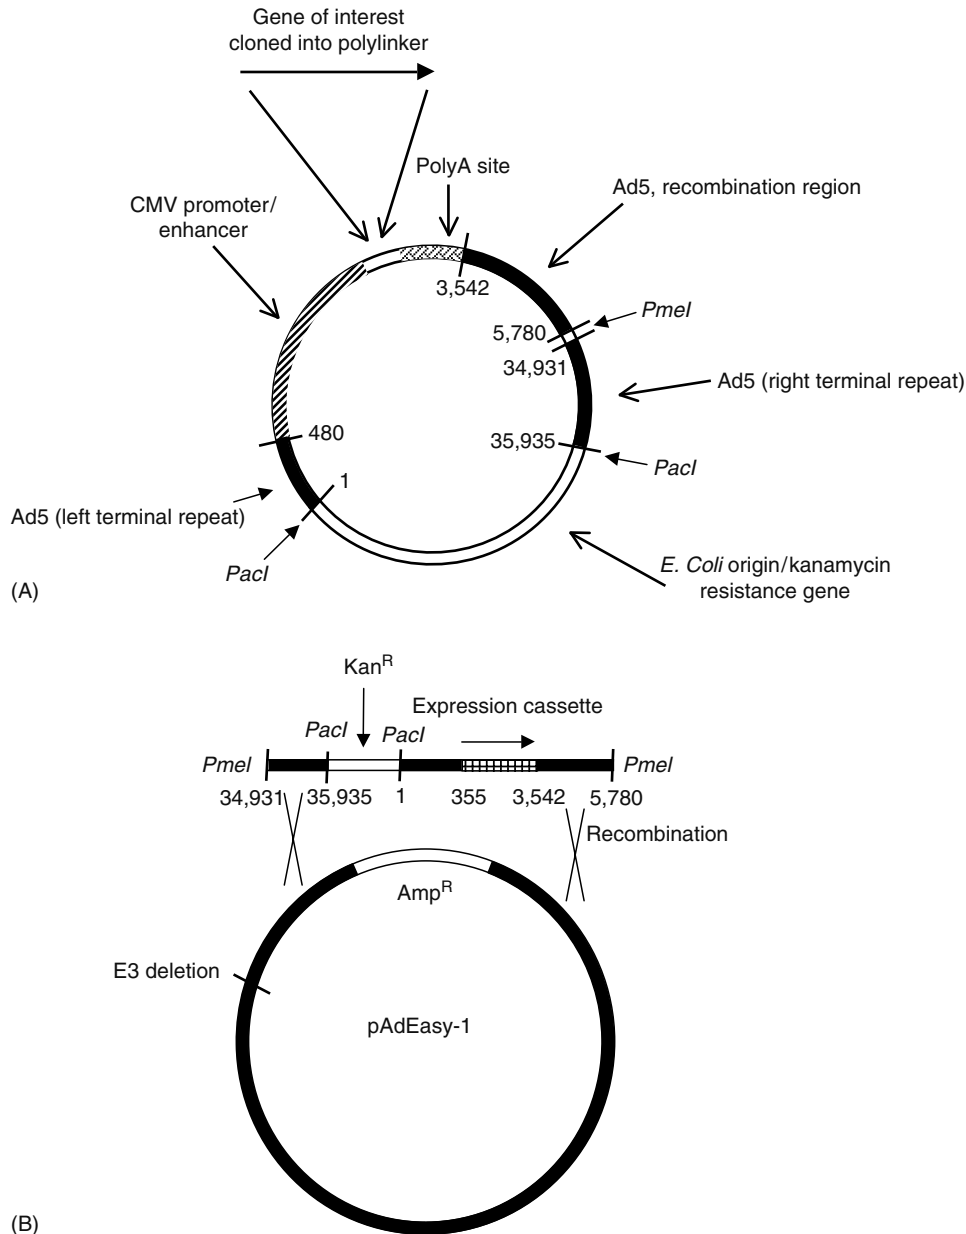

FIGURE 3.4 Production of the genome of a replication-deficient Ad vector by homologous recombination in *E. coli*. (A) A new cDNA is cloned into the kanamycin resistance plasmid pShuttleCMV between the CMV promoter and the polyadenylation site of SV40. Analogous plasmids are available which allow other promoters to be used [31]. The expression cassette lies between two portions of the Ad genome, nt 1–480 and 3542–5780. (B) Homologous recombination between PmeI linearized pShuttleCMV containing the gene of interest and supercoiled pEasy-1 results in a kanamycin resistant plasmid with a full length Ad genome bordered by Pacl sites. Plasmid pEasy-1 is used to make E1⁻E3⁻E4⁺ vectors or pEasy-2 to make E1⁻E3⁻E4⁻ vectors. The recombinant prepared in large amounts for transfection into E1 complementing cell lines where it will give rise to the desired vector.

in order to construct the vector. Since the E3 region is nonessential *in vitro*, this deletion does not affect propagation of the replication-deficient virus in 293 cells. However, for some therapeutic genes, if the extra space is not necessary, the E3 region can be retained.

The genomes of first generation (E1⁻, E3⁻) Ad are now typically constructed and amplified as *E. coli* plasmids (Figure 3.4) followed by transfection into 293 cells for the production of vector. In one widely used system [31], the Ad genome is created by homologous recombination between a shuttle plasmid and a backbone plasmid. The shuttle plasmid consists of the extreme right and left hand ends (map units 1–16 and 97–100) of the Ad genome with the expression cassette for the transgene in the deleted E1 region (map units 2–10 deleted). The backbone plasmid contains mostly the Ad genome (map units 10–100) except for the extreme left hand end and a deletion of E3. Recombinants between the shuttle and backbone plasmids containing the whole vector genome are selected by appropriate antibiotic resistance markers.

Once made, a new vector is plaque purified repeatedly in 293 cells (to remove any contaminating wild-type virus) and is then propagated to produce the required amounts of the vector. Under standard laboratory conditions, it is possible to produce up to 2×10^{13} viral particles from fifty 150 mm cell culture plates (about 10^9 293 cells). The recombinant Ad is easily purified from cell lysates on equilibrium cesium chloride density gradients. After purification, the vector is assayed for infectivity by plaquing efficiency on 293 cells, for the presence of contaminating RCA by the plaquing efficiency on A549 cells (an E1⁻ cell line) [32], and for the activity of the transgene (using whatever assay is relevant). Titer on 293 cells gives the titer in plaque-forming units (pfu) per mL. This has historically been the activity unit used to standardize doses for experimental animals and patients. However, it has become evident that the pfu is an arbitrary, poorly reproducible measurement, and thus most laboratories now use particle units (pu) as the dosing unit, based on the premise that highly purified viruses made by a standard protocol represent a uniform population of potentially infectious units. The particle count is calculated from the absorbance at 260 nm using the formula: $1A_{260} = 1.25 \times 10^{12}$ particles/mL, and is typically 10 to 100 times the titer in pfu [33].

3.3.2 IN VITRO STUDIES

The methods outlined above have been used to make a large number of first generation E1⁻E3⁻ adenoviral vectors. Occasionally, there appears to be an inhibitory effect of transgene expression on virus production. Conditional systems to suppress transgene expression during production have been devised to overcome this limitation [34,35]. Among the most widely used Ad vectors are those which express readily monitored reporter genes such as β -galactosidase, luciferase, chloramphenicol acetyl transferase (CAT), and green fluorescent protein (GFP) [36,37]. As a control, viruses with the same promoter driving expression of no transgene (AdNull) are used.

Using the reporter gene Ad vectors, there are many studies examining the ease of gene transfer to different primary

cells and cell lines. Some primary epithelial cells are easily infected by wild-type Ad type 5 and, as expected, are easily transfected by adenoviral vectors. By contrast, macrophages [38] and lymphocytes [39,40] are more difficult to infect and only very high multiplicities of infection in concentrated cell suspensions are effective. The discovery that CAR is the adenoviral receptor partially accounts for the relative ease of infection. There are several studies in which the overexpression of CAR was shown to be sufficient to make an otherwise refractory cell line susceptible to gene transfer by Ad [38,41]. But integrins and post-internalization factors must also affect the efficiency of gene transfer.

A large number of cancer cell lines have been shown to be susceptible to Ad-mediated gene transfer including cells derived from hepatoma [42,43], glioblastoma [44], myeloma [45,46], melanoma [47], prostate [48], and ovarian cancer [49,50]. On the other hand, lymphoma cell lines are resistant to infection [46]. Studies in which cells are infected *in vitro* are instructive in indicating what cell types and therefore diseases might be candidates for adenoviral gene therapy. It is difficult to evaluate if studies with reporter genes show that therapeutic levels of proteins are achievable in any cell type due to the use of Ad vectors with different promoters, reporter genes, multiplicities of infection, and times of exposure.

In cells infected *in vitro* with E1 deleted, replication-deficient Ad vectors, a low level of transcription of early and late genes [51,52] as well as a small amount of DNA synthesis [53] can be detected. The reason for this is not entirely understood, but is hypothesized to result from E1-like activities in the target cell which support expression of Ad genes. In dividing cells there would also be a high level of E2F which would support adenoviral transcription. However, measurements of viral load in cultures suggest that this does not translate into the production of infectious viral particles in the absence of contaminating wild-type Ad. While cells may continue to divide after infection, the absolute level of vector does not increase or decrease even if the amount of vector per cell does decrease to the point when a small minority of cells are infected. On the basis of this evidence, the Ad genome is likely to remain episomal and is not integrated into the cellular genome, although this is difficult to prove, as it is very hard to detect integrated DNA at a very low frequency.

3.3.3 IN VIVO STUDIES AND TISSUE SPECIFICITY OF GENE TRANSFER

The feasibility of Ad vector-mediated gene transfer *in vitro* posed the question of the efficiency of this vector system *in vivo*. Since Ad gene transfer vectors are made from human Ads, there was no a priori reason to believe they would infect rodents or other model animals. Some early studies used cotton rats since this species had been shown previously to be permissive for replication of human Ads [54–56]. For example, intratracheal administration of a replication-deficient virus expressing the reporter gene β -galactosidase to cotton rats resulted in expression of β -galactosidase in the airway epithelium [57]. Numerous other animals have

been used to demonstrate efficient Ad vector-mediated gene transfer, including rats, mice, pigs, rabbits, and nonhuman primates. From these studies, a number of general conclusions can be drawn. Importantly, many tissues can be infected based on the route of administration. As expected from the tropism of Ad5, the transgene delivered to the respiratory epithelium is readily expressed after intranasal or intratracheal administration. But intravenous injection into rodents results primarily in transgene expression in the liver and spleen [58–60]. It is not known if the hepatocytes or hepatic endothelium account for this tropism since surprisingly, the preference for liver does not correspond to the distribution of the CAR receptor among organs [13]. Direct injection into the peritoneum [36], kidney [61], pancreas [62], cerebral spinal fluid [63], skeletal muscle [64], brain [65], cardiac muscle [66], and into the coronary artery [67], and many other tissues result in local expression of the transgene. But the absolute efficiency of gene transfer and expression and leakage to other organs has seldom been calculated and it is often unclear if therapeutic levels of transgene expression can be achieved.

3.3.4 HOST RESPONSES

Another important concept that emerged from *in vivo* studies in experimental animals was the short duration of transgene expression mediated by Ad vectors. Typically, transgene expression levels peak in 1–7 days and decline rapidly to undetectable levels by 2–4 weeks (Figure 3.5). This is true for most routes of administration with the exception of direct

injection into a few immunoprivileged tissues such as brain [68–70]. Immediately upon administration, the innate immune system serves to eliminate a large amount of vector. Using viral DNA levels as a means to monitor viral clearance from the liver, approximately 90% of an intravenous bolus is cleared after 24 h [71]. Inhibitors of the reticulo-endothelium system reduce this early loss of vector, suggesting that macrophages are responsible for early vector clearance [72].

It is known that infection by wild-type human Ads results in a strong immune response in experimental animals and humans. It was not clear whether replication-deficient gene therapy vectors would have the same effect since the net expression of viral genes would be so much lower and the tissues involved would be different from those involved in natural infections. In practice, both cellular and humoral anti-vector immune responses are observed in rodents after intratracheal [73–75], intravenous [76,77], and intraperitoneal [36] administration. Antibodies against various adenoviral proteins including hexon are induced which can be detected by Western analysis and neutralizing assays. Anti-vector cytotoxic T lymphocyte (CTL) responses are also observed. The CTL are assumed, to eliminate cells infected by the vector *in vivo*.

When a transgene is used which is foreign to the host, CTL and antibodies are usually, but not always, detected against the expression product of transgene [52,78,79]. The basis for this is not fully understood. In classical antigen presentation pathways, a cellular immune response would result from antigens expressed in the antigen presenting cell and presented in the context of MHC class I. This would imply that Ad infects antigen presenting cells directly and there is good evidence both *in vivo* and *in vitro* that this occurs [80]. But *in vivo* there is also a strong humoral anti-transgene response to many proteins which would not be expected to be taken up by antigen presenting cells and presented by the class II dependent pathway. It is possible that apoptosis of Ad infected cells followed by uptake of apoptotic cells by antigen presenting cells is critical (cross presentation). The strong anti-transgene product response has proven useful in using Ad as a carrier for genetic vaccination in situations where both cellular humoral immunity is desired as described below.

These observations lead to the hypothesis that the immune response is essential for the elimination of adenoviral vectors. While the initial rapid phase of Ad clearance attributed to the innate immune system was equally rapid in immunodeficient mice and immunocompetent mice [81], overall duration of gene expression has been shown to be much longer in immunodeficient mice [81–83]. Practically, this suggests ways in which a partial, transient deficiency in the immune system might be exploited to prolong the expression of a therapeutic gene. Conventional immunosuppressants such as corticosteroids [84] and cyclosporin [85–87] have been used to reduce anti-Ad immune responses and increase the duration of transgene expression in experimental animals. The danger of applying this to human subjects is that opportunistic infections or infection from contaminating wild-type Ad may result. But greater persistence of Ad vectors

FIGURE 3.5 Quantification of β -glucuronidase expression in the lung over time following repeat administration of the same serotype vector or a vector from an alternate serotype. β -glucuronidase expression in the lung after initial intratracheal administration of Ad2 β glu (10^{11} particles) followed 14 days later by intratracheal administration of either the same vector (Ad2 β glu, 10^9 pfu, \circ), or a vector of the alternate serotype (Ad5 β glu, 10^9 pfu, \bullet) [73].

can also be achieved via simultaneous systemic administration of molecules such as antibodies against CD40 ligand [88,89] and CTLA4Ig [90,91] which block interaction between T cells and antigen presenting cells. These immunomodulators could be used locally, possibly co-expressed on the same Ad as the therapeutic gene, to give more specific immunosuppression.

The humoral and cellular responses also evoke immunological memory which prevents effective gene expression following subsequent administration of the same vector (Figure 3.5). Neutralizing antibodies sequester the readministered vector before it infects cells and cause its immune clearance. Thus, the barriers to readministration of a second vector should be serotype-specific, a concept that has been proven in experimental studies (Figure 3.5) [73]. Cellular immune system memory can also eliminate any readministered vectors that escape neutralization and infect host cells. The determinants of the cellular immune response are more conserved between serotypes and a second vector of different serotype is eliminated faster from immune animals than from naive animals (Figure 3.5).

3.4 IMPROVED Ad VECTORS

Two salient points emerge from the data discussed above. The first is that only some cells and tissues can be efficiently infected by Ad vectors. The second is that there is a strong immune response against adenoviral vectors which results in elimination of cells infected by the vector and the inability to achieve effective gene transfer and expression following readministration of the same vector. A number of approaches are being developed that might mitigate these problems.

3.4.1 ELIMINATION OF REPLICATION-COMPETENT Ad

Adenoviral vectors are produced in the 293 cell line which provides *in trans* the E1 functions that render them conditionally replication competent, permitting vector growth. The difficulty with this approach to propagate vectors is that there is the possibility of homologous recombination between the replication-deficient vector and the chromosomal copy of the Ad5 genome (Figure 3.6A) [32]. This inevitably occurs at a low frequency resulting in the production of E1⁺, E3⁻ RCA.

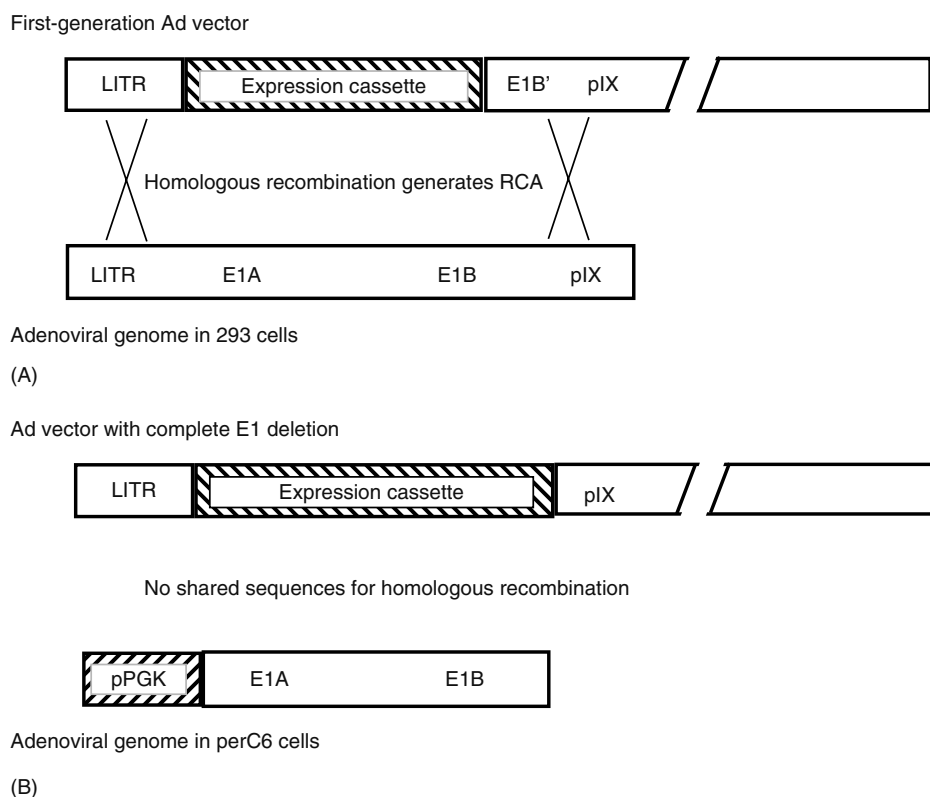

FIGURE 3.6 Production of replication-competent Ad by homologous recombination between Ad vector and genome of 293 cells. The 293 cell line (open rectangle) contains nucleotides 1–4344 from Ad type 5 including the left inverted terminal repeat (LITR), the E1A and E1B genes, and the adjacent protein IX gene (pIX). The E1 deletion in most first-generation vectors (top rectangle) stretches from nucleotides 355–3328 which is replaced by the expression cassette for the therapeutic gene. Therefore, two homologous recombination events (crossed line) can occur which restore the E1 region and give a replication-competent (albeit E3⁻) virus. In the second example, the extent of the E1 deletion in the vector has been extended to encompass all of the E1A and E1B genes. At the same time, the E1A and E1B genes in the complementing cell line (i.e., perC6 cells [163]) have no flanking sequence and expression is driven by the phosphoglycerol kinase promoter. As a result there is no homology at either end and only two illegitimate recombination events can result in the production of RCA. As a result the frequency is very low.

Ad Deletions and Complementing Cell Lines

Cell Line (Genotype)	Deletions Complemented	Comments	References
293 (E1A/B ⁺)	E1 ⁻	Human embryonic kidney cells transformed by nucleotides 1–4344 of Ad5	[28]
911 (E1A/B ⁺)	E1 ⁻	Human embryonic retinoblast cells containing nucleotides 79–5789 of Ad5. Enhanced plaquing efficiency over 293	[165]
perC6 (E1A/B ⁺)	E1 ⁻	Nucleotides 459–3510 of Ad5 driven by phosphoglycerate kinase promoter. Reduced production of RCA compared to 911 and 293	[163]
293-E4 (E1A/B ⁺ , E4)	E1 ⁻ , E4 ⁻	293 derivative with E4 gene expression driven by mouse α -inhibin promoter	[166]
293-ORF6 (E1A/B ⁺ , E4(ORF6) ⁺)	E1 ⁻ , E4 ⁻	293 derivative expressing E4-ORF6 from metallothionein promoter	[95]
IGRP2 (E1A/B ⁺ , E4(ORF6/7) ⁺)	E1 ⁻ , E4 ⁻	293 derivative with ORF6 and 7 of E4 driven by MMTV-LTR promoter	[167]
VK2–20 & VK10–9 (E1A/B ⁺ , pIX ⁺ E4 ⁺)	E1 ⁻ , E4 ⁻ , pIX ⁻	293 derivative expressing E4 and pIX from MMTV-LTR or metallothionein promoters allows larger genes to be inserted in E1 region	[168]
293 (E1A/B ⁺ , pTP ⁺)	E1 ⁻ , TP ⁻	293 derivative expressing terminal protein inducible by tetracycline	[169]
293 (E1A/B ⁺ , pTP ⁺ , pol ⁺)	E1 ⁻ , TP ⁻ , pol ⁻	293 derivative expressing both terminal protein and DNA polymerase	[170]
293-C2 (E1 ⁺ , E2A ⁺)	E1 ⁻ , E2A ⁻	293 derivative with 5.9 kb fragment of Ad5 containing E2a region	[171]
AE1–2a (E1A/B ⁺ , E2A ⁺)	E1 ⁻ , E2A ⁻	Lung epidermal carcinoma line A549 derivative transformed by E1 and E2A gene under glucocorticoid responsive promoters	[53]
AE1–2a (E1A/B ⁺ , E2A ⁺)	E1 ⁻ , E2A ⁻	293 derivative with tetracycline repressible E2a gene	[172]
293-Cre (E1A/B ⁺ , Cre ⁺)	All viral genes (with lox containing helper)	293 derivative expressing Cre recombinase which excises packaging signal from helper virus	[173]

Once formed, RCA will outgrow the replication-deficient gene therapy vector *in vitro*. To minimize the production of RCA, Ad is plaque purified several times on 293 cells and exhaustively tested for the presence of RCA which is readily detected on the basis of its ability to form plaques on E1 negative cell lines such as the human lung epithelial cell line A549 [32]. For clinical studies, adenoviral vectors should be uncontaminated by RCA (level <1 RCA per dose). However, the preparation of Ad vector of this quality is difficult and most *in vivo* animal and *in vitro* studies are done with preparations with uncharacterized levels of RCA that are probably >1 RCA per 10⁸ particles.

To reduce RCA production, two approaches can be used: reduce the size of the trans-complementing E1 region in the cell line or increase the size of the E1 deletion in the vector. Several cell lines have been developed that have less of the Ad genome (compared to 293 cells), while retaining the ability to supply the E1A and E1B functions *in trans* and the high productivity of the 293 cell line (Table 3.1). The E1 deletion in the first generation clinical vectors was smaller than optimal, retaining 31% of the 3' end of the E1B gene. Deleting this sequence in conjunction with cell lines that express E1A/B from non-adenoviral promoter allows production of Ads in circumstances where there is no overlap between the cellular sequence and the vector (Figure 3.6B). In these cell lines, RCA is virtually eliminated since it can only arise through two illegitimate recombination events, an occurrence that is very rare.

3.4.2 VECTORS WITH ADDITIONAL EARLY GENE DELETIONS

First-generation Ad vectors permit limited Ad gene expression and DNA replication which probably contributes to the immune response against the vector. In addition, the possibility of making RCA during propagation is a potentially dangerous feature. By making additional mutations or deletions in the Ad genome, both of these problems can be avoided. One implementation is to make an E1⁻ vector with an E2A mutation that renders the vector replication incompetent at 37°C [92]. Such temperature sensitive vectors can be propagated at 32°C, but cannot replicate in the mammalian host at 37°C even if E1-like activities were present. Further, if homologous recombination in 293 cells during production results in an E1⁺ viral genome, the ability to replicate in a mammalian host is not restored. *In vivo* studies show that this defect reduces the inflammatory response following vector administration and permits larger transgene expression [53,93,94]. However, the temperature sensitive mutation is unstable and partially replication competent at 37°C.

Other mutations in early genes have been utilized in Ad vectors, including partial and complete E2 and E4 deletions. Both of these genes are essential for viral replication and therefore necessitate the production of cell lines that complement both the E2 or E4 deletion as well as the E1 deletion. In general, this has been achieved using 293 cells transfected

with the appropriate E2 or E4 gene driven by an inducible promoter (Table 3.1). In a typical example, E4 deleted vectors were constructed in a cell line which expressed the E4 OFR6 behind an inducible metallothioneine promoter [95]. Cell lines of this type are more difficult to work with than 293 cells, and the efficiency of vector production is often lower. There is inconsistent data on whether additional genomic deletions result in a blunted immune response and whether this translates into longer persistence of transgene expression. Some studies are complicated by the immune response to the foreign transgene as well as to the vector and by the tendency of the commonly used CMV promoter to be inactivated over time without vector elimination. For example, one report [96] indicates that a complete E4 deletion has no effect on the time course of gene expression in immunocompetent animals after administration to lung or liver. This is at variance with other reports [52,97,98] showing that E4 deletion results in a reduced immune response and longer transgene expression. The details of vector construction, route of administration, promoter used [99], dose, and genotype of the recipient are critical to the efficacy of E4 (and other) deletion(s). It is likely that studies in humans will be necessary to determine if additional genomic deletions have an impact of the duration of expression of the therapeutic gene and whether this translates into a significant clinical impact.

3.4.3 E3 RESTORED VECTORS

The E3 region encodes genes that repress host response to infection through both reducing antigen presentation on the cell surface and protecting infected cells against TNF- α and fas/fas L-mediated apoptosis. E3 is deleted in most Ad vectors to make room for the transgene within the length constraints of packaging. Arguing that E3 expression might increase persistence of vectors, several groups have sought to restore one or more E3 function. In mice, expression of the E3gp19K protein has been shown to reduce MHC class I expression *in vitro* [100], and reduce CTL levels *in vivo* [101], but there are contradictory results on whether this translates into prolonged persistence [100,102]. On the other hand, two studies have shown that the whole E3 region does in fact prolong vector persistence *in vivo*. This is true whether the E3 region is expressed from an exogenous promoter in the E1 region [103] or expressed from its own promoter in the normal position [104]. Since E1 function is required for E3 expression, the latter result is surprising and may indicate that a low level of E3 expression is sufficient to prolong persistence. As with other modifications of the viral backbone, the critical question is if the expression of E3⁺ vectors would be longer in humans when administered in the route intended for therapy. This has not yet been answered.

3.4.4 HELPER-DEPENDENT VECTORS

On the premise that any adenoviral gene expression would cause an immune response, some investigators have developed methods to eliminate all the Ad genes from the vector. In fact, the size constraints imposed by some large genes such

as dystrophin require that most of the Ad genome be deleted simply to make space for the therapeutic gene [105]. An additional benefit of the higher capacity is the possibility of using the endogenous promoter and control elements such as matrix attachment regions to exactly regulate the expression level of the therapeutic gene [106]. But, deletion of all Ad genes requires that those functions be provided *in trans* for vector production. This is achieved by using helper viruses that are deficient in packaging. In an early implementation, a helper virus with defective packaging signals was used which is packaged into virion with much lower efficiency than the therapeutic virus which has two intact packaging signals. By this method, a mixed lysate is formed with two viruses that differ in size and therefore can be separated on cesium chloride equilibrium density gradients [107].

A refinement of this technology utilizes the lox/Cre system to negatively select for helper virus in a coinfection of helper and helper-dependent virus vectors [108]. In the lox/Cre system, the DNA recombinase Cre from bacteriophage lambda efficiently mediates recombination between lox sites; thus sequences between two lox sites in the same orientation are deleted. A helper virus called psi5 has been engineered that has lox sites flanking the packaging signal so that Cre recombinase excises the packaging signal and prevents packaging of the genome. The psi5 vector propagates normally in 293 cells but packages inefficiently in 293 derivatives expressing the Cre recombinase. Coinfection of psi5 and helper-dependent vector results primarily in packaging of the helper-dependent vector using proteins specified by the psi5 genome.

Helper-dependent vectors are beginning to attain widespread use and give long-term transgene expression in models where the recipients are immunologically tolerant to the expressed transgene. A helper-dependent vector expressing the human α 1-antitrypsin genomic configuration from the α 1-antitrypsin promoter can be administered to mice [109] and baboons [110] resulting in prolonged high-level gene expression with little decline over 10 months. Similar data has been reported for factor IX [111], erythropoietin, and dystrophin. In the case of apoE deficient mice, the genetic defect which results in high serum cholesterol has been corrected for over 2 years by administration of a helper-dependent vector expressing the wild-type apoE [112]. It is clear that the toxicology is for helper-dependent vectors is less than for first generation vectors in some situations but the acute response to vector, particularly in recipients which are immune to Ad type 5 is not affected by use of helper-dependent vectors.

3.4.5 SERO-SWITCH VECTORS

The induction of neutralizing antibodies is presumably one of the barriers against successful readministration of the same Ad gene transfer vector. In experimental animals, this has been observed for intravenous [113], intratracheal [73,114], and intraperitoneal [36] administration where the vector is exposed to antibodies prior to contact with the tissue. Effective readministration of the same vector has also been demonstrated to be possible using direct tissue injection [115].

Since prior infection by one Ad does not protect against infection by a different serotype [73], using different serotypes of gene therapy vector should allow readministration of the same transgene. Extensive testing of this concept is difficult because existing vectors are only of serotypes 2 and 5 since the E1 functions of these two viruses can be efficiently complemented by the 293 cell line. For example (Figure 3.5), when rats were administered intratracheally with Ad of serotype 2 expressing β -glucuronidase, there was expression which peaked at 3 days and declined to undetectable levels by 14 days. Readministration of the same vector resulted in a very low level of gene expression due to the immune response to the first vector administration. But a second administration of a vector expressing the same transgene but of serotype 5 resulted in a level of gene expression at day one comparable to that seen in a naive rat. The decline to baseline was faster than in naive animals, probably due to the elimination of infected cells by the cellular immune system using epitopes conserved between serotypes 2 and 5 [73].

These data posed the question as to which epitopes are responsible for preventing readministration of the same serotype. Vectors have been constructed with the capsid of serotype 5 but with the fiber gene of serotype 7a. Fortunately, the fiber protein from serotype 7a interacts with the penton base of serotype 5 allowing the assembly of serotype 7a/5 chimeric capsids. *In vivo* experiments show that the fiber switch from 5 to 7a does not facilitate readministration suggesting that the immune response to fiber is not the barrier that prevents readministration of the same serotype [116]. This is consistent with the concept that the primary humoral immune response is directed to the external loops of the hexon protein. Vectors have been constructed in which the hexon gene of Ad5 has been replaced by that of Ad serotype 2 [117]. Even though the level of serological cross-reaction between the pure Ad5 capsid and the variant with hexon from Ad2 was low, the hexon switch did not allow successful readministration *in vivo*. This illustrates the importance of other arms of the immune system and the diversity of epitopes which are involved in immune response to gene therapy vectors.

It is not clear if sero-switching is a viable strategy for long-term gene therapy. First, the difficulty of making efficient complementing cell lines for viruses of different subgroups is unknown. Second, the delivery of a therapeutic gene to the target tissue and its subsequent expression would not necessarily be the same among serotypes. Finally, even if this could be achieved, the therapeutic advantage of expressing the transgene once for a few days rather than several times for a few days might not be all that great in terms of genetic disease where persistent gene therapy is needed.

3.4.6 VECTORS WITH MODIFIED TROPISM

The specificity of adenoviral infections *in vitro* is dictated by the presence of the CAR receptor and integrins. The role of these receptors *in vivo* is less certain since the cell types to which a vector is exposed becomes a critical issue. Since a majority of vector administered intravenously in rodents is found in the liver, gene therapy for other tissues requires both detargeting from the normal trafficking route to the liver as

well as a delivery system to the target [118,119]. For lung epithelium, intratracheal administration is feasible. Direct injection is possible in some other applications, for example, into the myocardium or directly into a tumor. But vector that is inadvertently injected into capillaries or drains into the circulation through the lymphatic system will find its way to the liver. Alternatively, there are cell types such as lymphocytes [40] that are very difficult to infect with type 5 Ad vectors. These considerations raise questions about whether vectors can be retargeted to cells or tissues of interest, or at least if the expression of the transgene could be limited to that tissue.

Many vectors use the CMV immediate/early promoter/enhancer which was chosen on the basis that it directs a high level of transgene expression and is expressed in most tissues studied. But many times, expression in a specific tissue or cell type is more desirable and expression in other tissues might be toxic. Therefore, the promoters of genes specific to a cell type have sometimes been used for specific applications [120–122]. For example, carcinoembryonic antigen (CEA) and α -fetoprotein (AFP) are tumor specific antigens that are not expressed by normal cells. When a therapeutic gene is expressed from an Ad vector with an AFP promoter, expression should be confined to specific tumor cells expressing AFP and not normal cells. Kaneko et al. [120] have shown this theory to be correct and have further demonstrated that the expected selectivity is maintained *in vivo*. In this context, the vector Av1AFPTK1 [expressing thymidine kinase from herpes simplex virus (HSV-TK) from the AFP promoter] can prevent tumor growth in gancyclovir-treated nude mice implanted with an AFP-expressing tumor cell line but not in identical mice implanted with a control (non-AFP expressing) tumor cell line. By contrast, the vector Av1TK1 which expresses HSV-TK from the Rous sarcoma virus promoter protects gancyclovir-treated nude mice regardless which cell line is used to transduce the tumor.

Alternatively, modifications of the fiber/high affinity receptor interaction or the penton–integrin interaction might be used to modify tissue tropism. In this context, the sero-switch vectors described above [116] as well as capsid chimeras with part of the Ad3 fiber [123,124] or the fiber gene from Ad17 [125] might be more effective in certain tissues since, a priori, different serotypes of wild-type Ads with different known pathologies should target different tissues. In an extensive survey of the tropism of Ad5-derived vectors but with fibers derived from different serotypes, the fiber genes of Ad16 was found to be better at targeting fibroblasts and chondrocytes, that of Ad35 better at targeting dendritic cells and melanocytes and Ad50 better at targeting myoblasts and hematopoietic stem cells [126].

Some groups have taken the approach of directly screening for serotypes that replicate preferentially in brain or lung epithelium. In both cases, wild-type strains were screened for efficient replication and certain subgroup D viruses, including serotype 17, were identified to replicate more efficiently. On this basis, a serotype 2 virus with the fiber from Ad17 was constructed and used to study infection of various cell types *in vitro*. This hybrid is much more efficient at gene transfer to

human umbilical vein endothelial cells, neurons, glioma cell lines, and lung epithelial cells than the pure Ad2 gene transfer vector [125]. However, it is sufficiently proficient in infecting 293 cells that it can still be propagated and titered for production purposes. It is not known if this translates into better gene transfer efficiency *in vivo*.

A number of other approaches to modifying tropism have been identified (Table 3.2). For example, the fiber protein can tolerate some manipulation without impairing virus production. The determination of the three-dimensional structure of fiber in conjunction with mutagenesis studies [127] assists in the identification of amino acids essential for the interaction with CAR and identification of domains where insertions might be tolerated without grossly affecting structure. An early modification to fiber was the addition of an oligolysine motif to the C-terminal of the fiber protein, giving the virus an affinity for polyanions such as heparin sulfate [128]. This profoundly affects the cell types that can be infected *in vitro*, allowing cells lacking CAR, such as vascular smooth muscle cells and B-cells, to be infected. It has also been shown that this oligolysine addition allows for more efficient gene transfer to smooth muscle cells *in vivo*. Additional manipulations to either the C-terminus or in the HI loop of fiber (summarized in Table 3.2) have been described to modify the tropism of Ad vectors. The most widely used is the addition of an additional RGD integrin binding motif to the fiber knob domain thereby increasing the efficiency of infection of some important cell types including ovarian cancer cells, fibroblasts, and dendritic cells [129–131]. In a study that may point to future developments, phage display technology was used to identify peptide motifs that preferentially target human umbilical vein endo-

thelial cells. When this peptide sequence was incorporated into the HI loop of fiber, Ads were generated with a high preference for endothelium [129,130]. A similar approach was used to target neural precursor cells in the brain [132].

Bispecific antibodies have been used as a reagent to direct Ad towards particular cell types [40,133,134]. For example, using a bispecific antibody conjugate with one arm binding the Ad fiber and the other binding the epidermal growth factor (EGF) receptor [133], it was possible to increase the specificity of Ad vectors towards glioma cell lines with low levels of CAR but high levels of the EGF receptor.

The route by which Ad reaches the tissue and cell type is complex, especially after intravenous injection. The half-life of Ad in blood is about 2 min and the interactions with cellular protein components of blood are unknown [135]. In addition the degree to which Ad penetrate endothelium in various tissues is unknown meaning that *in vivo* tissue tropism is not a simple outcome of the abundance of CAR primary receptor and integrin secondary receptor. Moreover, in humans there will generally be antibodies against Ad so the formation of complexes with antibody will further complicate tropism. If retargeting is to be successful after an intravenous injection, both detargeting from the normal pathways [119] as well as retargeting to the novel pathways must be achieved.

A number of groups have eliminated the amino acids in the knob of fiber that is essential for interaction with CAR. This makes the resultant vectors difficult to propagate in 293 cells and therefore substitute pseudoreceptor-ligand systems have to be devised. For example, the addition of an HA epitope from the influenzae hemagglutinin gene permits a 293 derivative with an anti-HA single-chain antibody to be used

TABLE 3.2
Examples of Retargeting of Ad Gene Transfer Vectors

Modification	Target	Rationale	References
Ad5(fiber 7a)	Cells expressing Ad7 high affinity receptors	Replace whole of Ad5 fiber by that of Ad7a (subgroup B)	[116]
Penton LDV	Lymphocytes, monocytes	Replace RGD $\alpha_v\beta_3$ -binding motif in penton base by LDV which interacts with $\alpha_4\beta_1$ integrin	[17]
Conjugations to anti-Ad Fabs	Tumor cells	Conjugate ligands (e.g., FGF, folate) to Fab fragments specific to fiber; bind to vector before delivery to cells bearing cognate receptor	[174,175]
Bifunctional antibody	Tumor cells	Retarget to EGFR ^a expressing cells; bind virus with bispecific antibody against EGFR and Ad fiber	[133]
Bifunctional antibody	Smooth muscle cells, endothelium	Create vector with penton modified to express defined epitope (AdFLAG); use bispecific antibody versus FLAG and α_v integrin (or E selectin) to target cells expressing α_v integrin (or E selectin)	[176]
Bispecific antibody (anti-CD3)	T cells	Use AdFLAG vector and bispecific antibody (Anti-FLAG, anti-CD3) to target CD3 ⁺ T cells	[40]
Oligolysine	Cells with surface heparin sulfate	Add seven lysine residues to C-terminus of fiber	[128,177]
Fiber RGD	Cells expressing $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins	Add RGD integrin binding motif to knob of fiber	[41,129]
Ad5(fiber 17)	Endothelium, lung epithelium, brain	Replace fiber gene of Ad2 vector with that of Ad17 (subgroup D)	[125]
Ad5/9 (short shaft)	Melanoma, glioma, smooth muscle cells	Place knob of Ad9 on shaft of Ad5 after eight repeats	[178]

^a EGFR, epidermal growth factor receptor.

for propagation of vectors unable to interact with CAR or integrins [119]. The interaction of integrin and penton base has been modified both by elimination of the RGD motif in penton base and by its replacement by the LDV motif which should promote interaction with $\alpha_4\beta_1$ integrins, characteristic of lymphocytes and monocytes [17].

3.5 HUMAN APPLICATIONS

Before commencing clinical studies, batches of vector must be made under FDA current good manufacturing practice (GMP) and satisfy rigorous lot release criteria. As with all drugs, the identity (now including full DNA sequencing), purity, and potency of the vector must be verified in validated assays. For safety reasons, the absence of RCA is a major concern and vector destined for human usage must contain <1 RCA per dose. As dose increases, the challenge of making vector free of RCA in the 293 cell line becomes more problematic. Vectors must also be verified for the absence of not only human viruses but also animal viruses including porcine and bovine viruses that may be carried through from reagents used in cell culture. Taken together, these studies impose a high hurdle of cost and time before having a vector suitable for human administration on hand. Most production is now done in dedicated facilities with high overhead to maintain the required trained personnel, facility integrity, and quality control units.

Human clinical studies also require prior toxicology studies in experimental animals assessing the effects both vector and transgene expression. There is now considerable human data on the effects of administration of first generation Ad5-based vectors, so the effects of the transgene are usually the focus. Depending on the novelty of the application and the phase to which clinical studies have progressed, toxicology studies may need to conform to FDA good laboratory practice and may require nonhuman primates in addition to rodents. The information derived from toxicology studies is necessarily limited due to biological differences between experimental animals and humans, especially as it relates to the innate and acquired immune response. Experimental animals are naive to human Ads so the immune response to vector is primary while most humans have preexisting immunity to Ad5 and therefore the immune response is secondary. There are differences in antigen processing and presentation between inbred animals and humans and the effects of some E3 genes are limited to human MHC proteins. In addition, the potential effects of RCA are different since human Ads do not replicate in rodent cells but some human Ad are actually oncogenic in rodents but not in humans.

The final step of commencing a clinical study is obtaining regulatory approval which is also complex. Gene therapy, in general, and Ad, in particular, are generally perceived as being particularly hazardous and therefore multiple levels of review are required. The local institutional review board (IRB) and institutional biosafety committee (IBC) must approve as well as the recombinant DNA advisory committee of the National Institutes of Health. The investigational new drug application represents the last phase of approval. Each group has slightly

different concerns and the final result is a protocol that is conservative yet likely to be safe, ethical, and informative. All revisions to the protocol must be approved by all regulatory groups and therefore keeping the protocol current needs well-organized management. The actual clinical study must be performed under good clinical practice (GCP) with timely reporting of all adverse events to the FDA, RAC, IRB, and IBC. In addition, many institutions have added a data safety monitoring board to further ensure the safety of gene therapy studies.

Data on models of disease in experimental animals provided sufficient basis to proceed to Ad vector-mediated gene transfer in humans. The first human studies were commenced in 1993 and a total of 228 studies are listed in the current update of the database of the RAC. These have generally been small phase I or phase II studies (Table 3.3). While the first studies were directed at CF, the currently active studies are focused on cancer and cardiovascular disease. In total, 75% of the listed studies involve cancer with the same vector being studied in a number of different tumors or different patient subsets or concurrently with different concurrent therapies. In general, capsid modified vectors and second generation vectors have not been used in humans and it is unknown if the advantages these new vectors sometimes offer in experimental animals apply in humans.

In general, gene transfer of Ad vectors has been safe and well tolerated [136,137]. The notable exception is that intravenous administration results in dose-dependent toxicity that has resulted in one death [138–141]. This reaction is rapid and is believed to be related to the innate immune system [142]. In addition to showing safety, several studies have shown that there is also effective delivery of the vector to the patient and subsequent expression of the therapeutic gene. Demonstrations of actual therapeutic benefit will require critical placebo controlled testing. If an Ad vector does prove to be effective in a large study, there remain substantial production and support issues that will require a significant investment of time and money to provide the reliable supply of a marketed drug.

3.5.1 GENETIC DISEASES

When gene therapy is conceived as the addition of a good copy of a defective gene, it is natural that the initial focus was on genetic diseases such as CF. As described above, the feasibility of intratracheal administration to the lung was demonstrated in animals and the first clinical trial of an Ad vector was to the airway epithelium of CF patients [143]. The initial study was a dose-escalating safety study in which vector was administered to the bronchi in 20 mL of fluid. It became clear that this volume was not well tolerated and so subsequent studies used smaller volumes, or a spray of aerosolized vector into the bronchi. The relative accessibility of the site of administration allows that samples of respiratory epithelium can be recovered by bronchial brushing and the presence of vector and therapeutic gene expression can be assessed repetitively. By sensitive quantitative PCR methods, the expression of the CFTR gene delivered by the vector is seen at the site of

Cancer: Oncolytic virus + marker gene	CD/HSV-TK	Pancreatic cancer, prostate cancer, penile cancer	Intratumor	[277–279]
Cancer: Prodrug activation	hNIS	Prostate	Intratumor	[280]
	Cytosine deaminase (CD)/HSV-TK	Prostate cancer	Intratumor	[281]
	CD	Hepatic metastasis	Intratumor	[282]
	HSV-TK	Brain tumor, glioma, head/neck squamous cell carcinoma, hepatic metastasis, melanoma, pancreatic cancer, NSCLC, ovarian cancer, prostate, retinoblastoma, mesothelioma	Intratumor	[240,283–298]
	HSV-TK	Mesothelioma	Intrapleural	[299]
	HSV-TK	Ovarian cancer	Intraperitoneal	[300,301]
	Nitroreductase	Liver cancer	Intratumor	[302]
	hNIS	Head and neck cancer, prostate cancer		[303,304]
Cancer: Prodrug activation + immunotherapy	HSV-TK/IL2	Hepatic metastasis	Intratumor	[305]
Cardiovascular: Angiogenesis	VEGF	Coronary artery disease (CAD)	Intramyocardium	[146,147,306–308]
	FGF-4	CAD	Intracoronary	[309–311]
	PDGF-B	Peripheral vascular disease (PVD)	Intradermal/ulcer	[312] (Selective genetics)
	VEGF	PVD	Intramuscular	[313]
	HIF-1/VP16	PVD, CAD	Intramuscular Intramyocardial	[314]
Cardiovascular: Anti-restenosis	PDGF-B	Diabetic ulcers	Collagen gel on ulcer	[315]
	VEGF-D	AV anastomosis	Collagen collar in graft	[316]
	iNOS	AV anastomosis	Intra-graft	[317]
	Adenylate cyclase 6	Congestive heart failure	Intracoronary	[318]
Cardiovascular: Anti-angiogenesis	PEDF	Macular degeneration	Intravitreal	[319]
Glaucoma	p21	Glaucoma	Subconjunctival	[320]
Infectious disease	Engineered zinc finger nuclease	HIV-suppress receptor levels	Intravenous	(Sangamo Biosciences)
	env + rev, gag + protease, gag, pol, and nef	HIV	Oral or intranasal	[321] (Merck/NIH consortium)
Normals	CD	Adenoviral infection None	<i>Ex vivo</i> stimulation of CTL Intradermal, aerosol to airway	[322] [145,148]

Note: AFP, α -fetoprotein; CD, cytosine deaminase; CD40L, CD40 ligand; CEA, carcinoembryonic antigen; CFTR, cystic fibrosis transmembrane regulator; FGF, fibroblast growth factor; GM-CSF, granulocyte macrophage colony stimulating factor; HER2, c-erb B2/neu protein; HIF, hypoxia inducible factor; hNIS, human sodium iodide symporter; HSVTK, herpes simplex virus thymidine kinase; IFN, interferon; IL, interleukin; OTC, ornithine transcarboxylase; PDGF, platelet-derived growth factor; PEDF, pigment epithelium derived factor; PSA, prostate-specific antigen; RTVP-1, related to testes-specific, vespid, and pathogenesis protein-1; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

^a Compiled from the 228 protocols in the RAC database as of August 2007 and database searches. Protocols are organized first by general area, transgene, indication, and then route of administration/approach. Where possible the references are for clinical data and if not then supporting animal efficacy and/or toxicology.

administration at vector doses of 5×10^8 pfu and greater. The level of vector-derived CFTR mRNA is approximately 5% of the level of expression of the endogenous CFTR gene and this is believed to be sufficient for therapeutic effect. However, this level of expression is only achieved for a period of a few days and expression rapidly declines to baseline by 30 days [144]. Interestingly, the administration of the vector to the airway does not lead to a significant immune response against Ad reflected in either neutralizing antibodies [145] nor Ad-specific T-cell proliferation.

Since the initial safety of vectors expressing CFTR was demonstrated, a study with repetitive administration has been completed. The important result of this study is that expression is reduced or eliminated in subsequent administrations as expected from the data from experimental animals, presumably from the immune response to the first dose [144].

To date, only one study of adenoviral vectors for any metabolic disease has been initiated. This is not surprising since all animal data suggests only a short time of expression of genes delivered by Ad vectors to most tissues, and the rationale for a human study was not firmly established. Ornithine transcarbamylase (OTC) deficiency is a recessive metabolic disorder of nitrogen metabolism. A E1⁻, E4⁻ deleted Ad vector expressing the cDNA for OTC was constructed and administered by the intrahepatic route to adults with partial OTC deficiency and safety parameters and the efficiency of gene transfer are currently being assessed [138]. During this study it became apparent that a large dose of intravenous vector could be fatal. The use of a helper-dependent vector for the treatment of hemophilia by intravenous administration was stopped when toxicity was observed.

3.5.2 ONCOLOGY

Due to the unknown safety profile of Ad vectors, it is generally easier to design the early human trials for life-threatening disease. Of the protocols listed by the RAC, 75% involve cancer. Four basic approaches can be identified: local prodrug activation, tumor suppressor genes, immunotherapy, and oncolytic viruses.

One of the first strategies of human gene therapy for cancer was to locally deliver novel enzymes that metabolize prodrugs into the active chemotherapy agent. The general concept of these studies is that local activation of the prodrug in the tumor will concentrate the active agent in the tumor, thus limiting the systemic toxicity from the active drug. Two genes have been used in human clinical trials: the HSV-TK and the *E. coli* CD gene. The HSV-TK protein activates the prodrug ganciclovir to ganciclovir monophosphate, an inhibitor of DNA polymerase. For CD, the prodrug is 5-fluorocytosine, which is activated by CD into the active chemotherapeutic agent 5-fluorouracil. For both agents and activating enzymes, a theoretical benefit is the bystander effect in which active drug would be excreted from the vector-infected cells to kill the neighboring cells of the tumor. Thus, it is not essential to infect every cell of the tumor with the Ad vector.

Currently active protocols apply the prodrug strategy to many types of cancer including prostate cancer, CNS malignancies, ovarian cancer, mesothelioma, hepatic metastases of colon cancer, and squamous cell carcinoma of the head and neck (Table 3.3). Most studies involve phase I/II studies with intratumoral injection of escalating doses of vector prior to chemotherapy with the prodrug and subsequent scheduled surgery. Tumor removal provides samples for analysis of vector levels, for expression of the therapeutic gene, and for analysis of the activation of prodrug and histological studies for cell death and inflammation. The primary end point of these studies is safety, which has been established in some cases.

Tumor suppressor genes have also been used in human clinical studies: p53 (for ovarian cancer, prostate cancer, squamous cancer of the head and neck, breast cancer, non-small cell lung cancer, hepatic carcinoma, and hepatic metastases), retinoblastoma susceptibility gene (for bladder cancer), mda7 gene for melanoma, and p16 gene for prostate cancer. The concept is that tumor cells have defective tumor suppressor genes that cannot limit cell division, but restoration of the wild-type gene will limit cell division. The theoretical limitation of using anti-proliferative genes for tumor therapy is that they will only inhibit proliferation of the cell they infect and have no *cis* effect on neighboring cells. The trial designs are generally similar to those for the prodrug strategy.

A third general approach to Ad gene therapy for cancers has been immunostimulatory genes (Table 3.3). Several different genes have been used in human studies, including CD40 ligand for chronic lymphocytic leukemia, granulocyte macrophage colony stimulating factor for melanoma and non-small cell lung cancer, interleukin-2 for neuroblastoma, MART-1 (a melanoma-specific antigen) and B7 (CD80) for melanoma. The concept of immunostimulatory gene therapy is to promote the natural immune surveillance and elimination of tumors, which express abnormal antigens by giving a general boost to the cellular immune system (e.g., with IL-2) or with a tumor-specific antigen (e.g., MART-1) and anti-erbB-2 single-chain antibodies (for ovarian cancer) (Table 3.3).

A novel anti-proliferative approach has been used in human studies using conditionally replication-competent viruses. As described above, the E1B gene is essential to protect Ad infected cells from apoptosis and its mode of action is through interaction with p53. It follows that E1B function would only be effective in p53 positive cells, but not in p53 deficient tumor cells, i.e., E1B positive viruses would induce apoptosis only in p53 negative tumor cells, while normal cells should be protected by the p53 gene. In this context, E1A negative, E1B positive viruses have been demonstrated in animal models to show selective cytolytic effects against tumors. The same viruses have been used in phase I and phase II studies of human ovarian cancers, pancreatic cancer, and head and neck cancer with direct intratumoral injection in conjunction with chemotherapy. These studies are now being extended to phase III testing.

The simplest approach to therapy is to directly administer the vector to the tumor. But for some special applications an *ex vivo* approach is possible. This is complex due to the need to protect the cells cultured and infected *ex vivo* from adventitious agents while they are outside the patient. Three approaches have been used. The most common is to infect the tumor cells with an immunostimulatory vector (e.g., Ad expressing a cytokine) expecting to evoke an anti-tumor immune response upon returning the cells to the patient. Alternatively, dendritic cells, a potent antigen presenting cell, have been infected *ex vivo* with Ad expressing a known tumor antigen to evoke an immune response upon returning to the donor. Finally, bone marrow derived stem cells have been purged of possible contaminants by infection by an anti-proliferative vector prior to returning to a donor.

3.5.3 CARDIOVASCULAR

With the observation that there is only short-term gene expression from Ad vectors, the question arose as to which medical applications might benefit from transient expression of a therapeutic gene. The general area of tissue repair and engineering emerged as a good candidate where secreted growth factors would initiate the desired cascade of tissue remodeling which, once initiated, would not require the continuous presence of the therapeutic gene. For example, expression of vascular endothelial growth factor (VEGF) after injection of an Ad vector expressing VEGF into rat retroperitoneal fat pad is brief, reverting to baseline after 10 days (Figure 3.7). By contrast, the VEGF protein induces an angiogenic response that persists long after the stimulus has disappeared.

FIGURE 3.7 Time course of gene expression and anatomical response after administration of Ad expressing VEGF. The retroperitoneal fat pad of rats was injected with 5×10^8 pfu of either AdVEGF (a first-generation E1-E3⁻ vector expressing the 165 amino acid form of human VEGF, solid symbols) or the control vector expressing no transgene (AdNull, open symbols). At intervals, animals were anesthetized, a laparotomy performed, and the fat pad photographed. The number of vessels crossing a circle of 1 cm diameter centered on the injection site was measured (left axis: □, ■). The fat pad was also homogenized and the level of VEGF determined by ELISA (right axis: ○, ● [164]).

On the basis of extensive preclinical testing in animal models of angiogenesis, a number of groups performed clinical studies of adenoviral gene transfer to ischemic heart or ischemic limb in an effort to induce the growth of new vessels and to increase blood flow. While there is no rigorous efficacy data, there is preliminary evidence of improved cardiac function in a number of patients receiving either Ad expressing FGF-4 in the coronary arteries or Ad expressing VEGF121 in the myocardium [146,147]. Moreover, when injected into muscles of patients with peripheral vascular disease Ad expressing VEGF resulted in marginal improvements in some parameters of blood flow to that limb.

3.5.4 NORMALS

The early Ad gene therapy trials demonstrated that, while effective gene transfer could be achieved, persistence of expression is clearly a problem for Ad vectors. Although there was clearly an immune response to the vector and possibly the transgene itself, the biology of that response is not well understood. Animal models, particularly those involving inbred mice, have limited utility in predicting the immune response in humans. To assess the human–host response to Ad vectors, two trials with normal subjects have been performed using intradermal [148] or intratracheal administration of an Ad vector expressing the *E. coli* CD gene. The intent of these trials is to describe the immune response in humans to an E1⁻, E3⁻ Ad vector to provide a background to assess more advanced vectors on a rational basis.

3.6 FUTURE PROSPECTS

3.6.1 DECREASING VECTOR ELIMINATION

A number of approaches have been developed which should reduce the immune response to Ad vectors, prolong transgene expression, and enhance the efficiency of readministration. The basic hypothesis is that by reducing adenoviral gene expression, there should be a decrease in the host response to the vector and an increase in persistence. This is observed in some experimental animal models but not others. The basic problem posed by these data is whether prolonged persistence and reduced host response will be observed in humans with an administration route compatible with treatment. The only way to answer this question will be to perform the appropriate clinical studies in humans.

The limitations of Ad have prompted some investigators to make hybrids that exploit the wide range of cell types infected by Ad but allow persistence using features of other viruses such as retroviruses. For example, retroviruses can be produced in situ by coinfection of cells by two Ad vectors [149,150]. The first Ad contains the expression cassette for the therapeutic gene flanked by the retrovirus terminal repeats with the necessary *cis* sequences for packaging, all of this being transcribed from a CMV promoter. The second Ad expresses the trans factors (pol/gag/env) required for assembly of infectious retroviral particles which will then infect the neighboring cells and result in long-term gene therapy. The use of

such hybrids has been demonstrated both *in vitro* and *in vivo* but does not overcome the need of retroviral vectors for dividing cells, a limitation that might be overcome by making Ad/lentivirus hybrids or Ad/adenoassociated virus hybrids [151,152].

Phage display technology has provided an approach to select a peptide sequence with desirable binding properties. This has been exploited in selecting phages that target to different tissues after intravenous injection, presumably through interacting with the endothelium of that tissue. It is likely that these peptide motifs can be incorporated into the knob of the Ad fiber to facilitate targeting of Ad vectors to a desired tissue. This requires that the knob-modified vector be able to propagate in 293 cells, but strategies have been developed to overcome this production hurdle [119].

3.6.2 APPLICATIONS FOR TRANSIENT GENE THERAPY

The technical innovations described above are at best laboratory proofs that will require extensive animal studies before clinical testing. But the clinical data to date suggests that success with currently available Ad vectors is possible in applications where transient expression might be sufficient. For example, studies of therapeutic angiogenesis for coronary artery disease described above are a prototype of this type of application. Medical indications like cancer, infectious disease, tissue remodeling (angiogenesis, recovery from surgery, stroke, or injury) are areas where development might be most appropriate. On the other hand, metabolic and genetic disease, autoimmune disease, and other chronic conditions would seem to need substantial advances in adenoviral vector design or more likely some kind of hybrid vector before they become treatable on a persistent basis. Importantly, the knowledge of the cellular and host response to Ad infection in humans is still quite rudimentary and will need to be described in much greater detail before more rational approaches to prolonging expression can be devised.

3.6.3 AD VACCINE CARRIERS

The strong humoral and cellular immune response to the expressed transgene suggests that Ad vectors may be effective as vaccines for infectious diseases and cancer. It is possible that there is an inflammatory response to Ad capsids or to residual Ad gene expression that enhances the immune response over that obtained by expression from a plasmid vector. Alternatively, the ability of Ad to directly infect dendritic cells *in vivo* [80,153] and express the antigen gene may result in antigen presentation by the class I pathway. Examples of exploiting the cellular anti-transgene response include eliciting a cellular immune response to tumor antigens as discussed earlier. This property may also be useful in elimination of virus infected cells [154–156] or malaria [157]. It is clear that antigens expressed by Ad also elicit a strong humoral immunity that can be used to block initial infection by viruses [158,159]. In the context that most humans have been infected by wild-type Ads and have preexisting antibodies [160], it is

possible that use of Ad derived from other mammals may provide more effective vaccines [161,162].

4.1 INTRODUCTION

While still in its infancy, gene-based therapy has emerged as a potentially powerful therapeutic platform. The concept of gene therapy as a rational molecular intervention is simple, that is, to correct or eradicate defective tissues via delivery of nucleic acids. However, practical implementation of safe, highly effective gene-based interventions has been difficult due to the stringent and complex requirements of this paradigm. Indeed, the introduction of functional foreign nucleic acids into mammalian target cells without oncogenicity or significant toxicity or immune response represents a daunting task unique in biomedicine. This realization has spawned the field of vector design, which has for 20 years sought to engineer gene delivery vector systems compatible with the stringent mandates of human clinical use.

Vectors based on human adenovirus (Ad) serotypes 2 and 5 continue to show utility as gene therapy vectors, particularly

in the context of cancer gene therapy, owing to several innate biological characteristics: Replication-deficient Ad vectors display *in vivo* stability and superior gene transfer efficiency to numerous dividing and nondividing cell targets *in vivo* and rarely cause severe disease in humans. Further, production parameters for clinical grade Ad vectors are well established. In 2007, Ad vectors were employed in one-fourth of clinical trials worldwide (326 of 1309) with two-thirds of all trials being for cancer (871 of 1309) [1].

Nonetheless, clinical trial results of Ad vectors have clearly exposed the need to advance Ad vector technology. Relatively lackluster clinical performance of Ad-based agents to date has provided clear direction for vector modifications designed to improve efficacy and safety. In this regard, two distinct approaches have been employed: (1) transductional targeting, which limits the entry of agents to target cells and (2) transcriptional targeting, which restricts expression of

transgenes (or Ad replication, in some cases) to target tissues by using tissue- or tumor-specific promoters (TSPs). The following is a discussion of Ad biology, barriers to transductional targeting, and a review of the vector modifications applied toward transforming the human Ad into a clinically effective therapeutic agent.

4.2 Ad STRUCTURE

The family Adenoviridae contains over 100 serotypes, including 52 human serotypes that are divided among 7 species (A–G) based on genome homology and organization, oncogenicity, and hemagglutination properties [2–6]. The human Ad is a nonenveloped icosahedral particle that encapsulates up to a 36-kilobase double-stranded DNA genome. The Ad capsid is comprised of several minor and three major capsid proteins: hexon is the most abundant structural component with 720 copies per virion and constitutes the bulk of the protein shell; 5 penton monomers form the penton base platform at each of the 12 capsid vertices to which the 12 fiber homotrimers attach (Figure 4.1). The distal tip of each fiber is composed of a globular knob domain, which serves as the major viral attachment site for cellular receptors. Hexon appears to play only a structural role as a coating protein, while the penton base and the fiber are responsible for distinct virion–cell interactions that constitute Ad tropism. Detailed structures of hexon [7–11], penton base [12], and fiber [13,14] have been determined by crystallography; the high-resolution structure of the entire virion has been determined by various methods [15,16].

FIGURE 4.1 (See color insert following blank page 206.) Generalized Ad structure depicting major structural components of a wild-type Ad capsid. Hexon is depicted as a hexagon with 12 homotrimers per capsid face (only 12 of 240 trimers are shown). The penton base, comprised of five subunits at each vertex, and trimeric fiber and pIX structures are shown. Ad serotype-2 and -5 capsids contain a 36-kilobase double-stranded DNA genome (not shown).

4.3 Ad TRANSDUCTION PATHWAY

Intense research efforts into Ad biology have revealed crucial steps involved in gene transfer. The tropism of Ad is determined by two distinct virus–cell interactions: attachment to a primary receptor molecule at the cell surface, followed by interaction with molecules responsible for virion internalization. Initial high-affinity binding of the virion occurs via direct binding of the fiber knob domain to its cognate primary cellular receptor, which is the 346 amino acid coxsackie and adenovirus receptor (CAR) glycoprotein for most serotypes including Ad2 and Ad5, which are widely used in gene therapy approaches [17,18]. Other receptors have been described for Ad5, although the nature of their interactions with the Ad5 virion is unclear and their roles appear limited. These receptors include heparin sulfate glycosaminoglycans [19,20], class I major histocompatibility complex [21], and vascular cell adhesion molecule-1 [22]. Receptor binding is followed by receptor-mediated endocytosis of the virion via interaction of penton base Arg–Gly–Asp (RGD) motifs with cellular integrins including $\alpha v\beta 3$ and $\alpha v\beta 5$ [23], $\alpha v\beta 1$ [24], and $\alpha_3\beta 1$ and $\alpha_5\beta 1$ [25]. The virus enters the cell in clathrin-coated vesicles [26] and is transported to endosomes. Acidification of the endosome results in stepwise virion disassembly and subsequent release of the virus core into the cytosol, where it docks at the nuclear membrane. Further capsid disassembly and subsequent nuclear import of the Ad genome are then achieved via interaction of genome-associated Ad core proteins with transportin and importin components of the nuclear pore complex [27–29].

4.4 TRANSDUCTIONAL TARGETING OF Ad

Targeted gene delivery is ultimately predicated on the ability of the vector to discriminate between target and nontarget cells via interaction with unique cell- or disease-specific surface markers. However, the CAR dependence of Ad5 transduction results in a scenario wherein nontarget but high-CAR cells can be infected, whereas target tissues, if low in CAR, remain poorly infected. This may be of particular relevance in Ad-based cancer gene therapy, as increased CAR expression appears to have a growth inhibitory effect on some cancer cell lines, while loss of CAR expression correlates with tumor progression and advanced disease. Indeed, a lack or downregulation of CAR has been reported for various tumor types, such as ovarian, prostate, lung, breast and colorectal cancer, melanoma, glioma, and rhabdomyosarcoma [30–39] (reviewed in [40,41]). Further, this may be a general phenomenon associated with the carcinogenesis of various tumor types, as inverse correlation with tumor grade has been suggested [37,38]. CAR is a 346 amino acid glycoprotein containing a single membrane-spanning domain and is localized to tight junctions [42] where it mediates homotypic cell adhesion [43,44]. The functions of CAR are not fully understood, but it plays role in cell adhesion and perhaps cell cycle regulation, as it has a role in suppression of tumor growth [38]. Interestingly, a preliminary report has suggested inverse correlation between activity of

the tumor-associated Raf–MEK–ERK pathway and CAR expression [45]. For the treatment of cancer with Ad-based vectors, these associations are problematic since CAR-dependent approaches may not be useful against advanced disease if CAR is variably expressed in these tumors. Thus, targeting of Ad to tumor cells should be useful for increasing the clinical efficacy and safety of approaches. Further, considering the widespread expression of CAR, targeting approaches may be advantageous for increasing the specificity of any clinical Ad gene therapy application.

The biodistribution of Ad-based vectors *in vivo*, however, is not determined solely by receptor biodistribution [46]. Intravenous administration of Ad results in accumulation in the liver, spleen, heart, lung, and kidneys of mice, although these tissues may not necessarily be the highest in CAR expression [47,48]. Instead, the degree of blood flow and the structure of the vasculature in each organ probably contribute to the biodistribution. This is true with regard to the liver in particular, which retains the majority of systemically administered Ad particles via hepatic macrophage (Kupffer cell) uptake [49,50] and hepatocyte transduction [51], leading to Ad-mediated inflammation and liver toxicity [52–55]. Thus, the nature of Ad–host interactions that determine the fate of systemically applied Ad has come under considerable scrutiny.

To this end, initial attempts to “de-target” the liver were based on the supposition that CAR- and integrin-based interactions were required for liver transduction *in vivo*. Strategies to inhibit hepatocyte or liver Kupffer cell uptake by ablating CAR- or integrin-binding motifs in the Ad capsid have been largely unsuccessful, however, indicating that native Ad tropism determinants contribute little to vector hepatotropism *in vivo* [56–60]. These data notwithstanding, work by several groups has implicated the fiber protein as a major structural determinant of liver tropism *in vivo* (reviewed by Nicklin et al. [61]). For example, shortening of the native fiber shaft domain of the Ad 5 fiber [62] or replacement of the Ad5 shaft with the short Ad3 shaft domain [63] was shown to attenuate liver uptake *in vivo* following intravenous delivery. In related work, Smith and coworkers examined the role of a putative heparan sulfate proteoglycan (HSPG)-binding motif, KKTK, in the third repeat of the native fiber shaft [64]. Replacement of this motif with an irrelevant peptide sequence reduced reporter gene expression in the liver by 90%. This was also the first suggestion of the importance of HSPG as Ad receptors *in vivo*.

Critical work by Shayakhmetov and colleagues shed light on these apparently contradictory lines of evidence by uncovering a major role for coagulation factor IX (fIX) and complement component C4-binding protein (C4BP) in hepatocyte and Kupffer cell uptake of intravenous Ad [65]. A key finding was that these blood factors mediated *in vivo* tropism by cross-linking Ad particles to hepatocellular HSPG and the LDL receptor-related protein (reviewed in [66]). Kupffer cell sequestration of Ad particles was likewise dependent on Ad association with fIX and C4BP. Importantly, Ad5 vectors containing fibers genetically modified to ablate fIX and C4BP binding provided 50-fold lower liver transduction with

reduced inflammation and hepatotoxicity. Extending this work, this group also showed that Ad5 virions bind to circulating platelets *in vivo*, resulting in their aggregation, entrapment in liver sinusoids, and eventual clearance by Kupffer cells [49]. Further, Ad sequestration in organs was reduced by platelet depletion before systemic vector injection.

These efforts serve to highlight the complexity of vector–host interplay, and have identified genetic modifications that have important practical implications for designing safer and more effective Ad-based vectors for clinical applications. In the absence of a clinically defined upper limit for ectopic liver transduction in humans, it is clear that the concepts of “de-targeting” and “re-targeting” must be simultaneously employed to allow for maximum Ad vector efficacy at the lowest possible dose. Two distinct approaches have been employed to transductionally target Ad-based therapeutic vectors: (1) adapter molecule-based targeting and (2) genetic targeting via structural manipulation of the Ad capsid.

4.4.1 ADAPTER-BASED AD TARGETING

The formation of a molecular bridge between the Ad vector and a cell surface receptor constitutes the adapter-based concept of Ad targeting (Figure 4.2). Adapter function is performed by so called bispecific molecules that cross-link the Ad vector to alternative cell surface receptors, bypassing the native CAR-based tropism. This approach is predicated by the aforementioned two-step entry mechanism of the Ad virion wherein attachment is distinct from internalization. In this way, alternative means of cellular attachment do not impede Ad cell entry. The majority of current adapter-based Ad targeting approaches incorporate the two mandates of delivery targeting, that of ablation of native CAR-dependent Ad tropism and formation of a novel tropism to previously identified cellular receptors. Bispecific adapter molecules include, but are not limited to bispecific antibodies, chemical conjugates

FIGURE 4.2 Adapter molecules for receptor-specific Ad targeting. A generalized adapter molecule ablates native CAR-based tropism and targets Ad to an alternate cellular receptor molecule. The dual specificity of the adapter molecule for both the Ad and the alternative receptor provides novel, CAR-independent cell binding.

between antibody fragments (Fab), and cell-selective ligands such as folate, Fab-antibody conjugates using antibodies against target cell receptors, Fab-peptide ligand conjugates, and multidomain recombinant fusion proteins comprised of soluble CAR and peptide ligands or recombinant Fab.

The first *in vitro* demonstration of Ad targeting via the adapter method resulted in CAR-independent, folate receptor-mediated cellular uptake of the virion by cancer cells overexpressing this receptor [67]. This was accomplished using a bispecific conjugate consisting of an anti-knob neutralizing Fab chemically linked to folate. A similar targeting adapter comprised of the same anti-knob Fab as above fused to basic fibroblast growth factor (FGF2) was utilized to target Ad vectors to FGF receptor-positive Kaposi's sarcoma and ovarian cancer substrates [68,69]. Upon intraperitoneal injection of Ad-Fab-FGF2 coding for herpes simplex virus type I thymidine kinase (HSV-TK) into mice bearing human ovarian cancer, survival was prolonged [70]. Importantly, this targeting system also reduced hepatic toxicity and resulted in increased survival in melanoma [71] and ovarian cancer [72] xenograft mouse models. Other Fab-ligand conjugates targeted against Ep-CAM, Tag-72, EGF receptor, CD40, and other cell markers have been employed in a similar manner with promising results [31,34,73-77].

Dmitriev and colleagues developed a more elegant alternative to chemical conjugates by creating a single recombinant fusion molecule formed by a truncated, soluble form of CAR (sCAR) fused to either CD40 [78] or epidermal growth factor (EGF) [79]. Using the latter, a ninefold increase in reporter gene expression was achieved in several EGFR-overexpressing cancer cell lines compared with untargeted Ad or EGFR-negative cells *in vitro*. EGF-directed targeting to EGFR-positive cells was shown to be dependent on cell surface EGFR density, an additional confirmation of Ad targeting specificity. Addressed also was the issue of virion-adapter complex stability, a critical issue if targeting adapters are to be employed *in vivo*. In this regard, preformed Ad/sCAR-EGF complexes subjected to gel filtration purification showed the same targeting profile as those not purified, indicating adequate Ad-adapter complex stability. To further increase Ad/sCAR-ligand complex stability, Kashentseva and colleagues developed a trimeric sCAR-anti-*c-erbB2* single chain antibody adapter molecule. The trimeric sCAR-*c-erbB2* adapter displayed increased affinity for the Ad fiber knob while augmenting gene transfer up to 17-fold in six *c-erbB2*-positive breast and ovarian cancer cell lines *in vitro* [80]. In a similar work, Itoh and colleagues demonstrated improved efficiency of sCAR-based fusion molecule adapters [81]. Kim et al. showed that adapter trimerization yielded a 100-fold increase in infection of CAR-deficient human diploid fibroblasts compared to the monomeric sCAR adapter [82]. Importantly, *in vivo* employment of a nontargeted trimeric sCAR adapter attenuated liver transduction in mice following intravenous administration, indicating excellent *in vivo* stability of this Ad-trimeric adapter complex.

The above proof-of-principle studies and others have rationalized the further testing of targeting adapters *in vivo*. In this

regard, Reynolds et al. employed a novel bispecific adapter composed of an anti-knob Fab chemically conjugated to a monoclonal antibody (9B9) raised against angiotensin-converting enzyme (ACE), a surface molecule expressed preferentially on pulmonary capillary endothelium and upregulated in various disease states of the lung [75]. Following peripheral intravenous injection of the Ad/Fab-9B9 complex, reporter transgene expression and viral DNA in the lung was increased 20-fold over untargeted Ad and reporter gene expression in the liver, a nontarget, high-CAR organ, was reduced by 83%. Further, ACE-targeted gene delivery of bone morphogenetic protein receptor type 2 to the pulmonary vascular endothelium of rats reduced hypoxia-induced pulmonary hypertension, as reflected by reductions in pulmonary artery and right ventricular pressures, right ventricular hypertrophy, and muscularization of distal pulmonary arterioles [83].

In another adapter-based *in vivo* targeting model, Everts and coworkers used a bifunctional adapter molecule comprised of sCAR fused to a single-chain antibody (MFE-23) directed against carcinoembryonic antigen (CEA) [84]. Systemic administration of the Ad/sCAR-MFE-23 adapter complex increased gene expression in CEA-positive murine lung by 10-fold and reduced liver transduction, resulting in an improved lung-to-liver ratio of gene expression compared with untargeted Ad. In another study, the sCAR-MFE adapter was used to target Ad vectors to CEA-expressing cells *in vitro*, CEA-positive subcutaneous tumor grafts, and hepatic tumor grafts following systemic administration of the Ad/sCAR-MFE complex [85]. Of note, Ad/sCAR-MFE liver transduction was reduced by over 95% and CEA-negative tumors *in vivo* were not transduced, suggesting remarkable safety and specificity profiles for this approach.

Overall, adapter-based Ad targeting studies provide compelling evidence that Ad tropism modification can be achieved by targeting alternate cellular receptors and that this modality augments gene delivery to CAR-deficient target cells *in vitro*. Adapter-targeted vectors have also performed well *in vivo*, although data so far are limited. While single-component systems have been favored for employment in human gene therapy trials, rigorous analysis of the pharmacodynamics and pharmacokinetics, and systemic stability of vector-adapter complexes may provide the rationale for clinical translation.

4.4.2 AD TARGETING VIA GENETIC MODIFICATION: FIBER

Genetic manipulation of capsid proteins has yielded increasingly promising data in terms of Ad targeting. Direct capsid Ad modification may be advantageous over adapter molecules in that all virions harbor an identical modification and lack of stability is less likely. Redirection of Ad tropism via genetic capsid modification is conceptually elegant, but genetic targeting efforts must work within narrow structural constraints. The success of this approach depends upon modulation of the complex protein structure-function relationships that result in Ad tropism modification, without disrupting the innate molecular interactions required for proper biological function. Specifically,

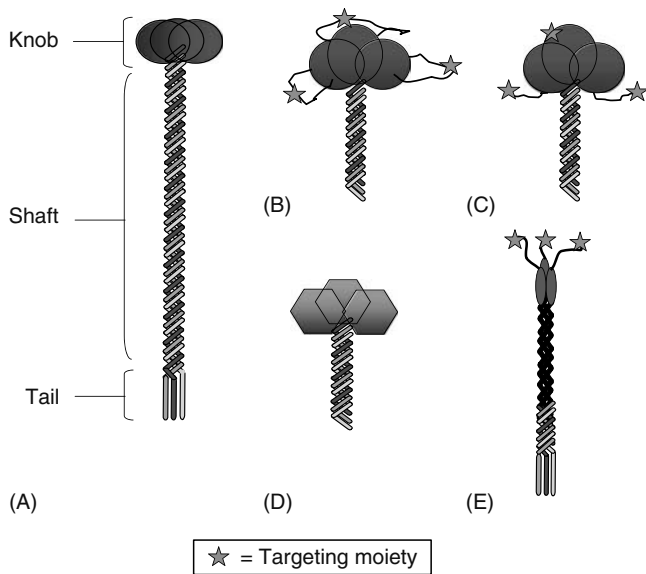

FIGURE 4.3 (See color insert following blank page 206.) Genetically modified fibers for Ad targeting. (See text for specific examples of each genetic targeting approach and targeting moiety used.) (A) Trimeric wild-type Ad fiber; tail, shaft, and knob regions are shown. (B) Ad5 fiber knob with a constrained targeting peptide in the flexible H-I loop. (C) Ad5 fiber knob containing a C-terminal targeting ligand. (D) Pseudotyped chimeric fiber bearing an alternate human or animal serotype knob domain. (E) “De-knobbed” fiber containing a heterologous trimerization sequence and a C-terminal targeting moiety.

genetic modification can affect fiber trimerization, production, stability, and ultimately packaging of infectious virions. On the basis of a clear understanding of Ad infection biology, development of genetically targeted vectors has rationally focused on the fiber, the primary capsid determinant of Ad tropism. In general, there have been three basic strategies for genetic tropism modification via structural modification of the Ad fiber: (1) so-called fiber pseudotyping, (2) ligand incorporation into the fiber knob domain, and (3) de-knobbing of the fiber coupled with ligand addition (Figure 4.3).

4.4.2.1 Fiber Pseudotyping

As previously mentioned, clinically relevant tissues are often refractory to Ad5 infection, including several cancer cell types, owing to negligible CAR levels. Ad fiber pseudotyping, the genetic replacement of either the entire fiber or knob domain with its structural counterpart from another human Ad serotype that recognizes a cellular receptor other than CAR, was first accomplished by Krasnykh et al. to circumvent CAR deficiency [86]. This vector expresses a chimeric fiber containing the Ad serotype 3 knob domain (Ad5/3) and demonstrates the same CAR-independent cell recognition as does Ad3. The use of another Ad5/3 vector selectively targeted low-CAR lymphoid cell lines *in vitro*, whereas these cells were refractory to Ad5 infection [87]. Ad5/3 has been useful for retargeting Ad5 to low-CAR primary ovarian carcinoma cells and cell lines [88,89] and primary glioma

[90–92] *in vitro* and *in vivo*. Other fiber pseudotyped Ad vectors display CAR-independent tropism by virtue of the natural diversity in receptor recognition found in human species B and D fibers [93]. In this regard, primary receptors for species B Ads have been recently identified, including the complement regulatory protein CD46 [94–97], CD80, and CD86 [98], although an additional unknown receptor is postulated [95]. Species D Ad receptors include CD46 and $\alpha(2-3)$ -linked sialic acid, a common element of glycolipids [99–101]. Fiber pseudotyping has identified chimeric vectors with superior infectivity to Ad5 in several clinically relevant cell types including primary ovarian carcinoma cells [88,89,102], vascular endothelial cells (ECs) [103], dendritic cells [104], B-cells [87], CD34 + hematopoietic cells [105], synovial tissue [106], human cardiovascular tissue [107], and others [108,109]. Interestingly, this strategy has been extended to exploit fiber elements from nonhuman Ads [110,111] and the fiber-like $\sigma 1$ reovirus attachment protein, which targets cells expressing junctional adhesion molecule [112,113].

4.4.2.2 Genetic Ligand Incorporation

To circumvent variable expression of CAR, targeting ligands have been incorporated into the Ad knob domain without ablating native CAR binding. This has resulted in Ad vectors with expanded, rather than restricted, cell recognition. These efforts are based on rigorous structural analysis of the knob domain and have exploited two separate locations within the knob that tolerate genetic manipulation without loss of fiber function, the C-terminus and the HI-loop. Since the C-terminus of the Ad knob is solvent exposed, extension of the knob peptide to include a targeting peptide moiety is conceptually simple. Ads with C-terminal integrin-binding RGD motifs and polylysine ligands have yielded some promising results *in vitro* and *in vivo*, but other peptide ligands were rendered ineffective in the C-terminus structural context [114], presumably due to steric or other inhibition. On this basis, Krasnykh et al. inserted a FLAG peptide sequence into an exposed loop structure that connects β -sheets H and I (HI-loop) within the Ad5 knob, showing that this locale is structurally permissive to modification [115]. Indeed, the Ad5 HI-loop tolerates peptide insertions up to 100 amino acids with minimal negative effects on virion integrity, thus suggesting considerable potential for ligand incorporation at this site [116]. On this basis, Magnusson and colleagues developed a targeting approach via incorporation of complex ligands in the HI-loop. This group genetically inserted tandem HER2/neu reactive Affibody molecules in the HI-loop of a CAR binding-ablated fiber, resulting in CAR-independent, HER2-mediated cell infection *in vitro* [117]. Dmitriev and coworkers introduced an integrin-binding RGD peptide sequence into the HI-loop. The resulting vector, Ad5lucRGD, used the RGD–cellular integrin interaction to enhance gene delivery to ovarian cancer cell lines and primary tumors versus unmodified Ad5 [33,118,119]. The expanded tropism of this vector has been useful in several other cancer contexts including carcinomas of the ovary, pancreas, colon cancer, and head and neck carcinomas, all of

which frequently display highly variable CAR levels (reviewed in [120]). Wu et al. demonstrated that Ad vectors with a double-fiber modification consisting of a C-terminal polylysine stretch, which interacts with heparan sulfates, and the HI-loop RGD provided increased infectivity in several CAR-deficient cell lines [121], as well as human pancreatic islet cells [122], ovarian carcinoma [123], and cervical cancer cells *in vivo* [124]. Other targeting peptides have functioned in the HI-loop locale, including a vascular EC-binding motif SIGYLPLP [125]. This fiber modification also provided cancer cell-selective infection [126].

Korokhov et al., Volpers et al., and others [127] have developed similar targeting approaches that embody elements of both genetic fiber modification and adapter-based targeting by incorporating the immunoglobulin (Ig)-binding domain of *Staphylococcus aureus* protein A into the fiber C-terminus or HI-loop [128,129]. As a result, these fiber-modified vectors form stable complexes with a wide variety of targeting molecules containing the Fc region of Ig. This provides the opportunity to screen numerous targeting molecules directed against a host of cell-surface elements. This approach was used to target and activate dendritic cells via an Fc-single chain antibody directed against CD40 [130]. This system was also used to target ovarian cancer cells via an antibody directed against mesothelin [131], as well as the pulmonary endothelium in a rat model *in vivo* [132].

4.4.2.3 Knob-Deleted Fibers with Complex Ligands

The structural conflicts emerging from knob modifications and the observation that fiber-deleted Ad vectors could be produced [133,134] provided the conceptual basis for replacing the native fiber with knobless fibers. Virions containing a knobless fiber would be ablated for CAR binding, a hallmark of targeted Ad vectors. Simultaneous addition of a targeting ligand to the knobless fiber would result in a more specifically targeted Ad. The technical barrier to this approach is the innate trimerization function of the fiber knob domain, required for proper fiber function and capsid assembly. A solution was devised by addition of a foreign trimerization motif to replace the native fiber or knob or both [135]. Krasnykh et al. replaced the fiber and knob domains with bacteriophage T4 fibritin containing a C-terminal 6-His motif [136]. This novel Ad variant lacks the ability to interact with CAR and demonstrated up to a 100-fold increase in reporter gene expression to cells presenting an artificial 6-His binding receptor. A similar de-knobbing strategy was employed by Magnussen and colleagues, wherein an integrin-binding RGD motif was utilized, resulting in selective infection of integrin-expressing cell lines *in vitro* [137], as well as human glandular cells [138]. On the basis of feasibility of knob replacement with foreign trimerization motifs, an elegant system was devised wherein the trimeric CD40 ligand was fused to the C-terminus of a knobless fiber [139]. Notably, this vector provided CD40-specific gene delivery *in vivo* following systemic delivery [140]. Further, this vector accomplished CD40-mediated infection of human monocyte-derived dendritic

cells, suggesting possible utility for cancer vaccine “antigen loading” approaches. In addition, Ad vectors simultaneously incorporating multiple fiber types with distinct receptor specificities have been proposed [141,142].

Modification of Ad tropism via antibody-based adapter molecules has demonstrated considerable target specificity, as discussed above. On this basis, the development of single-component Ad vectors with genetically incorporated recombinant antibodies, antibody-derived moieties, or other multidomain ligands has been a long-standing field milestone. However, genetic incorporation of any moiety into the Ad capsid requires that the peptide be compatible with the nonreducing environment within the cytosol and nucleus, wherein Ad capsid proteins are translated and assembled. Capsid incorporation of several classes of complex targeting ligands, including single-chain antibodies (scFv) and growth factors, has been severely hampered by the innate biosynthetic incompatibilities between the ligand and Ad capsid proteins, resulting in unstable or insoluble ligands and reduced Ad replication [143]. On this basis, rational development of complex ligands with cytoplasmic solubility and stability will be required for their application to Ad vectors. Exemplifying this concept, Hedley and colleagues developed a single-component antibody targeted Ad vector by incorporating a cytoplasmically stable scFv into a de-knobbed fiber [144]. This vector targeted its cognate epitope expressed at the cell surface, suggesting that cytoplasmic stability of the targeting molecule, per se, allows retention of antigen recognition in the context of genetic capsid incorporation. In another landmark report, Ulasov et al. created an Ad vector targeted to a glioma-associated receptor, the $\alpha 2$ chain of the interleukin-13 receptor (IL-13R $\alpha 2$), by fusing the full length human IL-13 cytokine was fused to the C-terminus of a de-knobbed fiber containing the T4 fibritin trimerization motif [145]. This targeted vector provided IL-13R $\alpha 2$ -specific gene delivery to passaged and primary human glioma cells *in vitro* and in a xenograft model *in vivo*.

4.4.3 AD TARGETING VIA GENETIC MODIFICATION: OTHER CAPSID LOCALES

The field-wide appreciation of the difficulty of incorporating complex ligands into the Ad fiber has prompted the identification of other capsid proteins amenable to genetic ligand incorporation. These approaches have the potential, through increased capsid valency and unique capsid microenvironments, to incorporate an increased number of ligands per virion. To date, the hexon capsid protein as well as minor capsid protein pIX have been used as platforms for incorporation of heterologous peptides.

4.4.3.1 Hexon

Hexon is the largest (952 amino acids) and most abundant capsid protein, and as such is an attractive locale for peptide ligand incorporation due to both its surface exposure and high valency (240 hexon homotrimers per virion). The primary sequence of the hexon monomer is highly conserved among human serotypes with exception of nine nonconserved

hypervariable regions (HVRs) of unknown function found mainly within solvent-exposed loops at the surface [8,146,147]. In this regard, Vigne and coworkers exploited hexon hypervariable region 5 (HVR5), a loop structure in hexon, as a site for incorporation of an integrin-binding RGD motif. Notably, virion stability was unaffected by the addition of the foreign peptide, while providing enhanced, fiber-independent transduction to low-CAR vascular smooth muscle cells [148]. Extending this work, Wu et al. identified HVRs 2, 3, and 5–7 as hexon sites tolerating 6-histidine (6-His) motifs without adverse effects to virion formation or stability [149]. Six-His motifs in HVRs 2 and 5 mediated virion binding to anti-6-His antibodies; however, 6-His-mediated viral infection of cells was not observed, in contrast to the findings of Vigne et al. as mentioned earlier, highlighting the importance of the nature and the length of the incorporated peptides. While not related to Ad vector targeting per se, it bears mentioning that genetic alterations of hexon HVRs have been used as a method for evading host neutralizing antibodies (NABs) [150], as most NABs are directed against hexon [151].

4.4.3.2 Protein IX

Protein IX (pIX) has emerged as a versatile capsid locale well suited for display of ligands, with utility for both targeting and imaging modalities (reviewed in Ref. [152]). The 14.3 kDa pIX is the smallest of the minor capsid proteins, a subset of capsid proteins that generally function to stabilize the capsid shell. In the mature Ad virion, 80 pIX homotrimers [153] stabilize hexon–hexon interactions during capsid assembly, and it is therefore termed a “cement” protein. Indeed, virions deleted for pIX have decreased thermostability and a DNA capacity that is approximately 2 kb less than the normal length [154–156]. Interest in employing pIX as a capsid site for incorporation of peptide ligands stemmed from the observation that the C-terminus of pIX is located at the capsid surface [157,158], which prompted several groups to explore the fusion of several polypeptides to this terminus.

Dmitriev and colleagues first reported the incorporation of functional targeting peptides at the pIX C-terminus by inserting polylysine or FLAG motifs, resulting in augmented, CAR-independent gene transfer via binding to cellular heparan sulfate moieties [159]. Similarly, Vellinga and colleagues fused an integrin-binding RGD peptide to pIX, and used α -helical spacers (up to 7.5 nm in length and 113 amino acids) to extend the RGD motif away from the virion surface [160].

Increased gene transfer to CAR-deficient endothelial cells was observed with increased spacer length, giving support to the notion that the pIX C-terminus may reside in a cavity formed by surrounding hexons. In a proof-of-principle study, this same group fused a hyperstable scFv directed against β -galactosidase onto a 7.5 nm pIX C-terminal extension [161]. Of note, the scFv was functional in this pIX structural context, as evidenced by binding of Ad particles to β -galactosidase protein *in vitro*.

To evaluate the utility of multiple ligand types at the pIX capsid locale, Campos and coworkers fused to the

pIX-C-terminus to a 71-amino acid fragment of the *Propionibacterium shermanii* 1.3S transcarboxylase protein, which functions as a biotin acceptor peptide (BAP) [162]. During virus propagation the BAP is metabolically biotinylated, rendering this virus compatible with a host of avidin-tagged ligands including peptides, antibodies, and carbohydrates. Importantly, it was noted in this study that coupling transferrin to virions via pIX-BAP resulted in specific transferrin receptor-mediated infection of C2C12 cells, but the use of an antibody directed against the transferrin receptor (CD71) did not. This dichotomy was not observed when these two ligands successfully redirected Ad tropism when incorporated into fiber. The authors speculate the difference was not due to a lack of receptor recognition by the pIX-anti-CD71 complex, but rather a difference between the dissociation of targeted fiber and pIX from the Ad particle in endosomes, resulting in trapping of the pIX-anti-CD71 variant, but not the fiber-anti-CD71 in the endosome. If this notion is fully validated, it will represent a key finding showing that the nature of pIX-incorporated ligands may influence successful redirection of Ad infection.

pIX has also been used for the display of relatively large imaging molecules such as C-terminal fusions. While Ad vector imaging is beyond the scope of this chapter, the successful incorporation of the 240 amino acid enhanced green fluorescent protein (eGFP) into pIX bears mentioning because of the size and complexity of this fusion. Of note, the presence of the pIX–eGFP fusion in purified Ad virions did not appreciably decrease virus viability or capsid stability, and has allowed monitoring of Ad localization *in vitro* and *in vivo* [163,164]. Other Ad vectors have been reported that harbor complex imaging polypeptides at the pIX C-terminus, such as herpes simplex virus type 1 thymidine kinase [165], a firefly luciferase–thymidine kinase fusion [166], and monomeric red fluorescent protein [167]. As a whole, these studies have established pIX as a highly relevant capsid locale marked by the highest structural compatibility with diverse targeting and imaging ligands observed to date. On the basis of its surface capsid position, pIIIa has been proposed as a platform for ligand display for modification of Ad tropism [168,169]. The minor capsid protein pIIIa is a 67 kDa monomer that is cleaved at the C-terminus during maturation of the virion, giving rise to the final 63.5 kDa form. Initial high-resolution imaging studies originally indicated that pIIIa is an elongated protein penetrating the capsid and is located along the icosahedral edges of the virion [15]. However, later structural studies performed at higher resolution place pIIIa below the outer surface of the virion, likely precluding its utility for foreign peptide display [170].

In the aggregate, these results highlight that genetic manipulation of a variety of Ad capsid proteins is currently feasible, and has brought to fruition several novel targeting and imaging paradigms. These successes confirm a level of capsid flexibility that was largely unexpected. There remains, however, an ongoing struggle to identify true targeting ligands that are structurally and biosynthetically compatible with Ad capsid formation and stability.

4.5 TRANSCRIPTIONAL TARGETING: USE OF TISSUE-SPECIFIC PROMOTERS

Transductional targeting approaches attempt to restrict Ad vector entry into target cells. In contrast, transcriptional targeting does not change vector tropism but instead restricts gene expression to target tissue by placing virally encoded transgenes under the control of cellular promoters that are specifically active or overactive in the target tissue. The ideal TSP element would exhibit the widest differential between “target on/liver off” expression profiles, key to ablation of liver toxicity from any ectopically localized vector. One of the first tissue-specific promoters (TSPs) explored for cancer was the CEA promoter, expressed in most gastric, pancreatic, and lung cancers [171]. For hepatomas, the promoter of the α -fetoprotein (AFP) has been investigated [172,173], while the L-plastin promoter (LP-P) was used in ovarian and breast cancer cell lines [174,175]. Other promoters tested for ovarian cancer include DF3 [176], Cox2 and midkine [177], mesothelin [131], and the secretory leukoprotease inhibitor (SLPI) promoter [178,179] as well as the ovarian-specific promoter-1 [180]. The Cox-2 promoter has also been explored in the context of gastric carcinomas [181]. The CXCR4 promoter was shown to have general transcriptional selectivity for cancer cells [182], breast cancer cell lines, and primary cells [183] as well as renal cancer cell lines [184]. The survivin promoter has emerged as a potentially powerful element for transcriptional control in glioma and melanoma, and exhibits a “liver-off” activity profile [185,186].

Osteocalcin (OC) is a bone protein expressed in osteotropic tumors and differentiated osteoblasts, as well as numerous solid tumors, including osteosarcoma and prostate cancer [187,188]. An Ad utilizing the OC promoter to drive *HSV-TK* expression in prostate cancer cells resulted in destruction of tumor cells *in vitro* and in subcutaneous or bone tumor xenografts. Interestingly, tissue-specific toxicity was seen in bone metastases. OC is expressed in osteoblastic lesions, thus offering the possibility for cotargeting of regenerating bone and tumor. Further, many types of cancers metastatic to the bone could be amenable to treatment.

The SLPI gene is expressed in several different carcinomas, including ovarian cancer. Its expression in normal organs, such as the liver, is low. Therefore, the SLPI promoter was utilized to drive transgene expression in ovarian cancer cell lines and primary tumor cells isolated from patient samples [178]. The promoter was activated in both cell lines and primary tumor cells in an Ad context *in vitro*. A murine orthotopic model of peritoneally disseminated ovarian cancer was used to demonstrate high tumor gene expression versus low liver expression with the SLPI promoter, and that Ad-delivered *HSV-TK* under the control of the SLPI promoter was able to increase survival.

4.5.1 VASCULATURE-SPECIFIC PROMOTERS

The vascular endothelium is an attractive therapeutic target for cancer, vascular, and cardiopulmonary diseases, and is

easily accessible to intravascular vector administration. The vascular endothelial growth factor receptor type-1 (flt-1) promoter has been used to restrict transgene expression to the endothelium in rodents while reducing liver gene expression [83,84,189]. E-selectin expression is minimal in normal blood vessels but high in the capillaries of tumors, and the promoter was used for driving gene expression in an Ad. Upon infection, EC lines expressed high levels of reporter gene expression, while non-EC lines showed low expression. The addition of TNF- α , an inducer of the promoter, further increased E-selectin's activity [190]. The murine pre-proendothelin-1 (PPE-1) promoter was also used as a TSP for adenoviral-mediated delivery to EC cells. Systemic administration to lung tumor-bearing mice resulted in gene expression in the new vasculature of primary tumors [191]. The Roundabout-4 receptor (Robo4) is a transmembrane receptor with endothelial-specific expression in embryonic vasculature as well as in the adult [192,193]. On this basis, the Robo4 promoter has been employed for transcriptional targeting of Ad gene expression to the endothelium [194].

4.5.2 TREATMENT-RESPONSIVE PROMOTERS

Another strategy for cancer gene therapy involves regulating gene expression with another form of treatment, such as radiation (reviewed in [195]). For example, the early growth response gene-1 (EGR-1) promoter, which is radiation inducible, has been used as a TSP for the specific expression of *lacZ* and *HSV-TK* in glioma and hepatocellular carcinoma cells. Radiation-induced transcription of EGR-1 in these cells was accomplished with relatively low doses [196]. Another approach for dynamically controlling promoter expression involves chemically inducible promoters. For example, a tetracycline-activated promoter can be used to regulate gene expression and subsequent protein production by giving oral tetracycline [197]. Withdrawal of the drug rapidly abrogates gene expression. Similarly, mifepristone- (RU486) and tamoxifen-inducible systems for controlled transgene expression have been developed [198,199].

4.6 DOUBLE-TARGETED Ad VECTORS

Transductional and transcriptional targeting can be combined to create double targeted viruses. Conceivably, this approach could be synergistic with regard to safety and efficacy. Initial proof-of-concept was achieved by using the vasculature-specific flt-1 promoter and a lung endothelium-targeted adapter strategy [189]. Impressively, the tumor-to-liver ratio of gene expression was increased 300,000-fold when both targeting modalities were utilized. Also, double targeting for ovarian cancer has been achieved *in vitro* and *in vivo* [179]. Transductional targeting with a sCAR-fibritin-antiErbB2-sFv adapter was able to increase gene transfer to target cells while reducing transduction of nontarget cells. When combined with transcriptional targeting with the SLPI promoter, an increase in selectivity was seen. Also, the transductional

targeting increased the level of SLPI-mediated transgene expression in target cells, thereby compensating for the lower gene expression typically seen with TSPs.

4.7 TRANSCRIPTIONAL AND TRANSDUCTIONAL TARGETING OF CONDITIONALLY REPLICATING Ad

Although nonreplicating first generation Ad vectors have provided high *in vitro* and *in vivo* transduction rates and good safety data, clinical cancer trials have suggested that the single agent antitumor effect may not be sufficient for all treatment approaches [40]. As early as the 1950s, the use of viruses that replicate and spread specifically inside tumors has been suggested as a way to improve tumor penetration with an additional benefit of local amplification of effect [200].

To this end, conditionally replicative adenovirus (CRAd) agents have been explored. These viruses are genetically modified to take advantage of tumor-specific changes that allow preferential replication of the virus in target cells [41,201,202]. The Ad replication cycle causes oncolysis of the cell, resulting in the release of newly generated virions and subsequent infection of neighboring cells. Thus, the antitumor effect is not delivered with a transgene but by replication of the virus *per se*. In theory, the oncolytic process continues as long as target cells for the virus persist. There are two main ways to control viral replication. One method is the control of replication regulators, such as the viral early genes, with tumor-specific promoter elements. The other method involves introduction of deletions in the viral genome that requires specific cellular factors to compensate the effects of these deletions. Further, both approaches can be combined with the potential for increased specificity.

Numerous tumor-associated promoters have been used to control viral replication (reviewed in Refs. [120,203]). Typically, the promoter element is placed to control expression of *E1A*, the crucial regulator of Ad replication, sometimes combined with other genes such as *E1B* or *E4*. An interesting concept is targeting CRAds to tumor vasculature [204]. However, this strategy is more challenging to study preclinically, as animal models are unavailable; ECs derive from the host in xenograft systems and murine cells do not support replication of human Ads. To further increase the oncolytic effect, transgenes for cytokines or prodrug-activating enzymes have been included in CRAds [205,206]. This approach may also allow noninvasive imaging and abrogation of virus replication in case of toxicity.

Heretofore, two approaches have been utilized for creation of deletion-type CRAds. The first was ONYX-015 (initially reported as *dl1520*), which has two mutations in the gene coding for the E1B 55-kDa protein [207,208]. The purpose of this protein is binding and inactivation of p53 in infected cells, for induction of S-phase, which is required for virus replication. Thus, this virus should only replicate in cells with an aberrant p53-p14ARF pathway, a common

feature in human tumors [209]. While this is still a subject of debate, initial studies suggested that this agent replicates more effectively in tumor than in normal cells [210–213]. Unfortunately, the function of E1B55 kD is not limited to p53 binding, which causes inefficient replication compared to wild-type Ad [207,208,214].

The second group of deletion mutant CRAds have a 24 bp deletion in the constant region (CR) 2 of *E1A* [215,216]. This domain of the E1A protein is responsible for binding the retinoblastoma tumor suppressor/cell cycle regulator protein (Rb), thereby allowing Ad to induce S-phase entry. Therefore, viruses with this type of deletion have reduced ability to overcome the G1–S checkpoint and replicate efficiently only in cells where this interaction is not necessary, e.g., tumor cells defective in the *Rb-p16* pathway. Appropriately, this pathway seems to be inactive in most human tumors [217]. It has been shown that replication of CR2-deleted viruses is attenuated in nonproliferating normal cells [215,216]. Importantly, abrogation of replication was also demonstrated when Rb was reintroduced into otherwise permissive cells [215]. Ads with mutations in both CR1 and CR2 of *E1A* have also been found to replicate selectively in tumor cells although increases in comparison to just CR2-deleted CRAds have not yet been demonstrated [218–221].

As Ad5-based vectors, CRAds have native CAR-dependent tropism. Unfortunately, CAR expression is low or variable in many types of clinical cancers [30–32,37–39,91]. Nevertheless, even CRAds with wild-type tropism have shown evidence of clinical utility [222–224]. These initial successes suggested that if efficiency of infection and specificity of replication of these agents could be enhanced, significant improvements in clinical efficacy could be gained. This was corroborated by a clear demonstration of the relationship between infectivity and oncolytic potency [225–227]. Consequently, genetic capsid modifications that allow CAR-independent or enhanced infectivity in nonreplicative Ads have been applied to CRAds, resulting in impressive gains in preclinical efficacy. For example, Ad5- Δ 24RGD features the integrin-binding RGD-4C peptide displayed from the HI-loop of the Ad5 fiber [228], and displays similar oncolytic potency to wild-type virus in ovarian cancer cells. Further, this virus is able to replicate in ovarian cancer primary cell spheroids and results in significantly prolonged survival in an orthotopic model of ovarian [229] and lung cancer [230]. In addition, Ad5- Δ 24RGD has also been evaluated against osteosarcoma substrates [231,232].

On the basis of superior infectivity of Ad vectors containing human serotype 3 fiber knob domains in ovarian substrates [89,233], a Δ 24-based CRAd featuring the serotype 3 knob (Ad5/3- Δ 24) was created [234]. This agent demonstrated dramatic antitumor efficacy in ovarian cancer cell lines, primary tumor specimens, and in orthotopic animal models of ovarian cancer. The first tumor-associated promoter-controlled infectivity-enhanced CRAd has been constructed and evaluated on ovarian, pancreatic, and gastric cancer substrates [235–237].

A major problem in assessing preclinical CRAd efficacy and safety is a severely limited number of appropriate animal

models. Human Ads (including CRAds) do not replicate productively in commonly used animal models. Therefore, meaningful safety data are difficult to obtain, and efficacy data is likely skewed because of deficient immune responses in xenograft models. Further, evaluation of host-virus interactions and their modulation has not been possible. To address this field-wide deficiency, Hemminki and colleagues have proposed the development of syngeneic CRAds for use in animal models of cancer [238]. To allow the evaluation of Ad5-based CRAds, the cotton rat has been put forth as a model [239,240]. Since this rodent is semipermissive for human Ad replication, this immunocompetent tumor model allows investigation of host immune system effects on the CRAd-tumor interaction as well as the effects on normal host cells *in vivo*. Another promising model system for CRAd evaluation is the Syrian hamster. Human Ads replicate well in Syrian hamster cell lines *in vitro*, and demonstrate significant antitumor efficacy following injection into Syrian hamster tumors *in vivo* [241].

4.8 CLINICAL TRIALS WITH MODIFIED Ad

No clinical trials have yet been completed with targeted Ads. Nevertheless, some trials are in progress. For example, the first transductionally targeted CRAd trial with Ad5- Δ 24RGD has received funding from the National Cancer Institute Rapid Access to Intervention Development program for vector production costs and has undergone full preclinical toxicological analysis in cotton rats [242]. As of this writing, a Phase I clinical trial is under way at the University of Alabama at Birmingham for recurrent epithelial ovarian cancer (Ronald D. Alvarez, M.D., personal communication).

4.9 FUTURE DIRECTIONS

Despite the advances in Ad-based gene therapy vectors described in this chapter, several obstacles remain. The vascular endothelial wall is a significant physical barrier prohibiting access of systemically administered vectors to tumors and other target tissues. To overcome this obstacle, strategies need to be developed to route Ad vectors via transcytosis pathways through the endothelium. As an example, Zhu et al. redirected Ad vectors to the transcytosing transferrin receptor pathway, using the bifunctional adapter molecule [243]. The transcytosed Ad virions retained the ability to infect cells, establishing the feasibility of this approach. However, efficiency of Ad trafficking via this pathway is poor, and current efforts are directed toward exploring other transcytosing pathways such as the melanotransferrin pathway [244], the poly immunoglobulin A receptor pathway [245], or caveolae-mediated transcytosis pathways [246]. One can envision the development of mosaic Ad vectors incorporating both targeting ligands directed to such transcytosis pathways as well as ligands mediating subsequent targeting and infection of target cells present beyond the vascular wall.

4.10 CONCLUSIONS

Ad-based vectors are the most widely used platform for gene delivery because of their efficacy in gene expression in dividing and nondividing cells. They are of particular utility for cancer gene therapy applications, where temporary gene expression is acceptable or even beneficial. The history of Ad-based gene therapy studies clearly illustrates and confirms the critical linkage between improved vector design and improvement in therapeutic potential. Indeed, clinical breakthroughs have been dependent on advances in vector development. With regard to Ad-mediated cancer treatment, high-level tumor transduction remains a key developmental hurdle. To this end, both Ad and CRAd vectors possessing infectivity enhancement and targeting capabilities should be evaluated in the most stringent model systems possible. Advanced Ad-based vectors with imaging, targeting, and therapeutic capabilities have yet to be fully employed; however, the feasibilities leading to this accomplishment are now being established.

5.1 INTRODUCTION

Gene therapy is the amelioration of disease through the use of nucleic acid. This broad definition reflects the large spectrum of diseases that can be potentially considered for treatment, as well as the many methods of introducing the nucleic acid into target cells, which may or may not be directly affected by the disease. This chapter focuses on one very specific area of gene therapy research: the development and application of helper-dependent adenoviral vectors (HDAds) (also referred to as gutless, gutted, mini, fully deleted, high-capacity, Δ , pseudo, encapsidated adenovirus [Ad] mini-chromosome) for gene therapy. Successful gene therapy requires a gene transfer vector that is able to efficiently transduce the target cells *in vivo* and provide high level and long-term transgene expression with minimal toxicity. How HDAds have measured up to these expectations are reviewed in this chapter.

5.2 ADENOVIRUS

The Ad has a non-enveloped icosahedral capsid containing a linear double-stranded DNA genome of ~30–40 kb. Of the ~50 serotypes of human Ad, the most extensively characterized are serotypes 2 (Ad2) and 5 (Ad5) of subgroup C (reviewed in [1]). The 36 kb genomes of Ad2 and Ad5 are flanked by inverted terminal repeats (ITRs) which are the only sequences required *in cis* for viral DNA replication. A *cis*-acting packaging signal, required for encapsidation of the genome, is located near the left ITR (relative to the conventional map of Ad). The Ad genome can be roughly divided into two sets of genes (Figure 5.1): the early region genes, E1A, E1B, E2, E3, and E4, are expressed before DNA replication and the late region genes, L1 to L5, are expressed to high levels after initiation of DNA replication. The E1A transcription unit is the first early region to be expressed during

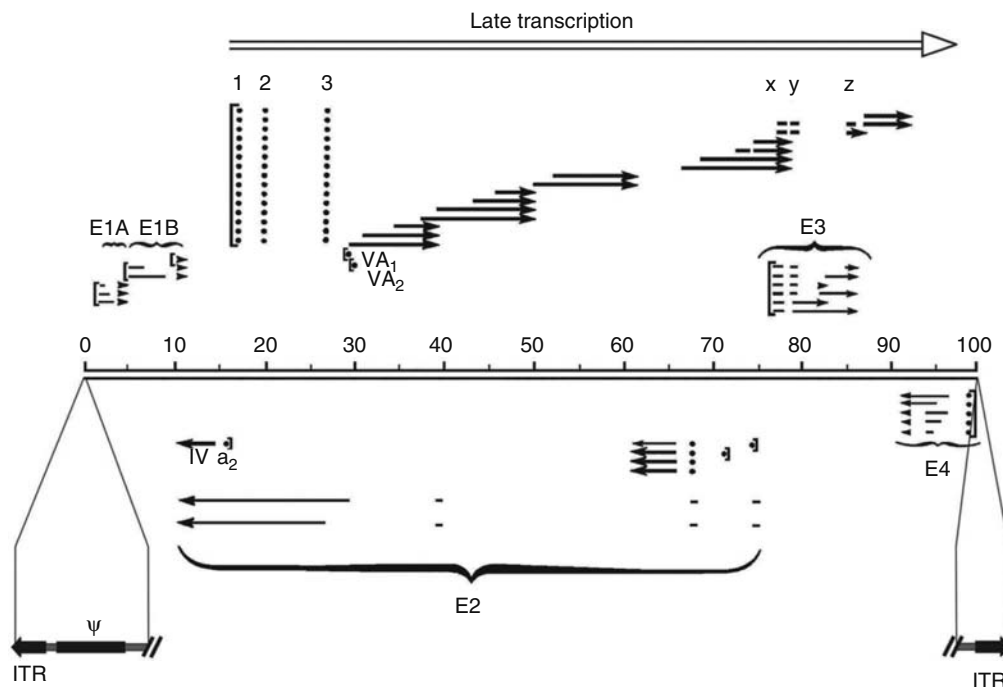

FIGURE 5.1 Transcription map of human Ad serotype 5. The 100 map unit (~36 kb) genome is divided into four early region transcription units, E1–E4, and five families of late mRNA, L1–L5, which are alternative splice products of a common late transcript expressed from the MLP located at 16 map units. Four smaller transcripts, pIX, IVa, and VA RNA's I and II, are also produced. The 103 bp ITRs are located at the termini of the genome and are involved in viral DNA replication, and the packaging signal (ψ) located from nucleotides 190 to 380 at the left end is involved in packaging of the genome into virion capsids.

viral infection and it encodes two major E1A proteins that are involved in transcriptional regulation of the virus and stimulation of the host cell to enter an S phase-like state. The two major E1B proteins are necessary for blocking host mRNA transport, stimulating viral mRNA transport, and blocking E1A-induced apoptosis. The E2 region encodes proteins required for viral DNA replication and can be divided into two subregions; E2a encodes the 72 kD DNA-binding protein and E2b encodes the viral DNA polymerase and terminal protein precursor. The E3 region, which is dispensable for virus growth in cell culture, encodes at least seven proteins most of which are involved in host immune evasion. The E4 region encodes at least six proteins, some functioning to facilitate DNA replication, enhance late gene expression, and decrease host protein synthesis. The late region genes are expressed from a common major late promoter (MLP) and are generated by alternative splicing of a single transcript. Most of the late mRNAs encode virion structural proteins. In addition to the early and late region genes, four other small transcripts are also produced. The gene encoding protein IX (pIX) is colinear with E1B but uses a different promoter and is expressed at an intermediate time, as is the pIVa2 gene. Other late transcripts include the RNA polymerase III transcribed VA RNA I and II.

Virus infection is initiated through the Ad fiber protein binding to the primary coxsackie-adenovirus receptors (CAR) on the cell surface [2–4] followed by a secondary interaction between the virion penton base and $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins

[5]. The efficiency with which Ad binds and enters the cell is directly related to the level of primary and secondary receptors present on the cell surface [6,7]. Penton–integrin interaction triggers Ad internalization by endocytosis following which the virion escapes from the early endosome into the cytosol prior to lysosome formation [8,9]. The virion is sequentially disassembled during translocation along the microtubule network towards the nucleus where the viral DNA is released into the nucleus [10]. Once in the nucleus, viral DNA replication, beginning 6–8 h postinfection, and assembly of progeny virions occur. The entire life cycle takes about 24–36 h, generating about 10^4 virions per infected cell. Ads have never been implicated as a cause of malignant disease in their natural host and in immunocompetent humans most infections caused by the most common serotypes are relatively mild and self-limiting. The reader is referred to the excellent review by Shenk [1] for a more comprehensive discussion of Ads.

5.3 FIRST-GENERATION ADENOVIRAL VECTORS

Ads are excellent mammalian gene transfer vectors due to their ability to efficiently infect a variety of quiescent and proliferating cell types from various species to direct high-level transgene expression. Consequently, Ad vectors are extensively used as potential recombinant viral vaccines, for high-level protein production in cultured cells, and for gene therapy (for

reviews see [11–15]). First-generation Ad vectors (FGAds) typically have foreign DNA inserted in place of early region 1 (E1). E1-deleted vectors are replication deficient and are propagated in E1 complementing cells such as 293 [16]. Typically, FGAds also have a deletion in the nonessential E3 region to maximize cloning capacity. The fundamental principle underlying all current methods of constructing FGAds is based on the discovery that up to 10% of Ad viral DNA molecules become circularized following infection of mammalian cells [17]. This permitted the cloning of the entire Ad genome as an infectious bacterial plasmid which could be manipulated with relative ease by standard molecular biology techniques. This Ad genomic plasmid could be stably propagated in *E. coli* and was capable of generating infectious virus following transfection into permissive mammalian cells at efficiencies comparable to purified virion DNA. An excellent review by Danthinne and Imperiale [18] covers the plethora of methods for constructing FGAd. While FGAds remain very useful for many applications, it has become clear that transgene expression *in vivo* is only transient. Several factors contribute to this, including strong innate and inflammatory responses to the vector [19,20], acute and chronic toxicity due to low level viral gene expression from the vector backbone [21], and generation of anti-Ad cytotoxic T-lymphocytes due to de novo viral gene expression [22–25] or processing of virion proteins [26]. While high-level transient transgene expression afforded by FGAd may be adequate, or even desirable, for many gene transfer and gene therapy applications, the toxicity and transient nature of expression kinetics renders these vectors unsuitable in cases where prolonged, stable expression is required.

5.4 MULTIPLY DELETED ADENOVIRAL VECTORS

While the deletion of E1 in FGAds theoretically results in a replication-defective vector following transduction of cells devoid of trans-complementing E1 functions, it has become clear that this is not the case and that the E2, E3, and E4 promoters are active resulting in viral DNA replication and expression of the late viral genes, especially following high multiplicities of infection [27–30]. Therefore, in an attempt to further attenuate Ad, additional deletions of essential viral genes have been pursued. Examples of these include deletion or mutation of the E2 or E4 regions in addition to E1. These multiply deleted Ad vectors (also referred to as second or third generation Ad vectors) are helper virus independent for propagation but require the generation of new producer cell lines that trans-complement the additional deletion [30]. Despite the potential offered by these multiply deleted Ad vectors, viral coding sequences still remain and therefore so does the potential for their expression. The advantages of multiply deleted Ad over FGAd remain controversial as some studies show them to be superior in terms of toxicity and longevity of transgene expression [31–37] while others do not [21,38–41]. Detailed discussion of multiply deleted Ad vectors is beyond the scope of this chapter and the reader is referred to an excellent and comprehensive review covering this subject by Parks and Amalfitano [42].

5.5 HELPER-DEPENDENT ADENOVIRAL VECTORS

5.5.1 HISTORICAL PERSPECTIVE

In theory, the easiest way to completely eliminate the toxicity associated with viral gene expression is to delete all of the viral coding sequences from the vector. Ads with large deletions of viral sequences were among the very first vectors reported. For example, in 1970, Lewis and Rowe [43] described a recombinant Ad in which essential viral genes were replaced with SV40 DNA. This replacement rendered the hybrids replication defective and they could only be propagated in the presence of a coinfecting wild-type helper Ad which provided trans-complementation. A recombinant Ad was also described in 1981 by Deuring et al. [44] following repeated high multiplicity of infection passage of wild-type Ad serotype 12 through human KB cells. These hybrids were found to contain symmetrically duplicated human chromosomal DNA flanked by approximately 1 kb of DNA from the left end of the Ad genome. As in the case of the Ad-SV40 hybrids, these symmetrical recombinants (SYRECs) were replication defective and could only be propagated in the presence of a coinfecting helper Ad12 by trans-complementation. The SYRECs were maintained for years in this manner and could be partially purified from the helper virus by CsCl density equilibrium centrifugation owing to differences in their genome sizes which bestowed different buoyant densities.

The defective helper virus-dependent Ad-SV40 and SYRECs hybrids demonstrated the possibility of generating vectors completely devoid of Ad coding sequences. In principle, only ~500bp of cis-acting Ad sequences necessary for DNA replication (ITR) and encapsidation (ψ) are required for propagation of these HDAds in the presence of a coinfecting helper virus. The advantages of HDAds are considerable: like FG and multiply deleted Ads, HDAds would retain the ability to very efficiently transduce a wide variety of cell types from numerous species in a cell cycle independent manner. However, unlike FGAd and multiply deleted Ads, deletion of all viral coding sequences would drastically reduce vector-mediated toxicity and significantly prolong the duration of transgene expression as described in detail below.

5.5.2 EARLY SYSTEMS FOR GENERATING HDADS

Although, as mentioned above, the very first Ad vectors were defective, helper-dependent viruses, with the development of E1 complementing 293 cells, vector systems focused on FGAd (E1-deleted) vectors because these were much easier to isolate and propagate than HDAds. The possibility of using HDAds for gene transfer was reexamined in studies reported by Mitani et al. [45]. These investigators used a β -galactosidase-neomycin fusion gene to replace 7.3 kb of essential Ad sequences in an Ad genomic plasmid. While this modification did not remove all of the viral coding sequences, it did render the recombinant defective and helper dependent. This vector was rescued by co-transfection of 293 cells with purified Ad2

DNA which provided helper functions. Following X-gal staining, 1%–5% of the resulting plaques turned blue indicating rescue of the recombinant virus. Blue plaque isolates were expanded by serial propagation on 293 cells and finally purified by CsCl ultracentrifugation. Fractionation through the gradient resulted in partial purification of the vector from the helper virus due to the difference in their buoyant densities. Significantly, the ability of the vector to transduce cells *in vitro* and express the reporter gene was demonstrated. However, the yield of vector was quite low. Furthermore, helper virus contamination remained rather high, at about 200- to 500-fold greater excess over the vector. In addition, the genome of the vector had undergone rearrangement.

Using a different strategy, Fisher et al. [46] constructed a plasmid bearing a 5.5 kb HDAd genome containing the Ad 5' ITR and packaging signal, LacZ reporter gene and 3' ITR. In this system, 293 cells were infected with an FGAD to serve as a helper virus and subsequently transfected with the HDAd plasmid DNA. The HDAd was amplified by serial coinfections and finally purified by CsCl ultracentrifugation. Using this method, partial purification of the vector could be achieved, but with the helper virus still 10- to 100-fold excess. Additionally, considerable genomic rearrangements, in the form of concatemerization of the vector, were observed, which were likely due to the small size of the vector genome [47]. Nevertheless, the vector was demonstrated to be capable of transducing cells *in vitro*. Using this strategy, a vector bearing CFTR [46] and dystrophin [48] expression cassettes was generated and shown to transduce cells *in vitro*.

Another strategy for generating HDAdS was reported by Kumar-Singh and Chamberlain [49]. In this system, 293 cells were co-transfected with a plasmid bearing the HDAd genome and purified Ad DNA to provide helper functions. The HDAd contained a LacZ reporter gene and dystrophin cDNA while the helper virus contained the alkaline phosphatase (AP) reporter gene. The vector was amplified by serial propagation and purified by CsCl ultracentrifugation. This resulted in a final vector preparation with 4% helper virus contamination as determined by AP:LacZ ratio. Importantly, this vector was capable of transducing myogenic cell cultures and expressing dystrophin in myotubes.

These early systems showed that HDAdS could indeed be generated and could transduce a variety of target cells *in vitro* to direct transgene expression. However, they also emphasized the need to further improve production strategies as the high levels of helper virus contamination, low vector yield and, in many cases, vector genome rearrangement were clearly obstacles, which needed to be addressed before the full potential of HDAd could be realized. In particular, relying solely on physical separation between the vector and the helper by CsCl ultracentrifugation was clearly inadequate to achieve the desired vector purities. Therefore, strategies to preferentially inhibit helper virus propagation while not affecting its ability to trans-complement the HDAd were required.

One system designed to specifically address preferential inhibition of helper virus propagation was reported in 1996 by Kochanek et al. [50]. This strategy was based on early studies

in Ad packaging by Gräble and Hearing [51], which showed that deletion of 91 bp from the packaging signal severely reduced, but did not abolish, encapsidation of the Ad genome into virions while not affecting viral DNA replication. More importantly, Gräble and Hearing observed a competition for packaging in cells co-infected with two Ads, one containing a wild-type packaging signal and the other having a mutant packaging signal: the former was packaged preferentially, over the latter. Taking advantage of these observations, Kochanek et al. deleted this 91 bp deletion from the Ad packaging signal of the helper viral genome thus impairing its ability to be packaged but not affecting its ability to replicate and thus trans-complement the HDAd genome [50]. In addition, because the HDAd genome contained the wild-type Ad packaging signal, it would be preferentially packaged over the helper viral genome. The combination of this strategy in conjunction with CsCl ultracentrifugation resulted in a final vector preparation with ~1% helper virus contamination. A similar strategy, but using a different packaging signal mutation, was employed by Alemany et al. [52] to generate HDAdS that were used in the only human trial to date (see Section 5.6.1.1). These strategies represented a significant improvement over the previous methods in terms of lower levels of helper virus contamination. However, helper virus contamination remained relatively high. Furthermore, the 91 bp packaging signal deletion resulted in 90-fold reduction in yield of helper virus. From a practical standpoint, this would render production of helper virus stocks problematic since large amounts would be needed to produce the considerable quantities of HDAd needed for clinical applications.

5.5.3 CRE/LOXP SYSTEM FOR GENERATING HDAdS

The first efficient method for generating HDAd was the Cre/loxP system developed by Graham and coworkers in 1996 [53] (Figure 5.2). In this system the HDAd genome is first constructed in a bacterial plasmid. Minimally, the HDAd genome contains the expression cassette of interest and ~500 bp of cis-acting Ad sequences necessary for vector DNA replication (ITRs) and packaging (ψ). As described in detail in Section 5.5.4, inclusion of stuffer DNA in the HDAd genome is often required for efficient packaging. To rescue the HDAd (that is, to convert the “plasmid form” of the HDAd genome into the “viral form”), the plasmid is first digested with the appropriate restriction enzyme to liberate the HDAd genome from the bacterial plasmid sequences. In this method, 293 cells expressing Cre are then transfected with the linearized HDAd genome and subsequently infected with the helper virus. The helper virus bears a packaging signal flanked by loxP sites and thus following infection of 293 Cre cells, the packaging signal is excised from the helper viral genome by Cre-mediated site-specific recombination between the loxP sites. This renders the helper viral genome un-packagable but still able to undergo DNA replication and thus trans-complement the replication and encapsidation of the HDAd genome. The titer of the HDAd is increased by serial coinfection of 293 Cre cells with the HDAd and the helper virus. Similar systems based on

FIGURE 5.2 (See color insert following blank page 206.) Cre/loxP system for generating HD vectors. The HDAd contains only ~500bp of cis-acting Ad sequences required for DNA replication (ITRs) and packaging (ψ), the remainder of the genome consists of the desired transgene (yellow) and non-Ad “stuffer” sequences (green). The HDAd genome is constructed as a bacterial plasmid (pHDAd) and is liberated by restriction enzyme digestion (e.g., *PmeI*). To rescue the HDAd, the liberated genome is transfected into 293 cells expressing Cre and infected with a helper virus bearing a packaging signal (ψ) flanked by loxP sites. The helper viral genome also contains a stuffer sequence in E3 to prevent the formation of RCA in 293-derived cells. Cre-mediated excision of ψ renders the helper virus genome unpackageable, but still able to replicate and provide all of the necessary *trans*-acting factors for propagation of the HDAd. The titer of the HD vector is increased by serial coinfections of 293 Cre cells with the HDAd and the helper virus.

using the yeast site specific recombinase FLP to catalyze recombination between 34bp *frt* sites were subsequently developed [54,55].

The Cre/loxP method of producing HDAd described above is a complex three-component system. Consequently efficient production of large quantities of high quality vector has been difficult, permitting production of only modest amounts of HDAd only suitable for small animal experiments or low-dose large animal studies. While results from these studies have been encouraging, improved methods to permit efficient and reliable production of large quantities of HDAd were needed to fully evaluate the safety and efficacy of these vectors in preclinical studies with larger animal models and ultimately for clinical applications. The production problem was addressed by the development of an improved system comprised of a suspension adapted producer cell line that expresses very high levels of Cre, a helper virus resistant to mutation and refined protocols [56]. With these improvements, $>1 \times 10^{13}$ viral particles (vp) can be easily produced from 3L of cells within 2 weeks of initial vector rescue, with

specific yields of $>10,000$ vp/cell and with exceedingly low helper virus contamination of 0.4%–0.1% without relying on CsCl purification and 0.02%–0.01% following CsCl purification as determined by DNA-based assays. This technological advancement has significantly improved our ability to assess this promising gene therapy technology, especially in large animal models and, perhaps ultimately, for clinical applications. Detailed methodologies for producing HDAd are described elsewhere [57].

5.5.4 CHARACTERISTICS OF THE HELPER-DEPENDENT VECTOR

In addition to the minimal cis-acting Ad sequences required for DNA replication and encapsidation, Sandig et al. [58] showed that inclusion of a small segment of noncoding Ad sequence from the E4 region adjacent to the right ITR increases vector yields, possibly by enhancing packaging of the HDAd DNA. Early studies of Ad have established a maximum packaging capacity of 105% of the wild-type genome

(~37.8 kb) [59]. Subsequently, using the Cre/loxP system for generating HDAd, Parks and Graham [47] established that the minimum genome size for efficient packaging into Ad virions was 27 kb. Vector genome sizes above the maximum packaging capacity were not efficiently packaged, if at all. Vector genome sizes below 27 kb were inefficiently packaged and frequently underwent DNA rearrangements to produce genomes closer to that of wild-type viruses (approximately 36 kb) [46,47,60]. Therefore, the size of the vector is an important consideration: for efficient packaging and stability, the vector genome should be between ~75% (>27 kb) [47] and 105% (<37.8 kb) [59] of wild-type. Since the minimal Ad cis-acting sequences and the transgene of interest are usually well below the minimal size required for efficient packaging the vector must often include stuffer DNA. The choice of stuffer DNA is important with regard to vector stability, replication efficiency, and *in vivo* performance [58,61,62]. While it remains unclear what constitutes a good stuffer, in general, noncoding eukaryotic DNA has been preferred while repetitive elements and unnecessary homology with the helper virus should be avoided to ensure vector stability and prolonged transgene expression.

In addition to the absolute size of the HDAd, its relative size compared to the helper virus has an impact on the level of helper virus contamination. This is because Cre-mediated selection against the helper virus, while efficient, is not absolute [56,63]; (see Section 5.5.6). If the genome size of the HDAd is sufficiently different from that of the helper virus then the two species can be physically separated by CsCl ultracentrifugation due to their different buoyant densities. HDAds with genome size between 28 and 31 kb are ideal because they are efficiently packaged, replicated, and easily separated from residual helper viruses (35 to 37 kb) following CsCl ultracentrifugation.

It is also becoming clear that the nature of the transgene has a significant influence on the degree and duration of transgene expression. Specifically, transgenes in their native genomic context have been demonstrated to be superior to their cDNA counterparts with respect to level and duration of expression [62,64,65]. This is likely due to a more physiological regulation of gene expression. In this regard, HDAds, because of the large cloning capacity of 37 kb, offer the advantage of potentially transferring many genes in their genomic context whereas other vectors (e.g., FGAd and multiply deleted Ads, retroviral, lentiviral, or adeno-associated viral vectors) cannot, due to their limited cloning capacity. In the case of cDNA, expression from a tissue-specific promoter was found to be superior to ubiquitous promoters in terms of toxicity and duration of expression [62,66]. This has been attributed to a reduction of transgene expression in transduced antigen presenting cells (APCs) following systemic delivery of vectors that carry expression cassettes under the control of tissue-specific promoters [66]. Expression from tissue-specific promoters has been demonstrated to be more "tissue-specific" within the context of a HDAd than an FGAd [67]. This may be due to the influence of Ad sequences from the FGAd backbone on transgene expression specificity which does not occur

with HDAds [67]. In addition, use of tissue-specific promoters may result in more robust amplification of the HDAd since high-level transgene expression in the producer cells may negatively impact viral replication during serial coinfections, especially if the transgene product is toxic to the producer cells.

Accurate and reliable methods for measuring the vector dose are crucial for preclinical and clinical investigation. There are two methods of expressing the concentration of Ad-based vectors: (1) Physical titer is the total concentration of vp obtained by measuring the amount of DNA in a vector preparation and is expressed as vp per milliliter. (2) Infectious titer is the concentration of vector particles capable of infecting permissive cells to cause cytopathic effect following an *in vitro* infection assay and is expressed as infectious units (IU) per milliliter. It should be noted that not all vp in a preparation are infectious. Therefore, a comparison of the vp:IU ratio provides a measure of the infectivity of the vector preparation. Determining the infectious titer of FGAd and multiply deleted Ads is straightforward because they cause cytopathic effect following infection of permissive cells. However, determining the infectious titer of HDAd is not straightforward because they do not cause cytopathic effect in transduced cells due to the absence of viral genes. If the HDAd contains a reporter transgene then the infectious titer can be determined. However, this is not the case with the majority of therapeutic HDAds thus rendering the infectivity of HDAd preparations difficult to ascertain and, as described below, accurate determination of vector infectivity is critical.

Following the tragic death of a partial OTC-deficient patient given systemic E1,E4-deleted Ad [68], the National Institutes of Health (NIH) Office of Biotechnology Activities established a Recombinant DNA Advisory Committee (RAC) working group on Ad safety and toxicity (AdSAT) to conduct a comprehensive review and analysis of the scientific, safety, and ethical issues associated with Ad-based human gene transfer [69]. One important deficiency cited by the AdSAT was a lack of standardization in determining the physical and infectious vector titers and they recommended the development of a fully characterized Ad reference standard (ARM) to address this problem [69,70]. The ARM is intended to be used as a reference standard in determining the physical and infectious titers of clinical grade Ad vectors. Furthermore, the FDA has recently recommended that clinical grade Ad vectors should have a vp:IU ratio of no more than 30:1 [69]. Demonstrating this requirement for HDAd has been problematic because traditional infectious titer assays are not possible as described above. Although a number of methods have been described to determine the infectious titer of HDAd [71–73], one study is particularly relevant as it is the only one to directly compare the infectivity of the HDAd to the ARM [74]. This assay is based on coinfection of 293 cells with the ARM and the HDAd which permits direct comparison of the amounts of ARM and HDAd virions that gain cellular entry. Because the assay relies on coinfection rather than comparisons between two or more independent single-infections (as is the case with all other methods described to date), the test article (the vector) and the reference standard (the ARM) experience identical

conditions thereby eliminating the numerous variables associated with time-to-time, person-to-person, laboratory-to-laboratory, and protocol-to-protocol variations. Moreover, it eliminates the inherent variability of biological assays that are significant hurdles in the accurate determination of physical and infectious Ad titers. This universal coinfection assay permits reliable comparisons within and between studies thus satisfying important criteria for clinical studies.

5.5.5 CHARACTERISTICS OF THE HELPER VIRUS

The most commonly used helper virus used for HDAd production is a serotype 5, FGAd (E1-deleted) with its packaging signal flanked by loxP sites (Figure 5.2). As with all FGAds propagated in 293 or 293-derived cells, the potential exists for the generation of replication-competent Ad (RCA; E1⁺) as a consequence of homologous recombination between the helper virus and the Ad sequences present in 293 cells. To prevent the formation of RCA, a stuffer sequence was inserted into the E3 region to render any E1⁺ recombinants too large to be packaged [53]. The length of the E3 stuffer is such that the total size of the helper virus genome is <105% of wild-type but >105% following homologous recombination with Ad sequences in the 293 cells. As of this writing, the emergence of RCA has yet to be reported using helper viruses with an E3 stuffer. In contrast, RCA is readily detected using helper viruses without an E3 stuffer when propagated in 293 and 293-derived cells [41,53]. The choice of sequence used as stuffer in the E3 region may be important as it has been observed that some E3 inserts result in poor virus propagation, perhaps due to interference with fiber expression (F. L. Graham, unpublished data). While it remains unclear what sequences constitute a good E3 stuffer, in general, noncoding sequences with no homology to the HDAd would be preferred. A number of sequences have been found to be stable and not to adversely affect virus propagation, including bacterial plasmid sequences, bacteriophage λ sequences, and human DNA [53–55,58,75]. The use of other E1-complementing cell lines engineered to preclude the formation of RCA is another option [76,77].

Since the HDAd genome does not integrate into the host chromosomes, but rather presumably remains episomal, it is likely that transgene expression will not be permanent. Should transgene expression fade over time, it would be desirable to simply readminister the vector. Unfortunately, this simplistic approach is not possible because the initial administration elicits immunity in the form of neutralizing anti-Ad antibody that renders subsequent readministrations ineffective. One strategy, known as “serotype switching,” may help to overcome this problem. In addition to the Ad serotype 5-based helper virus, Parks et al. have generated a serotype 2 helper virus [75]. Helper viruses based on serotypes 1 and 6 have also been generated (F. L. Graham, unpublished results). Therefore, genetically identical HDAds of different serotypes can be generated simply by changing the serotype of the helper virus used for vector amplification. Parks et al. demonstrated that mice injected with a serotype

2 HDAd produced serotype 2 neutralizing antibodies which prevented successful transduction with the same serotype HDAd [75] but did not prevent successful transduction following administration of a serotype 5 HDAd. Successful readministration of HDAd of alternative serotypes has also been demonstrated by Kim et al. [64] (see Section 5.6.1). As discussed in Section 5.2, there are ~50 human serotypes of Ad. Therefore, it may be possible to create a panel of different serotype helper viruses and use these to generate different serotype but genetically identical HDAds. These HDAds could then be given sequentially when transgene expression wanes from the previous vector administration. Because of the large number of Ad serotypes, this could theoretically continue for the lifetime of the patient, although development of the many helper viruses needed for this approach might prove challenging.

5.5.6 HELPER VIRUS CONTAMINATION

HDAd produced using the Cre/loxP systems is invariably contaminated with helper virus. Currently, the final purity of HDAd preparations is dependent on two enrichment steps. The first is Cre-mediated packaging signal excision during vector amplification. It has been shown that the level of helper virus contamination is related to the amount of Cre expressed by the producer cells; higher amounts of intracellular Cre result in lower levels of helper virus contamination as a result of higher efficiency packaging signal excision [56,78]. Using producer cells with very high levels of Cre expression, this enrichment step alone results in about 0.4%–0.1% helper virus contamination as determined by DNA-based methods of quantification (Southern blot hybridization and real-time PCR) [56]. Provided that the genome sizes of the HDAd and the helper virus are sufficiently different, further enrichment can be obtained by CsCl ultracentrifugation which can further reduce contamination levels to 0.02%–0.01% [56]. Although current systems cannot produce HDAd free of helper virus, it should be noted that the helper virus is essentially an E1-deleted FGAd at low contaminating amounts which are far below the much higher quantities of FGAd that have been given to numerous patients in clinical trials without adverse affect. It should also be noted that in mouse models, intravenous [41] or intramuscular [79] injection of HDAd with up to 10% helper virus contamination did not reduce the duration of transgene expression or result in significantly higher toxicity compared to preparations with only 0.1%–0.5% contamination. In summary, the low helper virus contamination levels achievable with optimal systems should not compromise safety and efficacy. Nevertheless, an accurate determination of helper virus contamination levels is important since high levels of helper virus contamination may affect experimental results and compromise safety. Knowing the level of helper virus contamination also allows for meaningful comparisons between different studies. A variety of methods for determining helper virus contamination have been reported, all of which can be divided into two basic categories. The first is based on determining the infectious titer of the contaminating helper virus in a HDAd preparation. These

methods included plaque assay on 293 cells (or 293-derived cells) or infectious unit assay based on the presence of a reporter transgene in the helper virus. Using these infectious titer assays, the level of helper virus contamination is often reported as a percent or a ratio of infectious helper virus in the vector preparation. However, these methods suffer from a number of shortcomings. First the units of measurement for the HDAd and helper virus are not the same and thus not directly comparable making it difficult to accurately determine the level of helper virus contamination. Second, it has been shown that infectious assays are 10- to 50-fold less sensitive than DNA-based assays described below, thus grossly underestimating the true level of contamination and may not be capable of detecting very low levels of helper virus contamination [41,72]. Alternative methods of determining helper virus contamination use direct measurement of the amount of HDAd and helper viral DNA in a vector preparation. This has been accomplished by standard Southern blot hybridization analysis [54,56,72] or quantitative real-time PCR assays [41,55,56,58]. Not only are these methods more sensitive and reliable, but also the unit of measurement is the same for both the HDAd and the helper virus therefore allowing the level of helper virus contamination to be expressed simply as a percentage of the total DNA.

5.6 IN VIVO STUDIES

As of this writing, numerous examples of *in vivo* HDAd-mediated gene transfer through different route of administration (intravenous, intramuscular, brain, subretinal, and intratumoral injection, airway administration) in various small and large animal disease models have been reported

(Table 5.1). The purpose of this chapter is not to provide a comprehensive review of all of these studies. Instead, examples of particular significance or interest are described.

5.6.1 LIVER-DIRECTED GENE THERAPY

The liver is very attractive target for gene therapy because it is the affected organ in many genetic diseases, the fenestrated structure of its endothelium permits exposure of the parenchymal cells to intravenously delivered vector, and permits secretion of vector encoded therapeutic proteins into the circulation for systemic delivery. To date numerous examples of *in vivo* liver-directed gene therapy for disease models using HDAd have been reported (summarized in Table 5.1). In general, all these studies have demonstrated that HDAd can lead to long-term phenotypic correction in the absence of chronic toxicity supporting the potential of HDAd for clinical applications. The correction of hypercholesterolemia in apolipoprotein E (apoE)-deficient mice is a paradigmatic example of this great potential [64]. In this study the efficacy of FGAd encoding mouse apoE cDNA (FG-Ad5-cE) was compared to a HDAd encoding the mouse apoE cDNA (HD-Ad5-cE), or a HDAd bearing the mouse genomic apoE locus (HD-Ad5-gE). Intravenous injection of ApoE deficient mice with 5×10^{12} vp/kg of FG-Ad5-cE resulted in an immediate fall in plasma cholesterol levels to within normal range (Figure 5.3A). However, this effect was transient and plasma cholesterol levels increased after 28 days, returning to pretreatment levels by 112 days. Correlative with the plasma cholesterol levels, the levels of plasma apoE immediately increased shortly after injection but rapidly declined to pretreatment levels by day 28 (Figure 5.3B). Similarly, intravenous injection of 7.5×10^{12}

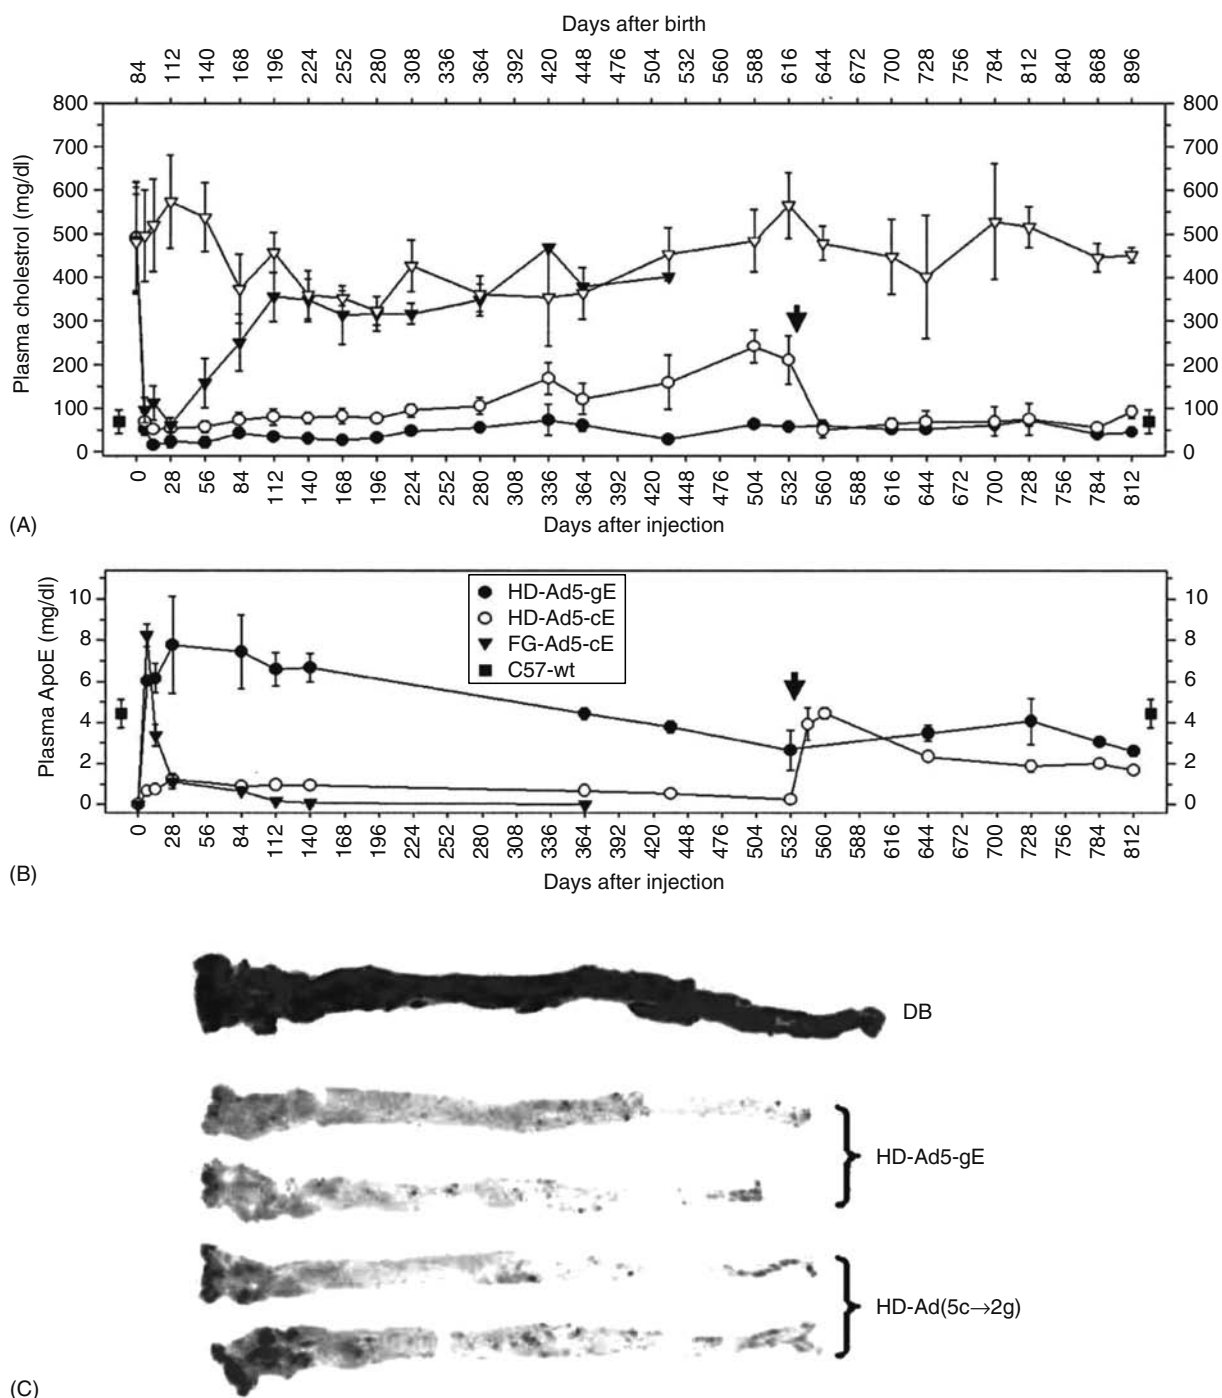

FIGURE 5.3 HDAd-mediated phenotypic correction of atherosclerosis in ApoE-deficient mice. (A) Plasma cholesterol and (B) plasma ApoE levels in ApoE-deficient mice injected with dialysis buffer (white triangle), FG-Ad5-cE (black triangle), HD-Ad5-gE (black circle) or HD-Ad5-cE followed (indicated by the bold arrow) by HD-Ad2-gE (white circle). (C) Aortas from HDAd-treated and control dialysis buffer (DB) treated mice stained with Oil Red at 2.3 years postinjection. Atherosclerotic lesion areas, stained red, determined by quantitative morphometry were 91.45 mm² for DB-treated animals; 0.81 and 0.31 mm² for HD-Ad5-gE-treated animals; and 5.89 and 1.74 mm² for HD-Ad5-cE followed by HD-Ad2-gE-treated animals. (Modified from Kim, I.H., Jozkowicz, A., Piedra, P.A., Oka, K., and Chan, L., *Proc. Natl. Acad. Sci. U S A*, 98, 13282, 2001. With permission.)

particles/kg of HD-Ad5-cE produced a complete and immediate lowering of plasma cholesterol to normal levels, but in contrast to FG-Ad5-cE, the reduced levels lasted about a year before gradually increasing (Figure 5.3A). ApoE appeared in plasma within a week and remained at a level ~25% of wild-

type (<10% of normal plasma levels of apoE is sufficient to maintain normal plasma cholesterol) but slowly declined to <10% of wild-type after about 1.5 years (Figure 5.3B), at which time plasma cholesterol levels rose to ~50% of untreated mice (Figure 5.3A). Intravenous injection of 7.5×10^{12}

particles/kg of HD-Ad5-gE also resulted in a complete and immediate lowering of plasma cholesterol to subnormal levels for about 9 months, with levels subsequently staying within the normal range for the rest of the natural lifespan of the animal (2.5 years) (Figure 5.3A). In this case, plasma apoE reached ~200% wild-type levels within 4 weeks and remained at supraphysiological levels for >4 months at which time it slowly declined to about wild-type levels at 1 year and remained at 60%–90% physiological concentrations for the lifetime of the animals (2.5 years) (Figure 5.3B). As the duration of ApoE expression from HD-Ad5-gE was superior to HD-Ad5-cE it would appear that genomic based transgenes may be more effective than cDNA based transgenes. Simple re-administration of the vector when transgene expression wanes is not possible due to the potent neutralizing anti-Ad antibody response that is elicited by the first administration. Indeed, mice previously treated with HD-Ad5-cE could not be successfully retreated again with the same vector. One solution to overcome this problem is to administer a vector of a different serotype. To evaluate this strategy, Kim et al. generated a serotype 2 version of the genomic ApoE vector (HD-Ad2-gE) [64] and showed that it could be successfully administered to mice previously treated with the serotype 5 HD-Ad5-cE to lower plasma cholesterol levels and raise plasma ApoE levels for the remainder of the animal lives (Figure 5.3A and B). Aortas in all mice, examined at 2.3 years after treatment with HDAds, were essentially free of atherosclerotic lesions as determined by quantitative morphometry (Figure 5.3C) demonstrating that a single injection of HDAd encoding ApoE could confer lifetime protection against aortic atherosclerosis. Kim et al. also investigated the associated toxicities and found that whereas injection of FG-Ad5-cE resulted in significant hepatotoxicity as indicated by significant elevation of AST and ALT (>10- to 20-fold), no such evidence of damage was observed following injection of any of the various HDAd constructs, even after a second administration with the serotype 2 HDAd [64].

In summary, this study demonstrated that a single intravenous injection of HDAd resulted in life-long expression of the therapeutic transgene and permanent phenotypic correction of a genetic disease. Second, negligible hepatotoxicity was associated with HDAd administrations. Third, this study showed the large cloning capacity of the vector which permits delivery of transgenes in their native chromosomal context results in superior kinetics and duration of expression. Indeed, should transgene expression diminish over time, administration of an alternative serotype HDAd is effective at circumventing the humoral immune response generated by the initial treatment.

Encouraging results have also been reported in the Crigler-Najjar syndrome animal model. Crigler-Najjar syndrome type I is a recessively inherited disorder caused by a deficiency of uridine diphospho-glucuronosyl transferase 1 A1 (UTG1A1) and characterized by severe unconjugated hyperbilirubinemia resulting in jaundice and increased risk of kernicterus. Current therapy consists of cumbersome and inconvenient life-long phototherapy to prevent kernicterus or liver transplantation

[80]. Toietta et al. [81] showed that a single systemic injection of a HDAd expressing UTG1A1 at doses of 1×10^{13} vp/kg or 3×10^{12} vp/kg resulted in life-long expression of UTG1A1 and permanent phenotypic correction of hyperbilirubinemia in the Gunn rats, the Crigler-Najjar syndrome animal model. However, at a lower dose of 6×10^{11} vp/kg, only partial, life-long correction was observed.

An interesting application of HDAd for the treatment of diabetes mellitus has also been reported. In this study, two HDAds, one expressing *Neurod1* (a transcription factor expressed in developing and adult β -cells of the pancreas), and the other expressing *betacellulin* (a β -cell growth factor), were co-injected into diabetic mice at the dose of 3×10^{11} vp and 1×10^{11} vp, respectively [82]. Following systemic vector administration clusters of cells with immunohistochemical and ultrastructural properties similar to pancreatic islet were surprisingly noted in the liver of the treated mice. Remarkably, the diabetic mice also showed a normalization of glucose levels for the duration of the experiment of at least 120 days. These results showed the presence of endocrine pancreatic precursors in the liver and the possibility to manipulate their development to induce pancreatic islet formation by HDAd-mediated gene transfer.

Importantly, long-term expression by HDAd has also recapitulated in a clinically relevant large animal model [83–85]. In the first study addressing the utility of HDAds in a large animal model, three baboons were intravenously injected with 3.3 – 3.9×10^{11} vp/kg of HDAd expressing hAAT [85]. The hAAT expression persisted for more than 1 year in two of the three animals (Figure 5.4). Maximum levels of serum hAAT of 3–4 mg/mL were reached 3–4 weeks postinjection in these two baboons and slowly declined to 8% and 19% of the highest levels after 24 and 16 months, respectively. The slow decline in hAAT expression was attributed to the fact that the baboons were young (7.5 and 9 months old) when injected, and that the decrease in hAAT concentrations was correlative to the growth of the animals. The third baboon injected with vector had significantly lower levels of serum hAAT which rapidly declined to undetectable levels after 2 months due to antibodies formation against the human AAT protein (Figure 5.4). It was significant that no abnormalities in blood cell counts and liver enzymes were observed in these three baboons at any time, starting 3 days postinjection. These results were in sharp contrast with the findings observed in the baboons injected with the FGAd expressing hAAT, in which the transgene levels were measurable for only 3–5 months after the injection (Figure 5.4). In the case of FGAd, this was shown not to be due to the generation of anti-hAAT antibodies but was attributed to the generation of a cellular immune response against viral proteins expressed from the vector backbone resulting in the elimination of vector transduced hepatocytes. These early experiments convincingly demonstrated that HDAd was superior to FGAd with respect to duration of transgene expression and hepatotoxicity in mice and, significantly, in a nonhuman primate. In another large animal study, the intravenous injection of 3×10^{12} vp/kg of a

FIGURE 5.4 Serum levels of hAAT in baboons following intravenous administration of the HDAd AdSTK109 or the FGAd AdhAATΔE1. Baboons 12402 and 12486 were injected with 6.2×10^{11} particles/kg of AdhAATΔE1. Baboons 12490 and 12497 were injected with 1.4×10^{12} particles/kg of AdhAATΔE1. Baboons 13250, 13250, and 13277 were injected with 3.3×10^{11} particles/kg, 3.9×10^{11} particles/kg, and 3.6×10^{11} particles/kg, respectively, of AdSTK109. Natl. Acad. Sci. U S A*, 96, 12816, 1999. With permission.)

HDAd expressing the canine coagulation factor IX in two hemophilia B dogs resulted in sustained phenotypic improvement of the bleeding diathesis for the duration of the experiment of at least 604 and 446 days [86].

5.6.1.1 Human Clinical Trial

To date, a single human clinical trial has been conducted using HDAd for liver-directed gene therapy. GenStar Therapeutics Corporation sponsored a hemophilia A gene therapy trial in 2001 using HDAd at a dose of 4.3×10^{11} vp/kg delivered by peripheral intravenous injection into one FVIII-deficient patient. That study was never published and little information is known about the outcomes of the trial. For example, the level of helper virus contamination was never disclosed, but the early system of relying on preferential packaging of the HDAd over a helper virus bearing a mutant packaging signal was notorious for high helper virus contamination levels [52,87]. According to the RAC [88]:

Approximately 5 hours after intravenous infusion of investigational agent (Mini-AdFVIII) the subject developed fever, chills, achiness, back pain, and headache. The fever peaked at 102.6°F, approximately 8 hours after investigational agent infusion, and resolved by about 12 hours. The subject, who has a history of multiple spontaneous bleeds, experienced a spontaneous hemarthrosis of the knee on Day 1 post investigational agent infusion, treated in the usual manner with recombinant factor VIII (r-AHF) with resolution of the bleeding event. The subject also experienced elevations in liver enzyme values with ALT peaking on post-infusion Day 7 and AST values peaking on post-infusion Day 7 and transient declines in factor VII levels and platelet counts. All laboratory values returned to baseline by Day 19 and were not considered clinically serious. Event attributions were not addressed in this submission.

In addition, no measurable increase in FVIII was detected in this single patient, and because the FDA required a log lower dose for the next patient, the trial was subsequently closed by the sponsor [87]. However, because the data was never formally published many important questions regarding this trial remain unanswered and it is impossible to critically interpret what little information is available. This, however, has not prevented unsubstantiated opinions and speculations regarding this failed trial. Although the outcome of this trial was disappointing, the knowledge and technological advancements acquired since 2001 along with the recent improvements in vector production, purity, and characterizations outlined in this chapter may yet resurrect HDAd as an important vector for liver-directed gene therapy, especially considering the plethora of encouraging and compelling preclinical studies obtained since this trial.

5.6.1.2 Threshold Effect to Hepatocytes Transduction

Several preclinical studies in small and large animal models clearly have demonstrated the tremendous potential of HDAd for liver-directed gene therapy (see Section 5.6.1). However, relatively high vector doses were required to achieve the results presented in those studies because such high doses are required to achieve efficient hepatic transduction following systemic intravascular delivery. It is now clear that there is a nonlinear dose response to hepatic transduction, with low doses yielding very low to undetectable levels of transgene expression, but with higher doses resulting in disproportionately high levels of transgene expression. Kupffer cells of the liver appear to play a significant role in the nonlinear dose response by sequestering intravenous Ad [89,90]. Antibodies, both specific and nonspecific for Ad, may also play a significant role in the nonlinear dose response. Studies have shown that the threshold effect to hepatic transduction by Ad is less

in antibody-deficient *Rag-1* and μ MT mice [89,90]. Perhaps opsonization of the virion by antibodies may enhance the efficiency of Fc-receptor mediated vector uptake by macrophages such as Kupffer cells. Furthermore, systemic administration of Ad vectors likely results in widespread transduction of a large number of various extrahepatic cell types (e.g., blood cells, endothelium, spleen, lung, etc.) which may also be important components of the barrier to efficient hepatocyte transduction. For example, although the liver takes up more vector than any other individual organ following systemic injection, the total amount of vector that is distributed throughout the body in mice [91], nonhuman primates [92,93], and a human patient [68] is significant on a vector genome copy number per microgram DNA basis.

It has also become clear that the liver microarchitecture plays a critical role in the efficiency of hepatocyte transduction by Ad vectors. The liver fenestrations normally form a structural barrier preventing large circulating macromolecules in the hepatic blood from accessing the hepatocytes. Several studies suggest that the size of the endothelial fenestrations of the liver (≤ 100 nm) plays a key role in the efficiency of Ad-mediated hepatocyte transduction (Ad virion ≥ 100 nm) (see Section 5.6.1.4) [94–96]. Specifically, it was demonstrated that there is a positive correlation between the size of the fenestrations and the efficiency of hepatic transduction following systemic administration of Ad [94,95].

5.6.1.3 Acute Toxicity

FGAd and multiply deleted Ad-mediated toxicity appear biphasic; not only does transduction by these early generation Ads, but not HDAd, cause chronic toxicity as described above due to viral gene expression from the vector backbone (late phase), but also results in acute toxicity (early phase). The acute response occurs immediately following vector administration, its severity is dose-dependent and is characterized by elevations in serum pro-inflammatory cytokines consistent with activation of the innate inflammatory immune response [91,92,97,98]. Indeed, the death of a partial OTC-deficient patient, whose clinical course was marked by systemic inflammatory response syndrome (SIRS), disseminated intravascular coagulation and multi-organ failure, was attributed to the acute toxicity from the administration of a second generation (E1 and E4-deleted) Ad vector [68]. Unlike FGAd-mediated chronic toxicity, several lines of evidence suggest that this acute toxicity is not dependent on viral gene expression from the vector backbone. First, this response is observed very shortly after vector injection, likely prior to viral gene expression [91,92,97]. Second, the response is observed following injection of vector rendered transcriptionally inactive by exposure to psoralen and UV in both mice [91,97] and nonhuman primates [92]. These observations have led to the hypothesis that the viral capsid is responsible for triggering the acute inflammatory response and therefore HDAd would also provoke an identical response since the viral capsid is presumably identical for both classes of vectors. Indeed, this was confirmed in nonhuman primates in which dose-dependent

acute toxicity, consistent with activation of the innate inflammatory immune response, was observed following systemic administration of HDAd [99]. In this study, two baboons were systemically injected, via peripheral vein, with 5.6×10^{12} vp/kg or 1.1×10^{13} vp/kg. Approximately 50% hepatocyte transduction was achieved at a dose of 5.6×10^{12} vp/kg (Figure 5.5A). This animal suffered mild and transient acute toxicity consistent with activation of the innate inflammatory response as evident by elevations of serum cytokine IL-6 (Figure 5.5E) but completely recovered by 24 h postinjection. Hepatocyte transduction of 100% was achieved in the animal injected with 1.1×10^{13} vp/kg (Figure 5.5B). However, this animal suffered severe acute toxicity with a stronger inflammatory response as evident by the dramatic increase in serum IL-6 (Figure 5.5F). This animal became moribund and was euthanized 8.5 h postinjection due to poor condition. Transduction of other organs and tissues was also observed in these animals and was significantly more extensive in the high dose animal. For example, substantial transduction of the spleen was noted at 5.6×10^{12} vp/kg (Figure 5.5C) but was even more extensive at 1.1×10^{13} vp/kg (Figure 5.5D). This suggested that a large proportion of the vector dose was not taken up by the liver but that widespread vector dissemination occurred following systemic injection which, as discussed below, may play a role in contributing to the severity of the inflammatory response.

The role of the viral capsid in causing the acute toxicity was further confirmed by Muruve et al. [100] showing that intravenous injection of either FGAd or HDAd into mice induced an acute expression of inflammatory cytokine and chemokine genes in the liver, including interferon-inducible protein 10, macrophage inflammatory protein 2, and TNF- α . Furthermore, like FGAd, HDAd induced the recruitment of CD11b-positive leukocytes to the transduced liver within hours of administration. However, FGAd, but not HDAd, also induced a second phase of liver inflammation, consisting of inflammatory gene expression and CD3-positive lymphocytic infiltrates 7 days postinjection. In contrast, beyond 24 h no infiltrates or expression of inflammatory genes was detected in the livers of mice injected with HDAd. These results demonstrate that HDAd induced intact innate but attenuated adaptive immune responses *in vivo*.

The mechanism(s) responsible for Ad-mediated activation of the acute inflammatory response is not known, although several have been postulated. Vector uptake and activation to secrete proinflammatory cytokines by macrophages and dendritic cells in the spleen have been implicated [91,92]. Indeed, the spleen appears to be a major contributor to IL-12 elevation following systemic Ad in mice [91]. Vector transduction of endothelial cells [101,102], peripheral mononuclear cells [103], and Ad-mediated complement activation [104–106] have all been implicated to play a role in acute toxicity. Several studies also suggest that antibodies may play a role. Both neutralizing anti-Ad antibodies [93,104] and non-neutralizing or naturally occurring (nonspecific cross-reacting) antibodies [89,90,104] may contribute to acute toxicity, perhaps by opsonizing the vp and rendering them more susceptible to

FIGURE 5.5 (See color insert following blank page 206.) High dose systemic injection of HDAd into nonhuman primates. Baboon injected with (A, C, and E) 5.6×10^{12} vp/kg or (B, D, and F) 1.1×10^{13} vp/kg of HDAd-LacZ. X-gal stained (A and B) liver and (C and D) spleen and (E and F) serum IL-6 from injected baboons. Circles, 5.6×10^{12} vp/kg; triangles, 1.1×10^{13} vp/kg. Note different scales in E and F. (Adapted from Brunetti-Pierri, N., Palmer, D.J., Beaudet, A.L., Carey, K.D., Finegold, M., and Ng, P., *Hum. Gene Ther.*, 15, 35, 2004.)

Fc-mediated uptake by macrophages which in turn may become activated to secrete proinflammatory cytokines. For example, systemic vector administration into nonhuman primates resulted in significantly higher IL-6 levels in animals with neutralizing anti-Ad antibodies compared to naïve animals [93]. Toll-like receptors (TLRs), crucial components in pathogen recognition processes, are recently emerging as another important players in Ad-mediated acute toxicity [107–113].

As discussed above (see Section 5.6.1.2), Kupffer cells of the liver are primarily responsible for the nonlinear dose response by preferentially sequestering systemic Ad, at least in mice, and their activation following uptake of Ad has been implicated to play a role in the acute innate inflammatory response [114]. However, their precise role in acute toxicity remains to be fully elucidated and warrants further discussion because of their potential role in HDAd-mediated, liver-direct gene therapy. Most studies in mice utilizing selective depletion of Kupffer cells prior to Ad administration did not investigate markers of innate inflammatory response such as serum IL-6

[19,115,116]. Of the studies in which this was addressed, depletion of Kupffer cells in mice by gadolinium chloride nearly eliminated TNF but resulted in a more robust IL-6 increase and did not affect NF- κ B following systemic Ad compared to mice bearing Kupffer cells [117]. In another study, depletion of Kupffer cells by clodronate liposomes in mice prior to systemic Ad appeared to have no effect on the serum levels of IL-2, IL-4, IL-5, IL-6, TNF- α , and INF- γ [114]. Likewise, Brunetti-Pierri et al. showed that the amount of Kupffer cell transduction did not correlate with serum IL-6 and IL-12 levels [96] and Manickan et al. showed that Kupffer cell death as a consequence of Ad uptake did not result in elevated serum IL-6 [118]. It is also interesting to note that systemic injection of low vector doses into nonhuman primates and mice resulting in low efficiency hepatocyte transduction almost certainly results in substantial transduction of Kupffer cells since they are the barrier responsible for the threshold effect to efficient hepatocyte transduction [89,90]. Yet, these animals exhibit little, if any, manifestations of acute toxicity. Taken together, these studies suggest that vector uptake by Kupffer cells, at least

alone, may not necessarily provoke a potent inflammatory response. Indeed it has been suggested that Kupffer cells may, in fact, play a protective role [119]. Clearly, a better understanding of the role of Kupffer cells in Ad-mediated acute toxicity is needed. Another contributing factors may be the variations in responses to vector due to inter-individual variations or pre-existing pathological conditions. Smith et al., for example, have shown that the biodistribution of adenoviral vectors is altered in cirrhotic rats due to the presence of pulmonary intravascular macrophages, which cause a shift in vector uptake from the liver to the lungs. Interestingly, the cirrhotic rats exhibited a potent activation of proinflammatory cytokines as compared to control non-cirrhotic rats [120]. These may have been a contributing factor in the death of one partial OTC-deficient patient given recombinant Ad [68,121].

Ultimately, the precise mechanism responsible for activation of the acute inflammatory response by systemic Ad is multifactorial and complex and remains to be fully elucidated. However, regardless of the precise mechanism, it is likely that a threshold of innate immune activation must first be attained, as a consequence of high dose and systemic exposure of the vector to many cell types and blood borne components, before severe and lethal acute toxicity manifests. Evidence of robust activation of the acute inflammatory response is observed in both rodents and nonhuman primates given comparable systemic high dose Ad (on a per kg basis). However, it is important to emphasize that unlike primates, lethal SIRS does not develop in rodents and in fact, such high doses are well tolerated. This may reflect species to species differences in the quality of the innate immune response or sensitivities of the end organs to pathologic sequelae [91,92]. This likely accounts for the plethora of studies reporting negligible toxicity in mice given high dose HDAd and underscores the importance of safety and toxicity evaluations in larger animals.

5.6.1.4 Overcoming the Threshold to Hepatic Transduction and Acute Toxicity

Given the tremendous potential of HDAd for liver-directed gene therapy, several groups have investigated different

strategies to overcome the threshold to hepatocyte transduction and the obstacle of the acute toxicity. Because the severity of the acute response is dose-dependent, one of these approaches aimed at preferential targeting of the vector to the liver thereby allowing the use of lower vector doses. For example, injection of HDAd directly into the surgically isolated liver in nonhuman primates was shown to achieve higher efficiency hepatic transduction with reduced systemic vector dissemination resulting in stable, high level, long-term transgene expression for the duration of the observation period of at least 665 days in one animal and at least 560 days in two other animals (Figure 5.6) [84]. Interestingly, this stability in transgene expression contrasts an earlier study in which transgene expression levels steadily declined to ~10% of peak levels over 1–2 years (Figure 5.4) [85]. The apparent difference in stability of transgene expression in these two studies may be attributed, in part, to differences in the age of the animals at the time of vector administration (juvenile baboons in the study by Morral et al. [85] and adult baboons in the study by Brunetti-Pierri et al. [84]) and, in part, to differences in the backbone sequences, cis-acting elements, and transgene [58,61,62]. Importantly, no chronic toxicity was evident during the entire observation period in either study. However, although the surgical approach has generated encouraging results, the method is not clinically attractive due to its invasiveness.

One outstanding question pertaining to the relevance of liver-directed HDAd-mediated gene therapy is whether high efficiency hepatic transduction necessarily results in severe acute toxicity. This was investigated using the technique of hydrodynamic tail vein injection to delivery HDAd into mice [96]. Hydrodynamic injection entails the rapid injection of a large volume (100 mL/kg injected within 7 s). Interestingly, hydrodynamic injection of HDAd resulted in significantly improved hepatic transduction efficiency, reduced systemic vector dissemination, and, importantly, appeared to reduce the severity of the innate inflammatory response. These results suggested that high efficiency hepatic transduction does not, at least alone, necessarily provoke a potent inflammatory

FIGURE 5.6 Stable, high level, long-term transgene expression in nonhuman primates following injection of HDAd directly into the isolated liver. Duration of transgene expression following administration of a HDAd expressing bAFP in three baboons. Black symbols represent 1×10^{12} vp/kg and white symbols represent 1×10^{11} vp/kg. (From Brunetti-Pierri, N., Ng, T., Iannitti, D.A., Palmer, D.J., Beaudet, A.L., Finegold, M.J., Carey, K.D., Cioffi, W.G., and Ng, P., *Hum. Gene Ther.*, 17, 391, 2006.)

response and that systemic vector dissemination may play a major role in the severity of the inflammatory response [96]. As discussed in Section 5.6.1.2, the size of the hepatic fenestrations plays a key role in the efficiency of hepatocytes transduction by Ad vectors and it is believed that the rapid injection of the large volume increases the intrahepatic pressure thereby enlarging the ≤ 100 nm fenestrations to permit extravasation of the ≥ 100 HDAd virion increasing access to the hepatocyte [96]. Importantly, this study also suggested that the therapeutic index of HDAd may be improved by preferential delivery into the liver. Unfortunately, this method of delivery is not feasible in large animals because of the rapid large volumes injected. However, considering its tremendous potential, a minimally invasive method to mimic hydrodynamic injection using balloon occlusion catheters was developed to achieve preferential hepatic delivery of the HDAd (Figure 5.7) [83]. This approach was developed to mimic the effect of hydrodynamic injection in larger animals but without rapid, large volume injection. In this method, hepatic venous outflow is occluded using two balloon occlusion catheters percutaneously placed in the inferior vena cava (IVC), above and below the hepatic veins (HV) (Figure 5.7). Because blood entering the liver from the hepatic artery (HA) and portal vein (PV) remains unobstructed, an increase in intrahepatic pressure is achieved, mimicking the high pressures achieved by systemic hydrodynamic injection in the mice. This pseudo-hydrodynamic injection method resulted in high efficiency hepatic transduction with minimal toxicity and stable, long-term transgene expression of at least 413 days [83].

An alternative potential approach to increase targeting to the liver may entail the use of drugs to enlarge liver fenestration [94]. Indeed, *N*-acetylcysteine combined with transient liver ischemia and Na-decanoate have been shown to increase the size of sinusoidal fenestrae and augment Ad-mediated

FIGURE 5.7 Pseudo-hydrodynamic injection of HDAd into non-human primates. Two balloon occlusion catheters are percutaneously positioned in the IVC above and below the HV. Inflation of the balloons results in hepatic venous outflow occlusion from the HV while blood inflow from the PV and HA increases the intrahepatic pressure. Following 30 min of occlusion, the balloon occlusion catheters are removed from the animal and HDAd is administered by systemic peripheral intravenous injection. (From Brunetti-Pierri, N., Stapleton, G.E., Palmer, D.J., Zuo, Y., Mane, V.P., Finegold, M.J., Beaudet, A.L., Leland, M.M., Mullins, C.E., and Ng, P., *Mol. Ther.*, 15, 732, 2007. With permission.)

hepatocyte transduction [95]. However, further studies are needed to determine the real clinical potential of these pharmacological approaches of increasing hepatocyte transduction by Ad for human applications.

Alternative strategies of “masking” the viral capsid have also been reported to attenuate the severity of the innate inflammatory response. Yotnda et al. [122] demonstrated that systemic injection of Ad encapsidated within bilamellar cationic liposomes resulted in a 70%–80% decrease in serum IL-6 compared to unencapsidated virions without compromising hepatic transduction efficiency. Likewise, two independent groups were able to demonstrate that systemic administration of PEGylated Ad into mice resulted in a 50%–70% reduction in serum IL-6 compared to unPEGylated vector without compromising hepatic transduction efficiency [123,124]. Although the precise mechanism by which these masking strategies operate to attenuate the acute inflammatory response is not fully understood, they nevertheless offer an intriguing and potentially important avenue for increasing the therapeutic index of HDAd.

5.6.2 LUNG DIRECTED GENE THERAPY

FGAd have been the most extensively used vector for pulmonary gene transfer with the goal of treating cystic fibrosis (CF). Although once thought to be an ideal vector for CF gene therapy, more than a decade of research has revealed a number of serious shortcomings and the enthusiasm for FGAd has greatly diminished. First, pulmonary delivery of FGAd in small animals, large animals, and humans is inefficient [125–129]. It was discovered that the cellular receptor for Ad (and other viral vectors) resided on the basolateral surface of the airway epithelial cells and that the tight junctions prevented vector–receptor interactions required for transduction [130]. However, the transient disruption of the tight junctions can significantly increase the efficiency of transduction thus dramatically decreasing the vector dose required to achieve therapeutic levels of transduction. Various strategies have been proposed to relax the tight junctions and improve adenoviral entry into airway epithelia and they include: calcium phosphate co-precipitates [131], EGTA [132], EDTA [133], polycations [134], sodium caprate [135], *L*- α -lysophosphatidylcholine [136,137], and other agents. Second, pulmonary delivery of FGAd resulted in dose-dependent inflammation and pneumonia [125,138–141] beginning about 3–4 days post-administration and became progressively more severe before eventually resolving. This has been attributed to expression of the viral genes present in the vector backbone of FGAd which is directly cytotoxic and also provokes an adaptive cellular immune response against the transduced cells consequently resulting in transient transgene expression and long-term, chronic toxicity [21–25,39]. This dose-dependent toxicity was partially addressed by using second generation Ad vectors deleted/mutated of other early viral genes, such as E2 or E4, in addition to E1 which further diminished, but did not eliminate pulmonary inflammation and pneumonia, likely as a result of continued leaky expression of the viral late genes [23,32,35,142].

FIGURE 5.8 (See color insert following blank page 206.) Epithelia transduction of the (A) proximal and distal airway, (B) trachea, and (C) bronchiole of mice 3 days post-intranasal administration of 2×10^{10} vp of HDAd-K18LacZ. Blue areas represent HDAd transduced cells. (From Toietta, G., Koehler, D.R., Finegold, M.J., Lee, B., Hu, J., and Beaudet, A.L., *Mol. Ther.*, 7, 649, 2003. With permission.)

Toietta et al. [143] compared the safety and efficacy of HDAd versus FGAd in mice for pulmonary transduction. In that study, a HDAd (called HDAd-K18LacZ) which expresses a nuclear-localized bacterial β -galactosidase reporter protein from the control elements of the human cytokeratin 18 (K18) gene was constructed. The expression pattern of K18 is similar to that of Cftr [144]; in the lungs, K18, like Cftr, is expressed in the epithelium of large airways and bronchioles and in submucosal glands, but with little expression in the alveoli. In contrast to commonly used viral promoters, the K18 promoter is less likely to suffer host “shut-off” and could reduce immune stimulation resulting in inappropriate expression in APCs [66]. The large cloning capacity of HDAds makes this vector ideal to accommodate the relatively large K18 control elements (4.1 kb) and reporter or therapeutic cDNAs. To assess the utility of this vector, mice were first given a 25 μ L intranasal administration of 0.4 M EGTA to disrupt tight junctions. Thirty minutes later, 2×10^{10} vp of HDAd-K18LacZ in 50 μ L was administered intranasally and their lungs were analyzed 3 days later. Extensive transduction was observed in the proximal and distal airways (Figure 5.8A). Trachea sections revealed extensive transduction of the epithelium and submucosal glands (Figure 5.8B). Extensive transduction was also

achieved in the bronchiolar epithelium with little transduction of the alveolar cells (Figure 5.8C). To directly compare the toxicity of HDAd versus FGAd, EGTA and then 4×10^{10} vp of either HDAd or FGAd were intranasally administered to mice and their lungs were examined 3 days later. As expected, administration of FGAd resulted in pulmonary inflammation with focal peribronchial lymphocytic infiltrates and focal alveolar macrophages (Figure 5.9A). In contrast, the lungs of mice given HDAd were free of inflammation (Figure 5.9B) and indistinguishable from saline treated animals. The duration of HDAd-mediated pulmonary transgene expression was also investigated using HDAd-K18hAFP, a HDAd expressing the human α -fetoprotein (hAFP) as a reporter gene [145] from the K18 promoter. In these studies, mice were first pretreated with EGTA and, 30 min later, 2×10^{10} vp of HDAd-K18hAFP in 50 μ L was intranasally administered. Serum and BAL fluid were collected from these mice at various times post-administration and revealed the presence of hAFP. Importantly, serum levels peaked at 50 IU/mL at 1 week and then decreased over time but remained detectable for at least 15 weeks post-administration. AFP immunohistochemistry performed on the lungs revealed the presence of hAFP positive airway epithelia cells, consistent with the interpretation that the serum

FIGURE 5.9 (See color insert following blank page 206.) Histology of representative mouse lung 3 days post-intranasal administration of a total of 4×10^{10} vp of an (A) FGAd or (B) HDAd. (From Toietta, G., Koehler, D.R., Finegold, M.J., Lee, B., Hu, J., and Beaudet, A.L., *Mol. Ther.*, 7, 649, 2003. With permission.)

and BAL hAFP had originated from these transduced cells. Taken together, the results of this study indicated that intranasal administration of HDAd following disruption of tight junctions resulted in high efficiency pulmonary transduction and use of the K18 promoter greatly restricts expression to the desired target cell types relevant to CF gene therapy. Additionally, HDAd, unlike FGAd, do not cause pulmonary inflammation (presumably due to the absence of viral gene expression), at least in mice, and at least when examined 3 days post-administration. Moreover, HDAd-mediated pulmonary transgene expression could persist for at least 15 weeks.

To test the therapeutic potential of HDAd for CF gene therapy, Koehler et al. constructed a vector called HDAd-K18CFTR bearing the human CFTR cDNA expressed from the K18 control elements [146]. This vector was found to express properly localized CFTR in cultured cells and in the apical airway epithelia of mice following intranasal administration of 2×10^{11} vp (preceded by EGTA pretreatment). Moreover, CFTR RNA and protein were present in whole lung and bronchioles for the duration of the observation period of at least 28 days. Importantly, the authors also demonstrated that HDAd-K18CFTR could improve resistance to acute lung infection in *cftr* knockout mice [146]. In these experiments, *cftr* knockout mice or their wild-type litter mates were given either saline or 2×10^{10} vp of HDAd-K18CFTR by intranasal administration following pretreat-

ment with EGTA. These mice were then challenged 7 days later with a clinical isolate of *Burkholderia cepacia* (Bcc). Five days post-Bcc, the lungs were harvested for histopathology. Wild-type mice given either saline (Figure 5.10A) or HDAd (Figure 5.10B) prior to Bcc had minimal to moderate patchy inflammation in the form of bronchiolitis and scattered foci of mild to moderate pneumonia. As expected, *cftr* knockout mice given saline prior to Bcc had marked inflammation in the form of severe pneumonia and bronchiolitis, inflammatory cell infiltration, exudation, consolidation, respiratory cell hyperplasia, necrosis, and high lung bacterial counts (Figure 5.10C). In sharp contrast, *cftr* knockout mice given HDAd-K18CFTR prior to Bcc had significantly less severe histopathology similar to what was observed in the wild-type littermates given Bcc and, importantly, their lungs harbored no live Bcc (Figure 5.10D). Taken together, these results indicate that HDAd can express properly localized CFTR in the appropriate target cell types for CF gene therapy *in vivo* as well as suggest that this vector could benefit CF patients by reducing susceptibility to opportunistic pathogens.

Despite the encouraging results in mice described above the requirement for two separate administrations—one to deliver EGTA to disrupt the tight junction and then a second, 30 min later, to deliver the vector—is suboptimal in terms of safety and efficacy because this increases the procedure time

FIGURE 5.10 (See color insert following blank page 206.) Lung histopathology following Bcc challenge. Representative H&E stained sections from wild-type littermates (A and B) and CFTR knockout mice (C and D) receiving saline (A and C) or HDAd-K18hCFTR (B and D) prior to bacterial challenge. (From Koehler, D.R., Sajjan, U., Chow, Y.H., Martin, B., Kent, G., Tanswell, A.K., McKerlie, C., Forstner, J.F., and Hu, J., *Proc. Natl. Acad. Sci. U S A*, 100, 15364, 2003. With permission.)

and compromises transduction efficiency because both the EGTA and the vector must be applied to the same location, which is not guaranteed in the case of separate, independent administrations. This obstacle was subsequently addressed by Koehler et al. [137] who demonstrated that high efficiency pulmonary transduction by HDAd can be obtained by formulating the vector in 0.1% L- α -lysophosphatidylcholine (LPC) thus permitting a single administration containing the vector and the tight junction opening agent. The intranasal delivery as performed in mice (spontaneous liquid inhalation) is not applicable to larger animals and a clinically relevant method of vector delivery was therefore developed by Koehler et al. [137]. In this study, an intracorporeal nebulizing catheter called the AeroProbe (Trudell Medical International) designed to aerosolize material directly into the trachea and lungs was utilized. Using the AeroProbe, Koehler et al. [137] aerosolized 1.25 mL of 0.1% LPC containing 5×10^{11} vp HDAd-K18LacZ into the lungs of 2.8 kg rabbits. The X-gal staining revealed extensive transduction of the trachea (Figure 5.11A). Although the intratracheal aerosolization was intended to deliver vector to the entire lung, X-gal staining revealed high interlobular variation. Nevertheless, in those lobes that received vector (Figure 5.11B through D), exceedingly high and unprecedented levels of transduction were achieved in all cell types of the proximal and distal airway epithelium (Figure 5.11E), from the trachea to terminal bronchioles. All rabbits, including those given LPC only as controls, exhibited a transient decrease in dynamic lung compliance immediately following aerosol delivery. Fever and mild-to-moderate patchy pneumonia without edema were also observed leading the investigators to speculate that LPC may have been a contributing factor and that these may be eliminated/minimized by further optimizing the dose of LPC or vector. Nevertheless, this study is significant because it is the first to demonstrate high efficiency transduction of the airway epithelium in a large animal which had been a major obstacle to CF gene therapy. The above described strategy of delivering HDAd in rabbits has recently been applied to nonhuman primates and has yielded similar encouraging preliminary results [147].

Despite the promising and compelling studies described above, several outstanding issues still remain to be addressed. First, the efficiency of transduction will likely be greatly reduced in severely diseased CF lungs possibly rendering it necessary to treat less affected lungs that may be more amenable to gene transfer. Second, the requirement to transiently open the tight junctions in order to achieve efficient transduction raises safety concerns since this may allow bacteria to penetrate the epithelium, especially from CF patient airway epithelium colonized with several microbial pathogens [148]. However, this potential concern should be weighed against potential benefits. Risk would depend upon the patient particular colonizing strain(s) and amounts, as well as their serum level of antibodies against the bacteria. Intravenous and inhaled antibiotics routinely prescribed to CF patients could be administered prophylactically around the time of gene therapy. Third, the duration of pulmonary transgene expression from HDAd remains unknown. In the case of liver-directed

gene therapy, HDAd has been shown to mediate transgene expression for 1 year or more in small and large animal models (see Section 5.6.1). However, the rate of turnover of airway epithelial cells is greater than hepatocytes and may likely be

FIGURE 5.11 (See color insert following blank page 206.) Pulmonary transduction in 2.8 kg rabbits following AeroProbe-mediated intratracheal aerosolization of 1.25 mL 0.1% LPC containing 5×10^{11} vp of HDAd-K18LacZ. X-gal stained (A) trachea, (B) right upper lobe, (C) left lower lobe, (D) right lower lobe, and (E) bronchus and bronchioles. Blue areas represent HDAd transduced cells. (From Koehler, D.R., Frndova, H., Leung, K., Louca, E., Palmer, D., Ng, P., McKerlie, C., Cox, P., Coates, A.L., and Hu, J., *J. Gene Med.*, 7, 1409, 2005. With permission.)

even greater in the CF lung. Fourth, vector re-administration may be challenging due to an adaptive humoral immune response against the HDAd capsid. Strategies such as transient immunosuppression at the time of vector administration [34,149–153], masking the vector with PEG [154,155], or switching to a different serotype vector have been successful for intrapulmonary re-administration [156,157] and may need to be considered. It should be noted that the vector genotype may influence re-administration. For example, Wilson and coworkers have demonstrated that, unlike first-generation Ad vectors (E1-deleted), second generation Ad vectors (E1 and E4-deleted) failed to generate a neutralizing antibody response against the vector in the BAL fluid in both mice and rhesus monkeys following intrapulmonary delivery [142]. The authors hypothesized that the absence of viral E4 gene expression from the second generation Ad vector resulted in an attenuated humoral response due to reduced inflammation and further implied that re-administration would therefore be possible although this was not directly demonstrated. Because HDAd are deleted of all viral genes, including E4, an attenuated adaptive humoral response may result but this remains to be determined as is its affect, if any, on re-administration. Fifth, uniform delivery of vector to all lung lobes will likely be important and this has yet to be achieved. With respect to the AeroProbe, further optimization will be needed and one possibility is to use the AeroProbe in conjunction with a bronchoscope to permit targeted lobar aerosolization [158].

5.6.3 MUSCLE DIRECTED GENE THERAPY

Duchenne muscular dystrophy (DMD) is a lethal X-linked degenerative muscle disease caused by mutations in the dystrophin gene, with a frequency of 1 in 3500 male births. Dystrophin is an essential structural component of the skeletal muscle cell membrane, linking intracellular actin filaments with the dystrophin-associated proteins in the sarcolemma. Dystrophin deficiency results in instability of the muscle cell membrane causing muscle fiber degeneration. Because of lack of effective treatments, DMD has been considered a prime candidate for gene therapy, the goal of which is to transfer normal copies of the dystrophin gene into the muscle fibers of affected patients. Various gene therapy vectors have been investigated and FGAd has actually been the first vector to successfully deliver a human dystrophin cDNA by intramuscular administration into *mdx* mice, a genetic and physiopathological model for DMD [159]. The length of the dystrophin cDNA (14 kb) precluded its inclusion into most gene therapy viral vectors and HDAds with their large cloning capacity can accommodate not only one full length dystrophin cDNA but also two copies of the gene [160,161]. Indeed, the first *in vivo* application of HDAds was transduction of skeletal muscle for DMD gene therapy [50]. HDAd vector expressing full-length dystrophin has been shown to restore in the skeletal muscle the full dystrophin–glycoprotein complex, resulting in a reduced level of muscle degeneration and amelioration of the physiological and pathological indices of muscle disease

[160–164]. Compared to *mdx* mice treated as neonates, higher doses of vector are needed to treat adult *mdx* mice because of inefficient infection of mature muscle by Ad [163]. Moreover, direct intramuscular injection of HDAd encoding full-length murine dystrophin resulted in only transient expression in adult-injected mice [164] because of a humoral immune response against the dystrophin protein. Importantly, such a response has not been observed in immunodeficient SCID mice suggesting that sustained expression could be achieved in the absence of an immune response to the transgene product [164,165]. A similar outcome could be predicted to occur in humans as well, since many DMD patients have large dystrophin gene deletions preventing the expression of epitopes encoded by deleted exons. In these cases the dystrophin produced by HDAd-transduced cells could be perceived as a neo-antigen thus preventing long-term expression [166]. To overcome this problem, co-delivery of immunomodulatory molecules such as CTL4A1g have been successfully employed in immunocompetent mice to prolonged dystrophin expression [167,168].

HDAd vectors have also been explored for *in utero* gene therapy of DMD. The immaturity of the immune system of the fetus coupled with the survival advantage of dystrophin-expressing muscle fibers over dystrophin-deficient muscle fibers may offer a significant advantage for this promising therapeutic strategy. In this approach HDAds were found to be less toxic than the FGAd and able to drive stable transgene expression and restoration of the disarcoglycan complex [169].

Respiratory insufficiency due to progressive weakness of the diaphragm and other respiratory muscles is the main cause of death of DMD patients when they are in their late teens or early twenties [170]. Therefore, diaphragm-directed gene therapy has been investigated in the *mdx* mouse using HDAd injected directly into the diaphragm exposed through a laparotomy [171]. This approach has led to reversal of functional abnormalities of dystrophic diaphragms but at the same time it also points to the difficulties of DMD gene therapy which, in order to be effective, requires the transduction of a critical number of muscle fibers throughout the body.

The muscle remains an attractive tissue for transduction because, like the liver, it may serve a more general purpose in gene therapy: (1) muscle constitutes as much as 40% of the total body mass and much of it is readily accessible, (2) skeletal myocytes can be transduced *in vivo*, (3) skeletal myofibers have a relatively long half-life and therefore represent a stable platform for transgene expression, (4) muscle is highly vascularized and skeletal muscle can efficiently secrete recombinant proteins into the circulation for systemic delivery, and (5) high seroprevalence in the adult human population of pre-existing anti-Ad neutralizing antibodies, an obstacle for intravenous vector delivery, may be minimized through localized delivery into the muscle. This strategy was investigated in a study by Maione et al. [79] in which mice were intramuscularly injected with a HDAd expressing mouse erythropoietin as a marker gene. All mice intramuscularly injected with a dose of 1×10^6 IU or 3×10^5 IU retained transgene expression for at least 4 months. At a dose of 3×10^6 IU, 30% of the mice slowly

lost transgene expression. In contrast, all mice injected intramuscularly with FGAd lost transgene expression by day 21. The effect of preexisting anti-Ad antibody on the effectiveness of intramuscular administration was also investigated. The authors found that successful intramuscular gene transfer could be accomplished in pre-immunized mice although a 30- to 100-fold higher dose was required to achieve 87% and 100%, respectively, the levels of transgene expression in naïve mice. This is in sharp contrast to intravenous gene transfer in which 60% of pre-immunized mice were completely refractory to transduction while the remaining 40% were transduced but exhibited transgene expression levels comparable to naïve mice intravenously injected with 1000-fold lower dose.

5.6.4 BRAIN- AND EYE-DIRECTED GENE THERAPY

The use of adenoviral vectors to deliver genes to the nervous system holds great promise for therapeutic applications. Stable, long-term transgene expression, in the absence of toxicity, is critical if gene therapy is to be successful in treating a variety of central nervous system (CNS) disorders ranging from simple monogenic disorders (such as spinal muscular atrophy, Lesch–Nyhan syndrome, leukodystrophies, lysosomal storage diseases, amyotrophic lateral sclerosis, Huntington's disease) to complex diseases, including common neurodegenerative disorders such as Parkinson's disease and Alzheimer's disease. Because of their ability to infect post-mitotic cells, including cells of the CNS [172], and to mediate long-term transgene expression, Ad-based vectors are particularly attractive for these applications. Unlike the rapid decline observed in transgene expression in peripheral organs following intravenous administration, FGAd-mediated transduction of adult brain cells leads to stable transgene expression [173,174]. Brain intraparenchymal injection of FGAd vectors in fact elicits a minimal, transient local inflammation which does not compromise sustained vector-driven expression. It is thought that FGAd-mediated long-term transgene expression occurs because the brain is relatively protected from the effects of the immune response, and in fact, Ad injection into the brain results in an ineffective T cell response against brain-transduced cells [175]. However, the immune system can and does respond to antigenic stimuli in the brain [176], and if a peripheral immune response against Ad is elicited after natural infection or vector readministration, loss of transgene expression and chronic inflammation are observed [177]. Interestingly, these detrimental effects are not seen when HDAd is used [177,178]. Moreover, when directly compared with FGAd, HDAd can mediate significantly higher transgene expression levels and induce a substantially reduced inflammatory and immune response as shown by a reduction in the increases seen in proinflammatory cytokines (IL-1 β and TNF- α) [179].

Encouraging preliminary results, including a significant inhibition of huntingtin protein aggregation, have been recently reported in a Huntington's disease animal model following stereotaxic injection into the striatum of a HDAd vector expressing a short hairpin RNA silencing the Huntington

disease gene [180]. However, this type of approach is far from being ready for clinical applications since the delivered vector had limited brain distribution not extending beyond a few millimeters from the needle track and because demonstration of efficacy using clinically relevant endpoints is still lacking. Being a complex organ with discrete and intricate interconnections between various types of cells, the brain is a complicated target for vector delivery aiming to correct a disease with diffuse involvement. Diseases requiring localized gene therapy to discrete set of neurons such as Parkinson's disease or brain tumors are more amenable for treatment. For brain cancer applications FGAd vectors have been used successfully in clinical trial for glioblastoma multiforme and intratumoral injection has been associated with increased survival in two different trials [181,182]. Given the high risk that FGAd treatment of glioblastoma multiforme can be compromised by exposure to natural Ad infection, HDAd vectors encoding a regulatable therapeutic genes could offer a significantly safer and more effective treatment for patients with this type as well as other forms of brain cancer [183,184].

There have been a limited number of studies investigating HDAd vectors for eye gene therapy. In one of these studies, subretinal injections of HDAd vectors were shown to transduce and rescue cells from the neurosensory retina in a mouse model of retinal degeneration following [185]. Moreover, HDAd was shown to be able to mediate long-term therapeutic genes in the retinal pigment epithelium (RPE) following subretinal injection without evidence of adverse immune reactions or significant toxicity [186].

5.7 CONCLUDING REMARKS

HDAd possesses many characteristics that make them attractive vectors for gene therapy of a wide variety of genetic and acquired diseases. However, acute toxicity provoked by the viral capsid is the most significant obstacle currently hindering the clinical application of this otherwise promising technology. Indeed, the tragic death of Jesse Gelsinger has justifiably raised serious concerns over the use of all Ad-based vectors, especially for intravascular delivery and liver-directed gene therapy. However, the potential of using HDAd, including intravascular delivery and liver-directed gene therapy, should not be dismissed but should instead proceed with caution considering the wealth of encouraging and compelling studies amassed to date. Studies to elucidate the mechanism(s) of Ad-mediated activation of the innate inflammatory response are clearly needed. Perhaps with a better understanding of this phenomenon, strategies can be developed to minimize, if not eliminate, this serious but ultimately surmountable problem of acute toxic response. When this is accomplished, then HDAd should be able to provide sustained, high level transgene expression with no further toxicity.

6.1 INTRODUCTION

In this chapter we summarize the state of development of adeno-associated virus (AAV) vectors and provide an overview of AAV as well as some historical comment on early seminal studies. We discuss the key advances in the recent years including improvements in vector production, the expanded understanding of AAV and AAV vector biology, studies on the applications for persistent gene expression, and update the extensive series of AAV vector clinical trials. We have not attempted to provide an exhaustive collection of references on development of AAV vectors. Other sources provide general reviews of AAV [1,2] and summaries on early development of AAV vectors [3–7].

AAV vectors have a number of advantageous properties as gene delivery vehicles. The parental virus has never been shown to cause disease. AAV vectors are the smallest and most chemically defined particulate gene delivery system and potentially could be classified as well characterized biologics for therapeutic applications. AAV vectors contain no viral genes that could elicit undesirable cellular immune responses and appear not to induce inflammatory responses. The primary host response that might impact use of AAV vectors is a neutralizing antibody response. The vectors readily transduce dividing or nondividing cells and can persist essentially for the lifetime of the cell. Thus, AAV vectors can mediate impressive long-term gene expression when administered *in vivo*. Consequently, these vectors may be well suited for applications where the vector is delivered infrequently and where any potential host antibody response to the AAV capsid protein may be less inhibitory. One limitation for AAV vectors is the limited DNA payload capacity of about 4.5 kb per particle.

The lack of good production systems that could generate high titer vectors was an early obstacle to the development of AAV vectors, but this has been overcome through significant advances in both upstream production and downstream purification of AAV vectors. Clinical development of AAV vectors has progressed significantly and studies of an AAV vector in cystic fibrosis (CF) patients [8–13] have been extended to phase II trials. Other AAV vectors then entered clinical trials for hemophilia B [14] and to date at least 20 AAV vectors have been introduced into clinical trials for a wide variety of therapeutic and prophylactic applications [15,16] (Table 6.1).

Since the second edition of this book [17] there have been further advances in application of AAV vectors in many animal models and analysis of AAV vector safety profiles and

host cell responses. Additional advances in understanding the structure and biology of AAV vectors including uptake into cells, trafficking to the cell nucleus, and the mechanism of genome persistence suggest possible ways to modify the biological targeting of AAV vectors, to enhance transduction efficiency and to overcome the packaging limitation. Also, there have been substantial advances in manufacture of AAV vectors [18,19].

Most of the early studies on AAV used AAV serotype 2, but genomes of serotypes 1 through 6 were cloned and sequenced [20]. Many additional AAV serotypes and sequences have been isolated [21], particularly from human and in nonhuman primate tissues and an extensive clade structure is now emerging [22–24]. The biological properties of individual serotypes include differences in the interactions with cellular receptors [25]. Other studies are now providing information on the structure of the AAV capsids and how their interactions with the cell may be modified. In addition, the resolution of the crystal structure of AAV2 [26] provided the foundation for structural studies of many other AAV serotypes [27]. Thus, together with additional studies on cellular trafficking pathways, it may be possible to modify the targeting of AAV vectors as well as to enhance their transduction efficiency [28,29].

Studies on the mechanism of persistence of vector genomes in transduced cells indicate that this involves formation of polymeric DNA structures or concatemers. Concatemers also can be formed between two different vector genomes introduced into the same cell. This provides a way to partly circumvent the packaging limit of AAV by dividing a gene expression cassette between two AAV vectors (dual vectors) and allowing recombination in the cell to generate the intact expression cassette.

6.2 ADENO-ASSOCIATED VIRUS

6.2.1 AAV DISCOVERY

AAV is a small, DNA-containing virus which belongs to the family Parvoviridae within the genus *Dependovirus*. AAV originally was observed as a contaminant of laboratory preparations of adenovirus, then was recognized as a virus that was different from adenovirus but was dependent upon adenovirus for its replication [30,31]. Soon after the discovery of AAV in laboratory stocks of adenoviruses, it was isolated from humans [32]. AAV has not been associated with any disease but has

TABLE 6.1
Current and Completed Clinical Trials with AAV Vectors

Disease Indication ^a	Protein Expressed	Capsid	Route of Administration	Phase	Subject Number Vector (Placebo) ^b	Status ^c
CF	CFTR	AAV2	Lung (bronchoscope), nose	I	25	Completed

^a All of these trials involve *in vivo* delivery of AAV vectors except for the cancer indications in which allogenic cells transduced *ex vivo* with an AAV vector are administered as a therapeutic cancer vaccine.

^b For ongoing trials, the number of subjects to be administered vector is indicated but does not necessarily reflect the enrollment to date. For placebo-controlled trials, the planned number of placebo subjects is indicated in parentheses. Projected enrollment numbers are not available for some trials.

^c For trials which are finished, "completed" indicates that subject enrollment was achieved essentially as originally planned, whereas "ended" indicates that enrollment was stopped short of the original goal. Ongoing indicates that the trial is under way as of mid-2007.

been isolated from humans, initially in association with infections by adenovirus [32]. More recently, endogenous AAV DNA sequences have been isolated from a variety of human tissue samples including adenoids, tonsils, leukocytes, lymph nodes, liver, muscle, and cervix [21–23,33–36]. Thus it is suggested [24] that AAV generally may enter humans via the oropharyngeal route in association with adenovirus and then spread to other sites perhaps as a result of replication.

Adenoviruses are efficient helpers for AAV replication in *in vitro* cell culture. The epidemiological evidence (Section 6.2.2) suggests that adenovirus is the normal helper in natural infections in humans. Also, adenovirus has been shown to be an efficient helper for AAV replication in animals such as rhesus macaques [37]. Herpesviruses can also function as helpers for AAV replication *in vitro* but they are much less efficient. In contrast, there is no evidence that herpesviruses

can act as a helper in humans or any animal species. In addition to not being associated with causing any diseases, it is not apparent that AAV plays any role in altering or affecting the course of *in vivo* infection with either type of helper, adenovirus or herpesvirus [24].

Multiple serotypes of AAV now have been distinguished. AAV1, AAV2, AAV3, and AAV4 have extensive DNA homology and significant serologic overlap [38–41], but AAV5 is somewhat less related [42,43]. AAV2 and AAV3 are the most frequently isolated from humans [32] whereas AAV5 has been isolated from humans only once [44]. AAV4 is a simian isolate that does not infect humans and AAV1 originally may have been isolated from a simian source [45]. More recent isolates, AAV6 [46], AAV7, and AAV8 [21], are discussed below. Other AAVs have been identified in a variety of other animal species [47] but less characterization of these AAV isolates has been reported [1]. However, it has been noted that the entire genus *Dependovirus* appears to be derived from avian AAVs [23].

6.2.2 EPIDEMIOLOGY

In the United States, a significant proportion of the population over age 10 may be seropositive for AAV2 and AAV3 [32]. AAV2 and AAV3 appear to be transmitted primarily in nursery populations in conjunction with the helper adenovirus and thus appear to be replication defective also in the natural human host. A signal epidemiological study of AAV was carried out in a population of children in an orphanage in Washington DC in whom seroconversion to AAV was observed during the course of an adenovirus infection [32]. In primary infected individuals, the virus may be shed in body fluids including sputum and stool. It is noteworthy that the early epidemiological studies also analyzed neutralizing antibody responses to AAV in humans. The presence of serum neutralizing antibody against AAV2 or AAV3 did not prevent reinfection of humans but did prevent shedding of the virus [32]. This observation is relevant for the use of AAV as a gene delivery vector because it suggests that repeat delivery may be feasible [48] and that shedding of vector may be less likely.

6.2.3 BIOLOGY OF AAV LIFE CYCLE

AAV is a defective parvovirus that replicates *in vitro* only in cells in which certain functions are provided by a coinfecting helper virus which is generally an adenovirus but may be a herpesvirus [1]. AAV has both a broad host range and wide cell and tissue specificity and replicates in many cell lines of human, simian or rodent origin provided an appropriate helper virus is present. There may be some limitations to AAV tissue specificity *in vivo* or at least some significant differences in efficiency of transduction of different tissues and organs. These limitations may reflect the receptor and co-receptors apparently utilized by different AAV serotypes for entry into cells as well as cellular trafficking of AAV. This aspect of AAV biology is becoming of increasing importance for development of AAV vectors. A second set of parameters that may

impact AAV tissue and organ specificity and its replication reflect the nature of the helper function provided by helper viruses.

An additional event required by AAV to function efficiently as a gene delivery vehicle is the need to convert the incoming single-stranded DNA genome to a double-stranded molecule to permit transcription and gene expression. This process is termed single-strand (SS) conversion or metabolic activation [49] and the rate at which it occurs may depend in part on the physiological state of the host cell, but the process may be accelerated by treatment of the cell with genotoxic agents or by certain helper virus functions.

Infection of certain cell lines by AAV in the absence of helper functions results in its persistence as a latent provirus integrated into the host cell genome [50,51]. In such cell lines, the integrated AAV genome may be rescued and replicated to yield a burst of infectious progeny AAV particles if the cells are superinfected with a helper virus such as adenovirus. Importantly, in cultured cells, AAV exhibits a high preference for integration at a specific region, the AAVS1 site, on human chromosome 19 [52,53]. The efficiency and specificity of this process is mediated by the AAV *rep* gene [54–56]. Rep-deleted AAV vectors do not retain specificity for integration into this chromosome 19 region [57] and generally do not integrate efficiently but remain as episomes (Section 6.9).

6.2.4 MODE OF CELL ENTRY AND HOST TROPISM

AAV appears to have a broad host range and different AAV serotypes replicate *in vitro* in many human cells and a variety of simian and rodent cell lines if a helper virus with the appropriate host range is also present. AAV also infects various animal species and human isolates of AAV will grow in mice or monkeys if the appropriate mouse or monkey adenovirus is also present. This indicated that cellular receptors for AAV were likely to be relatively common on many cell types.

Initial experiments demonstrated [58] that AAV2 particles can use heparin sulfate proteoglycans (HSPG) as a receptor and some cell lines that do not produce HSPG are impaired for AAV binding and infection. Further studies showed that AAV2 also utilizes a co-receptor for efficient internalization and two possible co-receptors, $\alpha_v\beta_5$ integrin [59] and human fibroblast growth factor receptor 1 (FGFR1) [60] were identified. It is of interest that the $\alpha_v\beta_5$ integrin co-receptor, which is used for a similar purpose by adenovirus type 2 and 5, is preferentially located on airway epithelial cells in the more distal areas of the conducting airway [61]. This may be important for use of an AAV2 gene therapy vector for CF since the distal airway is the region of the lung most impacted by the disease. It is also noteworthy that FGFR is expressed in most tissues but is of highest abundance in skeletal muscle and neuroblasts and glioblasts in the brain and these two organs appear to be good targets for AAV2 transduction.

The existence of more than one co-receptor suggests that AAV may have multiple mechanisms for cell entry and there is already some evidence to support this concept [62]. Also, real-time imaging of entry into HeLa cells by individual AAV2

particles labeled with the dye Cy5 [63] showed that endocytosis was rapid and that some particles could reach the nucleus within 15 min of first contacting the cell. However, there was evidence of free diffusion of both endosomes and AAV particles and also evidence for movement of each of these entities being driven by cellular motor proteins. Furthermore, cellular trafficking events following endocytosis of AAV, that may involve the ubiquitin-proteasome pathway, appear to play a significant role [64–67].

Cell entry may also be impacted by the route of delivery and AAV vectors can transduce airway cells when delivered directly to the lung [68,69], or brain cells [69] and myocytes [70,71] when delivered directly to these organs. However, when delivered intravenously by tail vein injection in mice [72,73], the vector preferentially accumulated in the liver and this may reflect both the presence of a much more porous vasculature in the liver and also the small size of the AAV particles. The small size of the AAV particle also may be of advantage in passing through the basal lamina pores in muscle and thus accessing a large number of myoblasts and myotubes.

The initial observations on AAV cellular entry and tropism are being greatly expanded upon in the context of AAV vectors. Recent development of AAV vectors based on different capsids has increased interest and provided many more detailed insights into the multiple receptors and co-receptors utilized by various AAV serotypes as well as generating much more information on cellular trafficking of AAV particles. This is discussed in more detail in Sections 6.7 and 6.8 below.

6.3 AAV MOLECULAR BIOLOGY

6.3.1 PARTICLE STRUCTURE

AAV is a nonenveloped particle about 20 nm in diameter with icosahedral symmetry which is stable to heat, mild proteolytic digestion, and nonionic detergents. The AAV particle is comprised of a protein coat, containing the three capsid proteins, VP1, VP2, and VP3, which encloses a linear single-stranded DNA genome having a molecular weight of 1.5×10^6 . The VP1, VP2, and VP3 proteins are present in the viral capsid in the ratio of 1:1:8. The DNA represents 25% by mass of the particle that therefore exhibits a high buoyant density (1.41 g/cm^3) in cesium chloride. The relative stability of the AAV particle is an important property since it can withstand robust purification procedures and this facilitates scaled-up production of AAV vectors.

The crystal structure of AAV2 was determined at 3.0 \AA resolution by x-ray crystallography [26] and this revealed several interesting features that have greatly facilitated efforts aimed at modifying the AAV capsid to alter targeting specificity. The structure (Figure 6.1) shows that each capsid comprises 60 protein subunits arranged in $T = 1$ icosahedral symmetry. All of the amino acids, except the 14 amino-terminal residues of VP1, could be localized in the structure. The surface of the capsid shows a distinctive topology with three peaks clustering around each threefold icosahedral axis (Figure 6.1). Each

FIGURE 6.1 Structure of AAV serotype 2. The structure was determined by x-ray crystallography at a resolution of 3.0 \AA . The surface topology is shown drawn to scale. The view is down a two-fold axis (center of the virus) with threefold left and right of center, and fivefold above and below. Overall, the outside surface is positively charged with a prominent ring of symmetry-related positive patches in a depression surrounding the fivefold axis. (Reprinted from Xie, Q., Bu, W., Bhatia, S., Hare, H.J., Somasundaram, T., Azzi, A., and Chapman, M.S., *Proc. Natl. Acad. Sci. U S A*, 99, 10405, 2002. With permission.)

of these threefold proximal peaks is formed from two interacting protein subunits and the sides of these peaks appear to be the regions that mediate the receptor binding interactions with heparin sulfate. Additional crystal structures of other AAV serotypes including AAV4 and AAV8 have also been determined. Most recently the structure of the AAV8 capsid was determined at 2.6 \AA resolution [74]. The overall topology of the common viral capsid protein of AAV8 is similar to that of AAV2 and AAV4 with an eight-strand β -barrel and long loops between the β -strands but there are significant differences at the surface protrusions around the two-, three-, and fivefold axes. At least for AAV2, these latter structures have important roles in transduction efficiency and antibody recognition. The surface of AAV2 has a basic charge at the region associated with heparin binding but at the analogous region AAV8 has a reduced distribution of basic charge. This is consistent with the lack of heparin binding by AAV8.

All other parvoviruses contain a phospholipase A2 activity in the capsid protein and AAV has a similar activity that is located in the unique amino-terminal region of the VP1 protein [75]. This activity appears to be required to mediate exit from endosomes and is important for infectivity [76,77]. No posttranslational modifications of the AAV capsid have been identified. Up to eight potential *O*- or *N*-glycosylation motifs,

of which three are on the surface near the protrusions at the threefold axes, can be identified in the AAV2 capsid. However, a recent analysis of purified AAV2 capsids using peptide mapping and high-resolution mass spectrometry showed that these sites are not glycosylated [78].

A novel feature of AAV is that although each particle contains only one single-stranded genome, strands of either complementary sense, “plus” or “minus” strands, are packaged into individual particles. Equal numbers of AAV particles contain either a plus or minus strand. Both strands are equally infectious and AAV displays single-hit kinetics for infectivity [79]. When DNA is extracted from AAV particles, the plus and minus strands anneal to generate duplex molecules of 3.0×10^6 molecular weight. However, Crawford and his colleagues [80] showed on the basis of a careful physical characterization of AAV particles that each particle appeared to contain DNA with a molecular weight of 1.5×10^6 . They suggested that the only way to reconcile this conundrum was to propose that individual plus and minus strands must be packaged into individual particles. An elegant proof of this conundrum was provided by Rose and his colleagues [81] who made two preparations of AAV particles, in which one preparation had thymidine substituted by bromodeoxyuridine (BudR) and the other was un-substituted. The two preparations of particles were mixed prior to extraction of DNA. Analysis of the duplex DNA obtained upon extraction showed components with intermediate density formed by individual strands from substituted or un-substituted particles that had annealed during extraction. This constituted formal proof of the novel DNA strand segregation exhibited by AAV during packaging of its DNA. BudR substitution of AAV DNA also permits separation of the plus and minus strands and this was used along with 5' end labeling and restriction endonuclease cleavage to determine the strand polarity of the AAV genome [82].

6.3.2 AAV GENOME STRUCTURE

Most of the fundamental studies of AAV genome structure and function were derived from AAV2. More recently, additional serotypes have been examined and most show a relatively similar genome arrangement and expression pattern although there are some differences particularly with respect to transcription as described below.

The AAV2 DNA genome [38,83] is 4681 nucleotides long and includes one copy of the 145 nucleotide long inverted terminal repeat (ITR) at each end and a unique sequence region of 4391 nucleotides long that contains two main open reading frames for the *rep* and *cap* genes (Figure 6.2). The unique region contains three transcription promoters p_5 , p_{19} , and p_{40} that are used to express the *rep* and *cap* genes. Transcripts from all three promoters are terminated at a polyA site at the right hand end of the genome. The ITR sequences are required in *cis* to provide functional origins of replication (ORI) as well as signals for encapsidation, integration into the cell genome, and rescue from either host cell chromosomes or

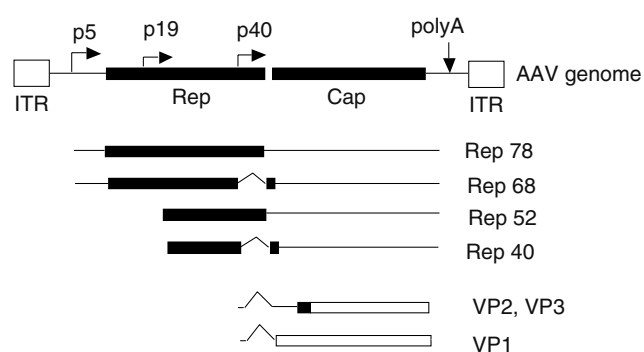

FIGURE 6.2 Structure of the AAV2 genome. The AAV2 genome is shown schematically at the top. Open boxes indicate the ITRs (replication origins) and the arrows indicate the three transcription promoters, p_5 , p_{19} , and p_{40} . The polyA site is indicated by the downward arrow. The six RNA transcripts are shown below with the introns indicated by the caret marks. The coding regions for the four rep proteins (Rep78, Rep68, Rep52, and Rep40) are shown by the solid rectangular boxes and for the viral capsid proteins (VP1, VP2, and VP3) by the open boxes. The three capsid proteins VP1, VP2, and VP3 all comprise the same common VP3 amino acid. The VP2 contains an additional N-terminal sequence (shown by the black box). VP1 comprises all of the VP2 sequence plus an additional N-terminal sequence.

recombinant plasmids. The genomes of other AAV serotypes have been sequenced and appear to have a structure similar to AAV2 [40–42,46].

The *rep* gene is transcribed from two promoters, p_5 and p_{19} , to generate two families of transcripts and two families of rep proteins (Figure 6.1). In addition, splicing of these mRNAs yields two different carboxyl terminal regions in the rep proteins. The capsid gene is expressed from transcripts from the p_{40} promoter that accumulate as two 2.3 kb mRNAs that are alternately spliced. The majority 2.3 kb transcript codes for the VP3 protein initiated from a consensus AUG initiation codon. However, at about a 10-fold lower frequency, translation of this transcript also occurs slightly upstream at a non-consensus ACG initiation codon to yield VP2. The minority 2.3 kb mRNA is spliced to an alternate 3' donor site 30 nucleotides upstream and this retains an AUG codon that is used to initiate translation of VP1. Thus, VP1 and VP2 have the same polypeptide sequence as VP3 but have additional amino-terminal sequences. This elegant arrangement results in generation of VP1, VP2, and VP3 in ratios of about 1:1:8 that are the same as the ratio of these proteins in the viral particle.

During construction of AAV vectors it was observed that the AAV2 ITR can function directly as a transcription promoter at a low level [84,85]. Recent studies [86] have shown that the AAV5 ITR is a very efficient transcription promoter. AAV5 transcription also has some other differences in that the two transcripts from the rep gene are terminated at a polyA site in the middle of the genome. Also, in AAV5 the rep protein does not appear to regulate expression of the *cap* gene as occurs in AAV2 [86].

6.3.3 REPLICATION

In a productive infection in the presence of a helper such as adenovirus [4,87], the infecting parental AAV SS genome is converted to a parental duplex replicating form (RF) by a self-priming mechanism that takes advantage of the ability of the ITR to form a hairpin structure (Figure 6.3). The parental RF molecule is then amplified to form a large pool of progeny RF molecules in a process that requires both the helper functions and the AAV *rep* gene products, Rep78 and Rep68. AAV RF genomes are a mixture of head-to-head or tail-to-tail multimers or concatemers and are precursors to progeny SS DNA genomes that are packaged into preformed empty AAV capsids [87,88]. Rep52 and Rep40 interact with the preformed capsid apparently to provide a DNA helicase function for DNA packaging [89].

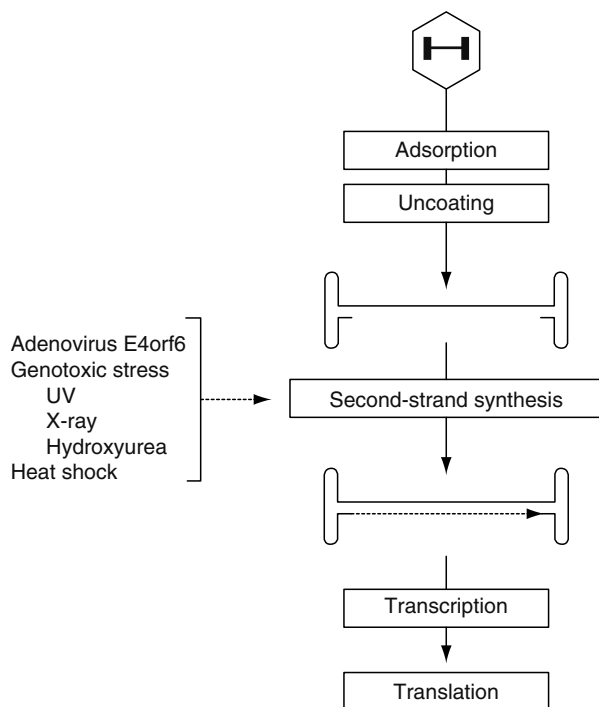

FIGURE 6.3 Metabolic pathway of AAV genomes in cells. Binding of AAV to cells is independent of helper virus functions. Trafficking of AAV to the nucleus may be enhanced by agents that interact with the ubiquitin pathway and proteasome processing. Conversion of the infecting SS genome to a duplex structure (or parental RF) through the process of metabolic activation (second-strand synthesis) can occur independently of helper virus. This process may be enhanced by infection with helper adenovirus genes such as E4orf6 or by other metabolic insults including genotoxic stress or heat shock. Treatments that enhance metabolic activation may enhance gene expression from the vector template. The single strand and duplex strands are drawn to show the ITR in the base-paired hairpin conformation that allows self-priming of replication to form a duplex template using cellular DNA polymerases. For further details see text. (Reprinted from Ferrari, F.K., Samulski, T., Shenk, T., and Samulski, R.J., *J. Virol.*, 70, 3227, 1996. With permission.)

The kinetics of AAV replication and assembly has been investigated [87,90]. In human HeLa or 293 cells simultaneously infected with AAV and adenovirus, there are three phases of the growth cycle. In the first 8–10h, the cell becomes permissive for AAV replication as a result of expression of a subset of adenovirus genes including E1, E2A, E4, and the VA RNA [82]. During this period, the infecting AAV genome is converted to the initial parental duplex RF DNA by self-priming from the terminal base-paired 3' hydroxyl group provided by the ability of the ITR to form a self-paired hairpin. This initial generation of a duplex genome also provides a template for transcription and expression of AAV proteins. In a second phase, from about 10–20h after infection, the bulk of the AAV *rep* and *cap* proteins are synthesized, and there is a large amplification of monomeric and concatemeric duplex AAV RF genomes to a constant level [90]. During the third phase of AAV growth, between 16 and 30 h, SS progeny molecules are synthesized by a strand-displacement replication mechanism and packaged into preformed capsids followed by accumulation of mature, infectious AAV particles [88,90].

The *rep* proteins perform important biochemical functions [4]. Rep68 and Rep78 bind to the ITR and are site-specific, strand-specific endonucleases that cleave the hairpin in an RF molecule at the site that is the 5' terminus of the mature strand. In addition, these proteins contain an ATP-binding site which is important for the enzymatic activity but not for binding to the ITR. Further, Rep78 and Rep68 have both DNA and RNA helicase activity. These *rep* proteins also regulate transcription [4,6,7]. Rep78 is a negative auto-regulator of the p5 promoter, i.e., of its own synthesis, but is an activator of the p40 promoter to enhance capsid protein production. Rep52 and Rep40 do not bind to the ITR but provide a helicase in assembly of mature particles. Also, the smaller *rep* proteins are anti-repressors and block the negative auto-regulation of p5 by Rep78 [87,91].

The AAV replication cycle is highly coordinated with respect to expression of *rep* and *cap* proteins and the relationship between replication and assembly [90,92]. Any vector production process that provides the *rep* and *cap* functions by complementation may decrease the efficiency of this highly regulated process. Nonetheless, AAV has one of the largest burst sizes of any virus and following infection of cells with AAV and adenovirus as helper, this may be well in excess of 100,000 particles per cell [1]. These considerations imply that a high yield of AAV vector particles per cell theoretically is attainable. Attaining high specific productivity is of crucial importance in developing scaled-up vector production because the ability to obtain maximum yields ideally requires high specific productivity (yield of particles per cell) or large biomass (total number of cells). Maximizing the specific productivity may avoid unnecessary increases in biomass.

6.3.4 GENETICS

The cloning of infectious AAV genomes in bacterial plasmids facilitated a molecular genetic analysis of AAV [93,94]. These studies showed that the *rep* and *cap* genes are required in

trans to provide functions for replication and encapsidation of viral genomes, respectively, and that the ITR is required in *cis* [4,6,83]. Mutations in the ITR have an Ori phenotype and cannot be complemented in *trans*.

Mutations that affect the Rep78 and Rep68 proteins have a Rep phenotype and are deficient for both the bulk replication and amplification of duplex RF molecules and for accumulation of SS, progeny genomes. A mutation that affected only the Rep52 and Rep40 proteins showed an Ssd phenotype in which duplex RF replication occurred normally but no SS progeny DNA accumulated.

The *cap* gene encodes the proteins VP1, VP2, and VP3 that share a common overlapping sequence but VP1 and VP2 contain additional amino terminal sequence. All three proteins are required for capsid production. Mutations that affect VP2 or VP3 have a cap phenotype, and block capsid assembly and prevent any accumulation of SS DNA. This indicates that VP3 and VP2 are primarily responsible for forming the capsid and that SS DNA does not accumulate unless it can be packaged into capsids. Mutations that affect only the amino terminus of the VP1 protein do not prevent accumulation of capsids or SS DNA but no infectious AAV particles accumulate. This phenotype has been described as either Inf or Lip (low infectivity particles).

These genetic studies together with additional biochemical studies show that Rep68 and Rep78 are required for replication, that VP2 and VP3 are required to form the capsid and that Rep52 and Rep40 appear to act in concert together with VP1 to encapsidate the DNA and stabilize the particles [4,5,89]. An additional role of VP1 appears to be to provide the phospholipase activity that is required for infectivity [75]. Thus, the Inf and Lip phenotypes may reflect the impact of various mutations on the lipase activity for endosomal release or on the packaging interaction between the capsid and rep proteins and the genome [95] (see also Section 6.8.1).

The rep proteins exhibit several pleiotropic regulatory activities including positive and negative regulation of AAV genes and expression from some other viral or cellular promoters, as well as inhibitory effects on the host cell. Because of the inhibitory effects of expression of *rep* gene products on cell growth, expression of rep proteins in stable cell lines was difficult to achieve, and this delayed development of AAV packaging cell lines [19]. For this reason, various approaches to AAV vector production have employed transient transfection of cells with AAV vector plasmids and complementing *rep-cap* plasmids. However, even in these transfection systems, the closely coordinated regulation of *rep* and *cap* gene expression and the interactions of the three AAV promoters [92] are important considerations in optimizing vector production.

6.4 AAV LATENCY AND PERSISTENCE

6.4.1 LATENCY

A U.S. Government screening program to assess human cell lines for vaccine production led to the observation that infection of primary cultures of human embryonic kidney cells

with adenovirus resulted in rescue of infectious AAV. The hypothesis that some cultures may have carried a latent form of AAV was tested directly [50] by infecting a human cell line, Detroit 6, with AAV at a high multiplicity of infection and passing the cell cultures until no infectious AAV genomes were present which required at least 10 cell passages. Following this, superinfection of the cultures with adenovirus resulted in rescue of infectious AAV. This provided an important demonstration of a way in which AAV may survive in a cell if conditions are not permissive for replication.

6.4.2 INTEGRATION

Analysis of a human cell line, Detroit 6, carrying latent AAV showed that the cells contained a relatively low number of AAV genomes that were integrated into the host cell chromosome mostly as tandem repeats. Early studies of cell lines stably transduced with AAV vectors expressing selectable markers, also showed that most stable copies in the cell existed as tandem repeats with a head-to-tail conformation [51]. Analysis of chromosomal flanking sequences showed that, for wild-type AAV, 50%–70% of these integration events occurred in a defined region [52,53]. When wild-type AAV infects human cell lines in culture, up to 50%–70% of these integration events occur at a region known as the AAVS1 site on chromosome 19 at 19q13ter. Both the specificity and efficiency of AAV integration are mediated by the AAV rep protein that binds to the ITR and to a site in the AAVS1 site on human chromosome 19 [54]. These studies were performed on cells in culture using high multiplicities of infection and it is noteworthy that naturally occurring, latent, integrated AAV genomes had not been well characterized in humans or any other animal species until recently. One study of wtAAV infection of rhesus macaques in the presence and absence of adenovirus infection detected by PCR amplification a single wtAAV–AAVS1 host cell DNA junction in only one of nine animals, suggesting that integration of AAV even under favorable conditions is very rare [96]. More recently [24], analysis of naturally occurring AAV detected wtAAV in only 9 of 175 human tissues samples that included tonsil, spleen, and lung. Furthermore all of the genomes appeared to be unintegrated episomal copies with no AAV–AAVS1 junctions being detected and the only possible cell–AAV junction that was detected appeared to be in a highly repeated element in chromosome 1. Consequently, the available evidence indicates that integration of wtAAV *in vivo* does not reflect the experimental *in vitro* observations, but rather appears to be a rare event and mostly AAV genomes appear to persist as episomes, as has also been demonstrated for AAV vectors (Section 6.4.3).

6.4.3 VECTOR PERSISTENCE

Some early studies with AAV vectors expressing selectable markers suggested that these vectors integrated also at AAVS1 [52,97]. But the vectors used in these studies also were contaminated by wild-type AAV particles and may represent rare integration events mediated by *rep* and enriched by the

selectable marker. In contrast, AAV vectors that contain no AAV *rep* coding sequences and no selectable marker have reduced efficiency and specificity for integration at the chromosome 19 AAVS1 site [56,57], and more usually persist in an episomal state. Initial evidence for this episomal persistence came from fluorescent *in situ* hybridization (FISH) analysis of cell lines transduced with AAV vectors which carried a low number of copies of an AAV vector as determined by Southern hybridization. FISH analysis of interphase nuclei compared to FISH analysis of metaphase chromosomes showed a reduced proportion of the cells carrying all the copies at a metaphase chromosomal site [57].

Studies performed *in vivo* in a variety of animal models now indicate that, in the absence of selective pressure, AAV vectors generally persist as episomal genomes. A number of studies have now shown that AAV can persist for extended periods when administered *in vivo* [68–72] and that the predominant form of the persisting vector genomes appears to be multimeric structures which are head-to-tail concatemers [98–101] that are circular [102–104]. How these head-to-tail multimers are formed is unknown but it cannot involve the normal AAV replication process because that requires *rep* protein and gives only head-to-head or tail-to-tail concatemers. Whether the circular concatemers are integration intermediates, as has been suggested for AAV integration [55,105], is also unknown. However, available evidence indicates that the majority of these head-to-tail concatemers are episomal and that integrated copies of vector in organs such as liver or muscle are very rare at least as judged from studies of AAV2 and AAV1 in rodents, rabbits, and nonhuman primates [96,106–108].

6.4.4 TARGETED INTEGRATION

Although AAV vectors that do not contain the *rep* gene do not integrate at the AAVS1 site at any significant frequency, they can be directed to integrate at the chromosome 19 site by supplying the *rep* gene in *trans*. For instance, a plasmid containing an AAV vector comprised of a reporter gene between the AAV ITRs and having a *rep* gene also in the plasmid, but outside the ITRs, resulted in integration of the AAV ITR vector cassette into the chromosomal site at 19q in human 293 cells *in vitro* [109]. Also, a baculovirus vector that contained an AAV reporter gene vector and separately contained an AAV *rep* gene was able to direct integration of the AAV vector into the AAVS1 site in human 293 cells [110]. Similarly, co-transduction of an epithelial tumor cell line (HeLa) or a hepatoma cell line (HepG2) with two hybrid Ad/AAV viruses, one carrying an AAV vector and the other expressing the *rep* gene resulted in integration of the AAV vector into the AAVS1 site [111].

In another study, the ability of AAV vectors to carry sequences that could mediate homologous recombination with chromosomal sequences was examined in cultured human cell lines. Homologous recombination at specific chromosomal sites could be attained [97] and additional studies showed that careful design of the interacting homologous sequences could

raise the efficiency of the process to about 1% [112]. However, this still requires a selective marker so its application to gene therapy may be limited.

6.5 AAV PERMISSIVITY

6.5.1 HELPER FUNCTIONS PROVIDED BY OTHER VIRUSES

The precise mechanism of the helper function provided by adenovirus or other helper viruses has not been clearly defined. These helper functions may be complex but relatively indirect and probably affect cellular physiology rather than providing viral proteins with specific functions in the AAV replication system. Studies with adenovirus [91] have clearly defined that only a limited set of adenovirus genes are required and these comprise the early genes E1A, E1B, E2A, E4orf6, and the VA RNA. The primary role of E1A is to transcriptionally activate the other adenovirus genes, but it may also transcriptionally activate the AAV p5 promoter. E1B and the E4orf6 protein of adenovirus interact to form a complex and these two genes provide the minimal function required to permit AAV DNA replication. The E2A gene of adenovirus has a complex function because it is a SS DNA binding protein that is directly involved in adenovirus replication but it also has an important role in regulating adenovirus gene expression. The role of E2A for AAV appears not to be a DNA replication function but to involve enhancement of AAV gene expression and particularly expression of AAV capsid protein. The VA RNA is also important in maximizing the level of AAV gene expression.

6.5.2 ALTERNATE PATHWAYS TO PERMISSIVITY

The concept that the helper virus renders the cell permissive by enhancing AAV replication in an indirect way is consistent with the evidence that helper virus genes do not appear to provide enzymatic functions required for AAV DNA replication and that these functions are provided by AAV *rep* protein and the cellular DNA replication apparatus [91]. This is also consistent with the observations that in certain cell lines, particularly if they are transformed with an oncogene, helper-independent replication of AAV DNA can occur if the cells are also treated with genotoxic agents such as UV or x-irradiation or with hydroxyurea [113,114]. In these circumstances, a small proportion of the cells could be rendered permissive for AAV replication but the level of replication and production of infectious AAV was very low.

6.5.3 REPLICATION OR PERSISTENCE

Two distinguishable phases of the AAV life cycle occur in permissive or nonpermissive cells. In either case the infecting single-stranded genome is converted to a duplex structure. There is evidence that the single-stranded genome may be converted to either linear duplexes or circular duplex molecules [102,103]. However, in permissive cells, in the presence of helper virus, this duplex genome then appears to follow the

pathway of bulk replication using the self-priming property of the ITR to yield a large pool of head-to-head and tail-to-tail RF molecules and ultimately a large burst of progeny particles. In nonpermissive cells, in the absence of helper, these genomes follow a pathway that leads to generation of head-to-tail concatemers that persist as episomes or become integrated into the host cell chromosome. In this nonpermissive state there are two important parameters that may have different consequences for AAV or AAV vectors. In either case there is no helper functions provided by another virus. However, for wild-type AAV, the rep gene is present and therefore may be expressed. This may explain why AAV integrates efficiently into the chromosome 19. For an AAV vector, the rep gene is not present and thus vectors may progress through the integration pathway more slowly, or not at all, and rather follow the pathway of persistence as a circular episome [106,107].

6.6 AAV VECTORS

6.6.1 DESIGN OF AAV VECTORS

The ability to generate AAV vectors was facilitated by the observation that molecular cloning of double-strand (DS) AAV DNA into bacterial plasmids followed by transfection into helper virus-infected mammalian cells resulted in rescue and replication of the AAV genome free of any plasmid sequence to yield a burst of infectious AAV particles [5]. This rescue may occur by a mechanism analogous to that used in reactivation of a latent provirus after superinfection of cells with adenovirus [115]. The general principles of AAV vector construction [4,5,7] are based upon modifying the molecular clones by substituting the AAV coding sequence with foreign DNA to generate a vector plasmid. In the vector, only the *cis* acting ITR sequences must be retained. The vector plasmid is introduced into producer cells that are also rendered permissive by an appropriate helper virus such as adenovirus. In order to achieve replication and encapsidation of the vector genome into AAV particles, the vector plasmid must be complemented for the *trans*-acting AAV *rep* and *cap* functions that were deleted in construction of the vector plasmid. AAV vector particles can be purified and concentrated from lysates of such producer cells.

The AAV capsid has three important effects for AAV vectors. There is a limit of about 5 kb of DNA that can be packaged in an AAV vector particle. This places constraints on inclusion of very large cDNAs and may also limit the ability to include extensive regulatory control sequences in the vector. The capsid also interacts with the AAV receptor and co-receptors on host cells and thus mediates cell entry. The capsid may also induce immune responses that could limit delivery of AAV vectors for some applications [116,117]. Except for the limitation on packaging size and the requirements for ITRs, there are no obvious limitations on the design of gene cassettes in AAV vectors. The ITR can function as a transcription promoter [84–86] but does not interfere with other promoters. Tissue-specific promoters appear to retain specificity [118,119] and a number of other regulated expression systems have now been used successfully in AAV

vectors [120–123]. Introns function in AAV vectors and may enhance expression, and more than one promoter and gene cassette can be inserted in the same vector. Importantly, transcription from AAV does not seem to be susceptible to *in vivo* silencing as shown by expression for over 6 years after delivery via multiple routes to multiple species, including humans [70,71,124–128].

6.6.2 PRODUCTION OF AAV VECTORS

AAV has one of the largest burst sizes of any virus as noted above and this implies that a high yield of AAV vector particles per cell theoretically is attainable [1,7]. Maximizing the specific productivity may avoid unnecessary increases in biomass during vector production. However, the cytostatic properties of the AAV rep protein presented an obstacle to generation of stable packaging cell lines for producing AAV vectors [129]. Consequently, AAV vector production initially was based on transient transfection of a vector plasmid and a second plasmid, to provide complementing rep and cap functions, into adenovirus-infected cells, usually the transformed human 293 cell line. The original vector production systems yielded a mixture of AAV vector and adenovirus particles and exhibited relatively low specific productivity [4,5]. Furthermore, recombination between the vector plasmid and complementing plasmids generated pseudo wild-type or replication-competent AAV (rcAAV) or other recombinant AAV species [130,131].

Upstream production of AAV vectors can now be accomplished by transfection-based methods in which adenovirus infection is replaced by DNA transfection with the relevant adenovirus genes, with engineered mammalian cell-based AAV production systems that do not require DNA transfection, recombinant herpes simplex viruses carrying AAV genes and genomes, or recombinant baculovirus (Section 6.6.3). Each of the vector production methods can give a specific productivity in excess of 10^4 vector particles per cell, some much higher. However, the DNA transfection systems may be limited in terms of scale-up for potential commercial vector manufacturing. Downstream processing and purification are now usually accomplished by chromatographic procedures that give a higher degree of purity than the earlier purification procedures using ultracentrifugation.

6.6.3 COMPLEMENTATION SYSTEMS

Multiple approaches have been taken with respect to upstream production of AAV vectors. First, in DNA transfection-based procedures, various modifications have been made to the complementing *rep-cap* cassette in an attempt to enhance specific productivity and to decrease production of rcAAV. One group demonstrated that expression of rep and cap proteins may be limiting [132] but two other studies [133,134] suggested that cap proteins were limiting due to downregulation of cap by increased production of rep. A packaging plasmid which has the Rep78/68 expression downregulated by changing the initiation codon AUG to ACG was reported

to give higher cap expression and higher yields of vector particles [134].

The only adenovirus genes required for full helper function are E1, E2A, E4, and VA, and transfection of the latter three genes into cells which contain the E1 genes, such as human 293 cells, can provide full permissivity for AAV [91]. The infectious adenovirus can be replaced as the helper with a plasmid containing only the adenovirus E2A, E4, and VA genes [135,136] that, together with the E1A genes supplied by 293 cells, provide a complete helper function in the absence of adenovirus production. Another group [137] used a plasmid containing nearly all of the adenovirus genome except the E1 region, but this yielded infectious adenovirus, probably by recombination with the E1 region in the cell. All of these systems require transfection with three plasmids, for vector, rep-cap, and adenovirus helper function, respectively. In contrast, Grimm et al. [138] combined all of the three adenovirus genes and the rep-cap genes into a single plasmid. In general, all of these approaches increased vector productivity compared to earlier systems such as pAAV/Ad [139], and productivities of at least 10^4 particles per cell have been reported. Nevertheless, these approaches still require DNA transfection and may be unwieldy for production scale-up.

An alternate approach to AAV vector production is to generate stable cell lines that contain the rep and cap complementing genes (packaging cells) or the vector genome or both (producer cells). In order to avoid DNA transfection, the cells must still be infected by a helper virus, adenovirus, but this can be removed readily as a result of advances in downstream purification processes (Section 6.6.5). Rescue of vector from a cell line having the vector stably integrated was demonstrated by transfecting the cells with a rep-cap helper plasmid and infecting with adenovirus [140]. Stable cell lines containing a rep gene, capable of generating functional rep protein, were constructed by Yang et al. [129] who replaced the p5 promoter with a heterologous promoter. Clark et al. [141] generated cell lines containing the rep and cap gene cassettes but deleted for AAV ITRs. Furthermore, the vector plasmid could be stably incorporated into the packaging cells to yield AAV vector producer cell lines [141–143]. Producer cell lines provide a scalable AAV vector production system that does not require manufacturing of DNA and may reduce generation of rcAAV. However, a new producer cell line must be generated for each individual AAV vector and this may be laborious.

A modification of the packaging cell line method is to use a cell line containing a rep-cap gene cassette that is then infected with an Ad/AAV hybrid virus. The Ad/AAV hybrid is an E1 gene-deleted adenovirus containing the AAV-ITR vector cassette [144,145]. After infection of cells containing the rep-cap genes, the AAV-ITR cassette is excised from the Ad/AAV, amplified and then packaged into AAV particles. This allows the same packaging cell line to be used for production of different AAV vectors simply by changing the Ad/AAV hybrid virus but it requires coinfection with adenovirus to provide the E1 gene function. The Ad/AAV hybrid viruses can also be used as delivery vehicles for AAV vectors [146–148] but this might suffer some disadvantages such as

induction of innate immune responses characteristic of the adenovirus capsid interaction with cells. Another packaging cell system was described [149] in which the packaging cell contains both a rep-cap cassette and the AAV ITR vector cassette, and both cassettes are attached to an SV40 replication origin. Also in the cells is a SV40 T-antigen gene that is under control of the tet-regulated system such that addition of doxycycline induces T-antigen that in turn results in amplification of the rep-cap and the vector cassettes. Subsequent infection of the cells with adenovirus renders the cells permissive for vector production.

Herpes simplex virus can be used in production of AAV vectors by generating HSV/AAV hybrid viruses. One approach [150,151] utilizes an HSV/AAV hybrid virus in which the AAV rep-cap genes, under control of their native promoters or altered promoters, were inserted into the HSV genome. This HSV/AAV rep-cap virus could generate AAV vector when infected into cells lines along with a transfected AAV vector plasmid or into cell lines carrying an AAV vector provirus. Alternatively, an HSV/AAV hybrid virus was constructed by inserting an AAV ITR vector cassette between HSV genome replication origins and then packaging this construct into an HSV particle [152–156]. Cells can be coinfecting with each of the recombinant herpes simplex recombinants, generating AAV vectors [157].

A recent approach to scalable AAV vector manufacture utilizes insect cells. In this system, baculovirus vectors containing rep-cap gene cassettes or the AAV-ITR vector cassette are used to infect insect cells and AAV vectors can be generated [158]. Since the original report, several groups have worked to develop this method of vector manufacture. Problems with instability of the recombinant baculoviruses and low infectivity of the vector particles were identified, and solutions were offered. Progress has been made in scaling this method, and it may become a viable approach to large-scale vector production, once all technical issues are identified and resolved [159–161].

6.6.4 REPLICATION COMPETENT OR WILD-TYPE AAV

Wild-type AAV is not a human pathogen but generation of pseudo wild-type or rcAAV during vector production needs to be avoided for several reasons. The presence of pseudo wild-type AAV in vector preparations may increase the likelihood of vector mobilization following a helper virus infection in the patient. This in turn could increase the likelihood of cellular immune responses to AAV proteins as well as causing significant alterations in the biology of the vector because of the pleiotropic effects of the rep proteins. The earliest AAV vectors [4,5] were produced by co-transfection with helper plasmids that had overlapping homology with the vector and this generated vector particles contaminated with pseudo wild-type AAV due to homologous recombination. Reduction of the overlapping AAV sequence homology between the vector and helper plasmids reduced, but did not eliminate, generation of pseudo wild-type AAV [130,139,140].

A combination of vector plasmid and packaging plasmid in which the AAV region containing the p₅ promoter was not

present in either plasmid prevented generation of wtAAV but some pseudo wild-type AAV (rcAAV) was generated at very low frequency by recombination [130,140]. This recombination was decreased to undetectable levels in a packaging system (split-gene packaging) carrying *rep* and *cap* genes in separate cassettes [130] so that three or four recombination events would be required to generate rcAAV. An alternate approach to decreasing pseudo wild-type or recombinant AAV is to insert a large intron within the *rep* gene in the helper plasmid so that any recombinants would tend to be too large to package in AAV particles [162].

It is likely that all vector production systems may have a propensity to generate pseudo wild-type AAV or other recombinants of AAV at some low frequency because it is not possible to eliminate nonhomologous recombination in DNA. Recent analysis of pseudo wild-type AAV recombinants has revealed that they appear to form through a mismatch repair pathway involving short regions of imperfect sequence identity of a size (~8–20 nt) that is small enough to occur at random in any stretch of DNA (B. Thorne, personal communication). Standardized assays to analyze and evaluate such rcAAV or recombinant species in AAV vector preparations have not yet been developed. However, to detect replication competent species, an assay that employs two cycles of amplification in non-*rep/cap* expressing cells and then a sensitive readout such as hybridization or PCR (rather than *rep* or *cap* immunoassays) is likely to be required [144].

6.6.5 PURIFICATION

Historically, AAV was purified by proteolytic digestion of cell lysates in the presence of detergents followed by banding in CsCl gradients to concentrate and purify the particles and separate adenovirus particles. Significant progress has been made in the downstream processing of AAV vectors and this has led to much higher quality and purity. This is critically important for preclinical studies and clinical trials. The reliance upon the original CsCl centrifugation techniques is being abandoned because it is a cumbersome procedure that does not provide high purity, it may inactivate some AAV vector and it is difficult to envision its use for commercial production. Several groups have employed nonionic iodixonal gradients as an initial bulk-recovery method [163,164]. A variety of chromatographic methods using standard ion-exchange resins; hydrophobic interaction resins; and antibody, heparin, or sialic acid affinity resins in both conventional filter and HPLC formats have been employed [138,161,165–184]. These results demonstrate the feasibility of developing scalable and well-controlled purification methods for AAV vectors that could lead to commercialization.

6.6.6 ASSAY OF AAV VECTORS

Characterization and testing of AAV vectors are critical elements for clinical development. While there is variability in assay methods and properties measured, the minimal testing should include a measure of vector strength by determining

the concentration of capsids containing vector genomes, a measure of total capsids, a measure of “infectivity,” an assessment of vector purity, and a measure of the vector potency.

Early in the development of AAV vectors, the concentration was measured using dot-blot hybridization of vector genomes and comparing the signal intensity to a standard curve derived from a plasmid containing the vector genome [185]. Recently, more precise and quantitative assays have largely supplanted the dot-blot assay. Measurement of vector concentration by real-time PCR amplification of the vector genome has resulted in increased precision and accuracy [166]. These assays measure the number of vector genomes that are encapsidated and thus protected from digestion by DNase. Consequently, vector concentration is expressed in units of DNase-resistant particles (DRP). This type of assay can be used to facilitate reliable quantitation of vectors during process development for production of multiple AAV serotypes [151].

Infectivity measurements of vector preparations are important mainly to establish a consistency of vector manufacturing rather than being an indication of vector potency *in vivo*. By their nature, AAV vectors are replication defective, so *in vitro* measurements of infectivity are artificial and generally require complementation with *rep* and *cap* as well as helper virus functions. Initially, vectors were measured by an infectious center assay in which wtAAV as a source of *rep* and *cap* and adenovirus were added along with dilutions of vectors to infect cells [186]. Cells that were replicating the vector genome were then scored by DNA probe hybridization to individual cells collected on a filter, hence the term infectious center. The development of cell lines containing *rep* and *cap* [187] has allowed infectivity measurements of vectors to be performed in a 96-well format assay that yields data with higher precision than the infectious center assay, and is amenable to a high throughput format that can be used for purification development [188]. In conjunction with the real-time PCR assay, this type of infectivity assay yields data on particle to infectivity (P:I) ratios of vectors with high precision thus aiding process development. It is important to recognize that the apparent particle to infectivity ratio of vectors based on different serotypes of AAV may be quite different due to the natural variation that exists in receptor usage and potentially in intracellular trafficking among the serotypes. A cell line containing *rep* and *cap* may be more efficiently transduced by one serotype as compared to a second serotype, yielding differences in P:I ratios that may not be reflective of differences in vector potency *in vivo* but rather a difference in the ability of a given serotype to efficiently infect the *rep/cap*-expressing cell line used in the assay.

It is imperative to establish an assay to measure expression of the transgene. For a phase I clinical trial it may be acceptable to evaluate transgene expression in cultured cells following transduction by the vector as a function of increasing multiplicity of infection using a Western blot of cell extracts. However, for later-stage clinical development, a more relevant potency assay will need to be established and applied to all vector lots during testing and release. The nature of the

potency assay depends on the properties of the expressed transgene product. For example, if the product is a cytokine, a potency assay could evaluate the binding of the cytokine to its receptor, or a downstream signal generated in the cell as a result of the cytokine binding.

Other aspects of vector preparations are also important to measure. The ratio of empty to full capsids can be determined using a capsid ELISA [189], negative-stain electron microscopy analysis [171,172], optical measurements [173], velocity sedimentation analysis, or a measure of total protein compared to concentration of genome-containing vectors. Vector purity is usually assessed by acrylamide gel electrophoresis. For clinical development it is important to measure the residual contaminants including host cell protein and DNA, as well as serum components. In cases where the vector is manufactured from a cell line of tumor origin, such as HeLa cells or A549 cells, a determination of the residual amount and size of host cell DNA is an important part of the release testing. If the vector is of high purity, its aggregation state can be assessed by using dynamic laser light scattering to measure the hydrodynamic radius. This provides a size distribution of particles in solution and the relative amount of particles in each size class [174]. This measure is useful for vectors at high concentration and can aid in the development of formulations that maintain vectors in a monomeric, nonaggregated state.

6.7 GENERAL PROPERTIES OF AAV VECTORS

6.7.1 SEROTYPES OF AAV

The growing appreciation of natural variation among AAV isolates and application of this knowledge to vector production and usage has added to the attractiveness of rAAV as a gene therapy modality. There are 11 serotypes of AAV reported, and more than 100 capsid sequence variants have been characterized from a number of species, both human and nonhuman [175]. Some of these new variant capsids have been used to make vectors, thus expanding the range of capsid sequences that can be employed with the goals of increasing vector transduction efficiency, decreasing vector dose, improving targeting using inherent tropisms, and avoidance of a preexisting host neutralizing antibody response.

Complete coding sequence information is available for serotypes AAV1 to AAV6, AAV10, and AAV11 [38–43,46,47] as well as capsid gene sequences for AAV7, AAV8, and for over 100 capsid gene sequences isolated from multiple animal and human species [21,23]. AAV6 is a recombinant between AAV1 and AAV2. In addition, there are two isolates and sequences of AAV3 that differ from each other in a number of amino acids in both rep and cap [46]. Receptor usage by these viruses varies and is reflective of their sequence diversity [58–60,190–198]. Sialic acid and heparin are the most commonly used primary receptors for cell binding. A number of secondary receptors used for cellular entry have been identified. Some serotypes are able to use multiple secondary receptors, such as AAV2 with at least four. This variation in receptor

usage, at least in part, is responsible for the increasingly appreciated efficiency of vectors of different serotypes to transduce specific cell types and tissues *in vivo*. The serotypes of AAV are highly related to each other with the notable exception of AAV5 [42,43]. AAV5 is the most distantly related of the serotypes, and also displays a serotype-specific terminal resolution site (TRS) in its ITR [195]. Even though rep proteins from other serotypes will bind the AAV5 ITR, they do not efficiently cleave at the TRS.

Most early studies with AAV vectors utilized serotype 2. A number of animal studies demonstrated transgene expression that persisted for months to years in muscle, liver, CNS tissues, lung, and retina [68–71,98–101,109,118,124]. As other serotypes of AAV have been used in vector production, it has become apparent that there are distinct and often advantageous differences among vector serotypes in their efficiency of transgene expression in various tissues and cell types, at least in small animal models [175]. It is difficult to list a hierarchy of transduction efficiencies of target organs relative to individual serotypes because there are conflicting data in the literature both with regard to organ tropism and the threshold of expression differences as reported from different laboratories. These differences may reflect differences among strains of animals used in the studies, or differences in vectors produced by different investigators. It is worth noting that the dramatically increased efficiency of transgene expression by several of the newer serotypes and isolates of AAV capsids relative to the classic AAV2-based vectors may not translate when tested in larger animals, so caution should be exercised when evaluating data from only mice and rats, for example [176].

Cellular receptors play an important role in AAV vector tropism. For instance, the increased transduction efficiency for AAV5-based vectors in mouse airway may be due in part to the demonstrated increase in binding to the apical surface of polarized airway epithelial cells [62,199–202]. However, cellular trafficking of vectors also plays a role in transduction efficiency [67]. Approximately 5% of hepatocytes are transduced as measured by transgene expression, following delivery of AAV2-based vectors to mice in spite of the fact that every cell contains vector DNA one day following administration [203]. This shows that events postbinding and internalization are important for successful transduction (Section 6.8.2). Interestingly, when vectors based on AAV5 or AAV8 were administered to mice, increased numbers of hepatocytes were transduced, up to 100% and increased levels of transgene expression were observed [21,204,205].

In the murine CNS, AAV4 vectors transduce ependymal cells almost exclusively, while AAV5 vectors transduce both neurons and astrocytes [206]. In retina, a number of studies have demonstrated large differences among serotypes in the ability to transduce photoreceptor cells and the retinal pigmented epithelium [175,190,207,208].

Vectors based on AAV6 and AAV8 have been shown to efficiently escape from the blood stream and transduce most muscle groups in small animals when administered systemically [209–212]. Thus AAV6 and AAV8 may have potential for

treating diseases such as muscular dystrophy in which multiple muscle groups are affected. A recent report demonstrates nearly complete transduction of a perfused skeletal muscle in both mice and monkeys with AAV6 and AAV8 vectors, but not AAV1 vectors [213]. This result makes it likely that a successful treatment for a number of muscle diseases could be developed with these serotypes.

While it is clear that there is great variability among different AAV serotypes and capsid sequences in the ability to transduce cells, tissues, or organs efficiently depending upon the route of administration and the capsid sequence, further work is needed to understand the relative importance of the factors contributing to differences in transduction efficiencies with different serotypes of AAV vectors.

6.8 VECTOR METABOLISM

Early studies of AAV vectors led to the suggestion that the major factor limiting the efficiency of transduction was the process of converting the SS genome to a duplex molecule. More recent studies are beginning to reveal a complex pathway of events that impact upon the function of AAV vectors. Thus, delivery of the AAV vector genome to the cell nucleus may be influenced by the availability of specific receptors and co-receptors for AAV binding and entry and by cellular trafficking including a potential diversion of AAV particles into an ubiquitin-mediated proteasome degradation pathway. After the genome is successfully delivered into the nucleus, a succession of events converts the vector into larger concatameric molecules. Most of these concatameric molecules appear to be maintained for prolonged periods, perhaps for the lifetime of the cell, within the nucleus as episomal molecules, and very few if any integrate into the host genome [24,107,108].

6.8.1 CELLULAR BINDING AND TRAFFICKING OF AAV VECTORS

The ability of a vector particle to interact with a specific receptor molecule on a target cell is critical for successful transduction. The primary binding receptors identified, heparin sulfate and sialic acid, are commonly found on many cells and are also the receptor molecules utilized by a large number of viruses besides AAV. This suggests that additional receptors that lend more specificity to attachment and penetration of cells might exist and several such co-receptors have been identified (Section 6.7.1).

While cellular attachment is the critical first event, it does not necessarily imply that the vector will be able to efficiently transduce the cell. This has become increasingly apparent from a more detailed understanding of the trafficking and uncoating of AAV vectors [62–67]. For example, polarized human airway epithelial cells are transduced with varying efficiencies by AAV2-based vectors depending on the route of delivery and entry from the basolateral surface results in about a 200-fold increase in gene expression in the cells

compared to vector administered from the apical surface [62,214]. Surprisingly, the difference in vector attachment to the two cell surfaces is only about fivefold. This finding led to the discovery that the vectors traffic differently in these cells depending on the side of the polarized airway to which they bind [62,214]. Vectors administered from the apical surface are modified by ubiquitination. The addition of proteasome or ubiquitin-ligase inhibitors led to an increase in transduction following apical administration of vectors. These comparisons of differences in binding and differences in transduction efficiency have led to an appreciation that cellular trafficking of vectors is important for successful transduction, and that it may differ between cell types and even within individual polarized cells between the apical and basal surfaces.

After binding to the cellular receptor, AAV2 is internalized by an endocytosis mechanism that for heparin binding appears to be mainly via clathrin-coated pits [215,216] although some clathrin-independent uptake may also occur [217,218]. Additional studies using fluorescent Cy3-conjugated AAV2 vector particles showed that endocytosis can be mediated by an $\alpha_v\beta_3$ integrin/Rac1 dependent mechanism and that subsequent trafficking to the nucleus requires activation of PI3-kinase pathways as well as functional microtubules and microfilaments [217,218]. Evidence for the involvement of early endosomes in AAV trafficking, as well as the involvement of microtubules and microfilaments, exists mainly from the use of inhibitors [64,65]. Recent studies indicate that AAV can traffic through late and recycling endosomal compartments in a dose-dependent manner [66]. Escape of vector particles from endosomal compartments into the cytoplasm appears to be mediated by a latent phospholipase activity resident in the N-terminus of VP1 [75,219] that becomes externalized and active in the endosome. Transcytosis of AAV vector particles has been reported to allow trafficking through endothelial and epithelial barriers that would normally restrict their spread [220].

There is consensus that, in the absence of helper virus, there is a block at the step of import of viral vector genomes into the nucleus of the cell [216,221,222]. However, there is no clear understanding as to how or where the viral genome is uncoated or how the vector enters the nucleus, although it does not appear to use the nuclear pore complex for this step [222,223]. Evidence has been presented that, once the capsid enters the nucleus, the rate of disassembly may vary among serotypes and this may influence transgene expression levels in a tissue or target cell type [224,225]. Recent work from Akache et al. [226] provides strong evidence that cellular proteases, cathepsins, act on the incoming capsid in the endosome, perhaps leading to efficient uncoating once the cathepsin-cleaved capsids enter the nucleus of the cell. Nuclear entry and uncoating are areas of AAV biology that remain incompletely understood.

6.8.2 VECTOR DNA METABOLISM

In order for rAAV vectors to transduce a cell, the SS DNA genome must be converted into a double-stranded form [49]

as shown in Figure 6.3. Several reports, based upon transduction of cells *in vitro*, indicated that this single strand to double strand conversion step might be rate limiting in the absence of helper virus coinfection [227–229]. The adenovirus E4 or F6 protein has been shown to increase the level of transgene expression and to increase second-strand DNA synthesis [230]. More recently a cellular protein that bound to the single-stranded d-sequence of the AAV ITR was identified as the well-known FK506-binding protein (FKBP-52). This protein has been implicated in controlling the conversion of SS to DS DNA in vector-infected cells and phosphorylation of FKBP-52 influences its ability to bind the d-sequence [231–234]. When phosphorylated at tyrosine residues (by the epidermal growth factor receptor protein tyrosine kinase), FKBP-52 binds to the SS d-sequence region of the ITR that is present in infecting vector genomes, and second-strand DNA synthesis is impaired. The efficiency of transduction in a number of cell types *in vitro* and *in vivo* correlates with the phosphorylation state of FKBP-52. In HeLa cells, overexpression of a cellular phosphatase (TC-PTP) that can use the FKBP-52 protein as a substrate led to dephosphorylation of the FKBP-52, an increase in AAV second-strand DNA synthesis, and an increase in transgene expression. Transgenic mice expressing either the wt or a catalytically mutant form of the phosphatase were created. Hematopoietic stem cells from transgenic mice expressing the wt TC-PTP phosphatase were transduced by an AAV2 vector, but those from mice expressing the phosphatase-negative mutant were not. These results suggest that the block to second-strand DNA synthesis is due to binding of FKBP-52 to the d-sequence of infecting vector genomic DNA and that this binding is regulated by phosphorylation.

A second mechanism for conversion of SS DNA to DS DNA has been proposed. In this model, annealing of negative and positive sense SS DNA genomes, both of which are packaged with equal efficiency into individual AAV particles, occurs in cells to form ds DNA in the absence of second-strand DNA synthesis. There is some experimental evidence for this self-annealing model both *in vitro* and *in vivo* [235] although it is not consistent with observations that AAV infection displays single-hit kinetics [79]. However, it is possible that double-stranded DNA may be formed via either pathway in cells transduced with rAAV vectors.

Further support for the idea that conversion of single-stranded vector genomes into transcriptionally active double-stranded forms is crucial for transduction and is a rate-limiting step comes from a study demonstrating that vector genomes smaller than half the size of the AAV genome are packaged in multiple ways [236]. Particles contain either a single vector genome, two copies of the small vector genome, or a covalently linked double-stranded hairpin molecule equivalent to a replicative intermediate formed during vector genome replication. In a separate study, vectors containing these small self-complementary genomes (scAAV) were shown to be relatively insensitive to the enhancing effects of adenovirus on transduction, resistant to the effects of DNA synthesis inhibitors, and displayed altered kinetics of transgene

expression *in vivo* [237]. When these vectors were administered to mice, an increase in transduction from the usual 5% to more than 50% of hepatocytes was observed [205,238,239]. These results strengthen the model that second-strand DNA synthesis is a rate-limiting step for transduction, at least in hepatocytes. These self-complementary vector constructs are attracting attention since they seem to overcome the barriers to efficient transduction seen with many single-stranded AAV vectors [240].

Once the vector genome is converted into a double-stranded DNA molecule, a number of fates have been reported. One group of studies convincingly demonstrates that the viral genome circularizes, and that these circular monomers recombine at the AAV ITRs to form larger circular concatemers of head-to-head, head-to-tail, and tail-to-tail arrangements both *in vitro* and *in vivo* [102,103,241,242]. These genomic concatemeric molecules, containing a “double-D” ITR structure (an ITR bracketed on each side by the d-sequence and presumably formed by an ITR-ITR recombination event), persist extra-chromosomally as episomes and are responsible for the long-term persistent transgene expression seen with rAAV vectors. SCID mice that are deficient in DNA-dependent protein kinase activity (DNA-PK) lack the ability to convert rAAV genomes into circular concatemers [243]. Rather the concatemers formed in these mice appear to be linear molecules, suggesting that DNA-PK activity is involved in the formation of circular episomes. In both normal and SCID mice, transgene expression persisted for at least one year at similar levels. A second group of reports [235,244,245] suggest that vector genome concatamerization occurs by recombination of linear monomeric genomes. It is possible that both mechanisms of concatamerization are operative and perhaps there are tissue-specific differences, such as muscle or liver, in which one or the other pathway is more likely to occur. Despite the differences reported on the substrate for concatemer formation, it is clear that long-term transgene expression is mainly mediated by episomal concatemers of viral genomes rather than integrated molecules [106,107]. A recent report provides evidence that there are multiple fates for the double-stranded DNA once it is formed, and that the rate-limiting step for successful transduction of a cell leading to long-term transgene expression may be stabilization of the double-stranded vector DNA [246].

Evidence that DNA repair and recombination are directly involved in circularization or concatamerization of AAV vector genomes is supported by recent insights into possible biochemical mechanisms of their formation [243,245]. In fibroblasts from a patient with ataxia telangiectasia (ATM) there is greatly enhanced formation of AAV vector circular forms and enhanced integration of the head-to-tail concatemers as proviral genomes [247]. The ATM gene is a PI-3 kinase that regulates the p53-dependent cell cycle checkpoint and apoptotic pathways and in these ATM cells the DNA double-strand break (DSB) repair systems that normally can be activated by UV irradiation appear to be already activated maximally. Consequently, AAV vectors in these cells yield a high level of transduction and this is not activated further by

UV irradiation [247], in contrast to the observations in normal cells [227–229]. Additional evidence that DSB repair pathways are involved in regulating AAV transduction comes from observations that the proteins Ku86 and Rad52, which are known to recognize DNA hairpin structures and DNA termini and to promote repair of DSB, could associate with the AAV DNA ITR [248].

6.8.3 DUAL VECTORS

The ability of AAV vectors to form concatemers and the evidence that intermolecular recombination is directly involved in their generation has been used to extend the capacity of AAV vectors beyond the 4.5 kb payload limit in the dual-vector system. It is now possible to divide a gene expression cassette that is up to 9 kb in size between two AAV vectors and, following coinfection with both vectors, take advantage of the intermolecular recombination to generate the intact expression cassette. This process has been demonstrated both *in vitro* and *in vivo* and shows remarkable efficiency [244,249–251].

Both *cis*-activation [249] and *trans*-splicing [250] modes of dual vectors have been described. In *cis*-activation, one vector carries a high efficiency enhancer of transcription and the other vector carries the transcription promoter and the gene sequence to be expressed. Recombination after infection places the enhancer in *cis* with the expression cassette and increases transcription. In the *trans*-splicing mode, one vector carries the transcription promoter and the 5' part of a gene, and the other vector carries the 3' part of the gene. By judicious arrangement of splice donor and acceptor sites, the appropriate mRNA can be derived from the read-through transcript using the heteroconcatemeric template. Interestingly, the intervening ITR sequence does not appear to inhibit read-through transcription or RNA splicing [249,250]. It does appear, however, that in these dual-vector constructs, some transcription may be seen directly from the ITR either because of its own promoter activity or because of enhancement from the *cis*-acting elements provided by the second vector [249,250].

Cis-activation was demonstrated using a vector containing super-enhancer elements comprising parts of the SV40 and CMV enhancers together with a second vector containing the luciferase gene. This dual enhancer combination gave robust expression of luciferase in mouse skeletal muscle at levels that compared well with that from administration of a single vector expressing the same elements [249]. In another study, two vectors containing a LacZ reporter cDNA or an enhancer promoter cassette from human elongation factor EIF α , respectively, were shown to yield reporter gene expression in livers of mice after dual administration by portal vein injection [244].

Trans-splicing was demonstrated using one vector that contained a transcription promoter and the 5' part of the erythropoietin (EPO) genome locus and a second vector that contained the 3' region of the EPO locus [250]. Dual injection of the two vectors into mouse skeletal muscle provided therapeutic levels of EPO sufficient to protect the mice from adenine

induced anemia. Similarly, another group used two vectors, one containing the CMV promoter with the 5' half of the LacZ gene and the second containing the 3' half of the LacZ gene [251]. These vectors also gave robust expression of intact LacZ after dual injection into mouse skeletal muscle. Improvements in the design of these *trans*-splicing has led to greatly increased efficiency of transgene expression [252,253], with a recent report demonstrating equivalent transgene expression from a set of *trans*-splicing vectors compared to a single AAV vector encoding the same final mRNA.

The dual-vector approach to packaging and expressing large genes in rAAV vectors was extended to an investigation of the use of homologous recombination between two vectors, each containing an overlapping DNA sequence to drive recombination [254,255]. The data demonstrated that non-ITR-mediated recombination between two genomes can occur and result in expression of a large transgene. However, the efficiency of this homologous recombination process may vary depending on the tissue type. In mice, the efficiency in muscle was low and yielded less than 1% of the level of expression seen from an intact vector, whereas in lung the efficiency approached that seen with an intact vector construct.

The dual-vector approaches to packaging and expressing larger transgenes in AAV particles offer a way to almost double the payload capacity of AAV vectors that should extend the utility of this vector system to larger genes. Careful analysis will be required to determine additional safety issues or risks this approach might present for clinical use. For instance, for some applications such as hemophilia A, it may be deleterious to express a partial FVIII protein. Nonetheless, as these systems are better characterized they may well prove to have clinical utility.

6.8.4 CAPSID MODIFICATIONS AND TARGETING OF VECTORS

There is an interest in modifying the capsid structure of AAV vectors to target transgene expression to a specific cell type [28,29]. Multiple approaches have been taken. One approach involves attaching ligands. Thus, retargeting was obtained by the use of a bi-specific antibody having one arm specific for AAV capsids and the second arm specific for a receptor on a cell [256] while not involving capsid modifications, this method did achieve vector targeting to the specificity of the antibody used. Another group conjugated growth factors to the capsids [257] and achieved increased transduction in cells expressing receptors for the growth factors. A third group engineered an immunoglobulin-binding domain into the capsid of AAV and then used this modified particle to bind various targeting antibodies [258].

A second approach to vector targeting involves alterations or additions directly to the amino acid sequence of the capsid proteins. The overall goal of this approach is to replace the natural receptor interactions of the capsid with a receptor interaction that would be engineered into the capsids as an amino acid sequence or receptor ligand. There are a number of studies that describe such attempts at vector retargeting,

and some reports describe a systematic analysis of insertions into the capsid and the effect on vector yield and tropism [258–261]. It is possible to generate vector particles with modified tropism as a result of amino acid substitution or addition to the capsid and further work will reveal the usefulness of this approach for clinical gene therapy applications. Peptide ligands that are specific for various receptors have been successfully engineered into AAV2 capsid proteins VP1, 2, and 3 with the resultant vector target specificity being achieved [258,260,262–264]. Capsid retargeting can also be achieved by screening a library of capsid protein mutants containing random insertions of short amino acid sequences on a target cell type of interest [265–267].

Several groups have produced vectors containing a mosaic of capsid proteins from two different serotypes [268,269]. The resulting particles retained properties from each serotype, but some combinations led to properties unique to the mosaic. Work is under way in several labs to identify domains of one serotype that lend it a unique property, and then combine these domains into chimeric capsids [270,271]. Lastly, Warrington et al. [272] demonstrated that capsids of AAV could be formed without VP2, and then constructed AAV particles containing assorted peptides fused to the N-terminus of VP2, including green fluorescent protein. This approach may allow the generation of specifically targeted vectors but this objective has yet to be achieved.

6.9 PRECLINICAL STUDIES, HOST RESPONSES, AND TOXICITY

AAV vectors will most likely be applied to target nondividing cells with infrequent delivery in view of the episomal persistence of the vector. A substantial body of studies have now been carried out to analyze the safety and biodistribution of AAVs vector to support a number of clinical trials. These studies have generally shown a good safety profile and provided information on host immune responses, which for AAV vectors appear to be relatively modest. In addition, the biodistribution studies have allowed a determination of the integration frequency of AAV vector genomes and support the concept that generally AAV vectors persist as episomes. Nevertheless, it is important to assess the likelihood of integration and the possibility of resulting deleterious effects, and to assess host responses particularly if they would limit application of AAV vectors.

There have been few reports or indications of toxicity mediated by AAV vectors. The first safety studies of AAV vectors were conducted to support the clinical trials of an AAV-CFTR vector. Toxicity was examined extensively for a vector expressing the CF transmembrane regulator (CFTR) protein following delivery of these AAV-CFTR vector particles directly to the lung in rabbits and nonhuman primates. In rabbits, the vector persisted and expressed for at least 6 months but no short- or long-term toxicity was observed and there was no indication of T-cell infiltration or inflammatory responses [68]. Similarly, in rhesus macaques, AAV-CFTR

vector particles were delivered directly to one lobe of a lung and also persisted and expressed for at least 6 months [273]. Furthermore, no toxicities were observed by pulmonary function testing, by radiological examination, analysis of blood gases and cell counts and differential in bronchoalveolar lavage or by gross morphological examination or histopathological examination or organ tissues [273]. Importantly, preclinical studies of the biodistribution of the AAV-CFTR vector following pulmonary delivery in rabbits and macaques showed that there was minimal spread of vector to organs outside of the lung, no vector in gonads, and no toxicity in any organ. However, use of different delivery routes may lead to more extensive biodistribution.

Studies in rhesus macaques were also performed to determine if the AAV-CFTR vector could be shed or mobilized from a treated individual [37]. AAV-CFTR particles were delivered to the lower right lobe of the lung and high doses of both wild-type AAV particles and an adenovirus capable of replicating in macaques were administered to the nose of the animals. These studies indicated that the vector was not readily mobilized and that the probability of vector shedding and transmission to other individuals was likely to be low. The favorable safety profile of AAV in these preclinical studies has been predictive of a similar safety profile observed in clinical trials of the AAV-CFTR vector in CF patients [9–13]. These clinical studies showed that there was only a very low level of vector shedding in sputum after administration to the lung and in a study in conjunction with an aerosol delivery trial, it was demonstrated that there was no transmission of vector to others such as health care workers [274].

An AAV-FIX vector was studied in preclinical rodent and canine models in support of clinical trials in hemophilia B patients via intramuscular injection or intravenous delivery via the hepatic portal vein. The vector showed a good safety profile when administered by intramuscular injection to hemophilia B dogs that were reflected in the intramuscular injection clinical trial [14] (Section 6.10). However, in a second clinical trial, following intravenous hepatic administration of the AAV-FIX vector, patient semen was positive for the vector genome for a few weeks. This indicated that vector had apparently been distributed to gonads but further investigation indicated that the vector was not present in motile sperm [275]. A more extensive study of AAV-FIX vector delivery by both intramuscular and intravenous routes, using a sensitive DNA-PCR assay, showed that there was a dose-dependent detection of vector genomes sequences in the gonads of males of several animal species including mice, rats, rabbits, and dogs [275]. However, although testis tissue of these species was positive for vector for a short period after delivery, in both rabbits and dogs, semen and sperm were negative for vector sequences, suggesting that the risk of inadvertent germline transmission of vector sequences after intramuscular or intravenous delivery is extremely low [276,277]. Additional studies of AAV2 vectors expressing FIX [278] or α -1-antitrypsin (AAT) [279] genes, after intramuscular delivery into rhesus macaques, again showed excellent safety profiles and did not detect transmission of vector sequences to gonads. On the

other hand, an AAV1 α -1-antitrypsin vector delivered to mice and rabbits by intramuscular injection did show appearance of vector sequences in rabbit semen but this was dose-dependent and declined over a period of 60 days. Additional safety and biodistribution studies have been reported for an AAV1-calpain vector delivered intravenously to mice [280]. Several safety and biodistribution studies for AAV2 or AAV4 vectors delivered subretinally in rodents, dogs, and cynomolgus monkeys have been reported and all show minimal toxicity of the vector and almost no spread of vector beyond the retina [281–284]. Although one study of subretinal delivery of an AAV2 vector did show ocular inflammation, it was subsequently demonstrated to be due to impurities in the vector preparation [282,283]. Even if biodistribution studies show transfer of vector genome sequences to gonads, provided that the signal is dose dependent and disappears over time and does not appear in motile sperm, then vertical transmission is considered highly unlikely.

As discussed in Section 6.4.3, a variety of studies indicate that AAV vectors persist for prolonged periods as episomal structures and that integrated copies of AAV vector genomes are very rare, including in such tissues as liver and muscle [96,106–108]. Some of the more extensive biodistribution studies with AAV2 and AAV1 vectors in rodents and rabbits [106–108] using several hundred animals facilitated an estimation of the maximum integration frequency that is likely. These studies [106] lead to the estimation that the integration frequency of AAV vectors is several orders of magnitude lower than the spontaneous rate of mutation for human genomes so that the likelihood of insertional mutagenesis by AAV vectors is very low. Indeed, using similar methods of analysis the integration frequency of AAV vectors in animals is as rare as that following transduction with adenovirus or plasmid DNA vectors. After discussion of this information at a public meeting [285], the U.S. FDA issued guidelines for long-term follow-up of gene transfer research subjects in clinical trials which indicate that AAV is considered as a nonintegrating vector.

Consistent with its low integration frequency, AAV has never been associated with any disease or shown to promote tumorigenesis. Indeed, several studies show that AAV or AAV ITRs can inhibit tumorigenesis [286,287]. Also, studies in rhesus macaques infected with wild-type AAV2 by intramuscular, intravenous, and intranasal routes showed that although there were some antibody responses against the AAV capsid, there was no cellular immune response to AAV components and there was no indication of any tumorigenesis [96]. However, there was an anecdotal observation of tumors occurring in mice having a homozygous mutation in the β -glucuronidase gene, that were treated as neonates via head vein injection with an AAV vector expressing β -glucuronidase (BGUS). These mice exhibit the lysosomal storage disease mucopolysaccharidosis VII (Sly syndrome) that is characteristic of the human disease and, if left untreated, the animals die in several months. The mice treated with the AAV-BGUS vector survived up to 18 months and showed a remarkable biochemical and physiological correction of the disease [288]. However, at

12–18 months some of these mice developed hepatic tumors but vector genomes could not be found in all of the tumors and not at any higher frequency than in nontumor tissue from the same animals [289]. Thus, these tumors did not appear to be caused by insertional mutagenesis and clonal expansion. A more recent study by the same group [290] in the same mouse model did report integrated vector in the tumors but there is no explanation as to the disparity with the previous result. Furthermore, most other studies of AAV vectors, including intravenous delivery in the same animal model and a variety of other animal disease models, have never shown any tumor formation [289,291,292]. The only other study that has reported tumors, after transduction of OTC deficient mice with an AAV-LacZ vector, concluded that the phenomenon was apparently related to expression of the transgene [293]. The tumors in the MPSVII mice remain as an unexplained observation since in the first study there were no sham-treated control mice that survived as long as the treated mice [288]. In the second study a promoterless vector was used but it still retained the transcriptionally active ITR so it may be an inadequate control [289]. It is possible that the tumor formation is specific for this disease, or the particular animal model, or for ectopic production of BGUS, or to some other unknown cause and does not have any direct relation to the use of an AAV vector. However, some caution needs to be exercised, and MPS VII disease possibly may not be an attractive candidate for gene therapy with an AAV vector.

Host immune responses, including innate immune responses, cellular immunity, or humoral antibody responses, may hinder the use of some gene therapy vectors. However, administration of AAV vectors does not induce pro-inflammatory cytokines, unlike adenovirus vectors [48]. Cellular binding and biodistribution of AAV vectors is controlled by the viral capsid. A recent examination of AAV infection of human diploid fibroblasts using gene array chips showed very little change in gene expression profiles upon binding of AAV capsids with only a nonpathogenic response and no induction of immune response or stress response genes [294]. In contrast adenovirus binding induced a wide array of genes associated with pathogenic responses, including immune and stress response genes. Also, AAV vectors are replication defective and contain no viral genes, so cellular immune responses against the viral components should not be evoked readily. In all of the *in vivo* studies of AAV vectors in rodents, rabbits, or rhesus macaques, there has been little evidence of cellular immune responses to viral components.

AAV vectors may be used mainly for clinical applications requiring only infrequent delivery, but potential humoral immune responses against the viral capsid, either preexisting in the human population or induced by vector administration, must be considered [3,28,29]. Reinfection of humans by AAV is not prevented by serum neutralizing antibodies [3,31,32]. However, more extensive studies will be required to assess whether induction of neutralizing antibody responses will pose any limitations to AAV vectors.

Induction of anti-AAV capsid antibody responses after vector administration may reduce the efficiency of transduction

upon re-administration [70,295,296]. This depends upon the route of administration [96,297,298] and also may depend upon the quality of the vector preparations. In one study in which two AAV vectors expressing the reporter genes bacterial β -galactosidase or human alkaline phosphatase were successively administered to lungs of rabbits, expression from the second administered vector was impaired and this was ascribed to a neutralizing antibody response [299]. Similar studies in mice also implied that neutralizing antibodies impaired re-administration of AAV vectors but that this could be partially or completely overcome by transient immunosuppression with anti-CD40 ligand antibodies or soluble CTLA4-immunoglobulin at the time of the initial vector administration [296,300]. However, interpretation of such studies may be complicated by the expression of the foreign reporter proteins that could represent confounding variables. Furthermore, other studies showed that immune responses to AAV capsid were greatly reduced following airway administration of AAV [96] and that vector transduction could be seen after at least three repeated administrations to the lung of rabbits [48]. Thus, up to three successive administrations of AAV vectors to rabbit lungs over a 20-week period did not prevent gene expression from the third delivery of vector [48] in spite of a dose-dependent rise in serum antibody against the AAV capsid. This was reflected in clinical trials of an AAV-CFTR vector administered to the airway of CF patients. Subjects who were not serum antibody positive for AAV capsid antibody prior to vector administration did seroconvert for serum AAV antibody in a dose-dependent fashion [9–13].

It remains to be determined how neutralizing antibody responses to AAV vector capsids might impact applications of AAV vectors. This will most likely require studies in humans to determine if the various animal models such as rodents or rabbits are predictive for the immune response to AAV vectors in humans and whether such immune responses will pose any limitations to their therapeutic application. As discussed in Section 6.10, in clinical trials so far, preexisting anticapsid antibody in serum has not appeared to impact delivery of an AAV-CFTR vector by aerosol to the lung or an AAV-FIX vector to muscle, but intravenous delivery of an AAV-FIX vector to the liver may have been impacted. For relatively infrequent administration of AAV vectors, transient immune blockade [295,296] has been suggested but may not be an attractive option for therapeutic use of AAV or any other gene delivery vectors. It has been suggested also that vectors with capsids of different serotypes could be used for subsequent administrations [202]. However, although in rodents and rabbits the several serotypes of AAV do not generate cross-reacting antibodies this may not be predictive for humans. Recent examination of various human sera indicates substantial cross-reaction between, for instance, AAV1 and AAV2 anticapsid antibodies which is not seen in smaller animals (R. Peluso, unpublished data).

Immune responses to the transgene expressed by an AAV vector vary and may depend upon the route of delivery. Both MHC class II-restricted antibody responses and MHC class I cytotoxic T-lymphocytes have been reported but this may

vary with the route of administration (297). In some studies, such as intramuscular delivery in mice, there was no immune response to an expressed foreign reporter gene such as bacterial β -galactosidase and it was suggested that AAV may be a poor adjuvant or may not readily infect professional antigen presenting cells in muscle [301,302]. However, an AAV vector expressing the herpes simplex virus type2 gB protein was delivered intramuscularly into mice and elicited both MHC Class I-restricted CTL responses against the gB protein and anti-gB antibodies [303]. Following intramuscular delivery of an AAV human FIX vector [273,304,305] there was an antibody response, but not a CTL response, against the FIX protein. The rules governing immune responses to foreign transgenes following AAV vector delivery remain to be elucidated more fully but AAV may have utility as a viral vaccination vector (Section 6.10.8).

A recent observation in a clinical trial in hemophiliacs of a potential AAV vector capsid specific CD8⁺ CTL response [306] led to an additional report that healthy subjects carry AAV capsid-specific CD8⁺ T-cells and that AAV-mediated gene transfer can stimulate their expansion [117]. However, the mechanism of this is not understood [117] and it has not yet been possible to model this phenomenon in animals [307–309]. Interestingly, AAV2-induced human T-cells [117] also proliferated upon exposure to alternate AAV serotypes, indicating that other serotypes are unlikely to evade capsid-specific immune responses. Surprisingly, this has not been the case in animal studies, since no such expansion occurred in mice after AAV-mediated gene transfer. Moreover, when mice were immunized with adenoviral vectors expressing AAV capsid, they developed lytic CD8⁺ T-cells in blood, lymph tissues and liver, but these were unable to eliminate AAV-transduced hepatocytes following infusion with an AAV vector expressing human factor IX under a hepatocyte-specific promoter, and FIX expression was sustained and comparable in AAV-preimmune and naïve animals [307]. Furthermore, in AAV2-pretreated hemophilia B dogs, canine FIX expression increased from less than 1%–16% of normal levels when treated with an AAV2/8 vector, and a high level of expression has lasted for more than 2 years. Additionally, no significant liver toxicity or canine FIX-specific antibodies have been detected in these animals [308]. A more recent analysis suggested that the apparent CTL response observed by Manno et al. [306] could actually be directed at an epitope expressed from a +1 reading frame shift in the factor IX transgene ([310], R.J. Samulski, personal communication).

If the above observations are substantiated, they would imply that in the human subject, hepatocytes displaying AAV capsid sequences complexed to major histocompatibility complex class I molecules on their surface of transduced cells were destroyed by capsid-specific CD8⁺ cells. However, the AAV capsid is not encoded in the vector and is introduced to hepatocytes temporally during vector infusion, so one potential solution to mitigate the host T-cell response in humans and to allow long-term expression of FIX may be to induce transient immunosuppression until AAV capsid is cleared from the transduced cells. The safety of co-administration of

immunosuppressive agents mycophenolate mofetil and tacrolimus, during AAV8-FIX vector infusion to the hepatic artery of rhesus macaques, was tested recently and resulted in successful transduction of the liver and expression of FIX without toxicity [311]. However, these animals did not develop elevated liver enzymes or T-cell response to AAV8 capsid also in the absence of immunosuppression. Therefore, it is not yet known if these immunomodulators can really mitigate the anti-AAV capsid T-cell response observed in the human subjects during the clinical trial.

With the exception of the potential CTL response in a hemophiliac, the preclinical studies for AAV2 vectors, and to a more limited extent for AAV1, have been quite predictive of the benign safety profile observed thus far in clinical trials (Section 6.10). The predictive accuracy of efficacy in various animal models with respect to clinical benefits awaits evaluation in more advanced clinical trials. There appears to be a reasonable predictability for scaling of delivery efficiency, at least as judged for AAV2 vectors, when comparing small animals such as rodent to larger animals including rabbits, dogs, and monkeys. As noted in Section 6.7.1, there are many additional AAV serotypes being evaluated as vectors, but the predictability for scaling from rodents to larger animals has yet to be established. Indeed a recent evaluation of AAV8 and AAV9 vectors in mouse and dog models of hemophilia A showed that neither vector scaled predictably to the larger animals [177,311].

6.10 AAV VECTOR APPLICATIONS: CLINICAL TRIALS

AAV vectors are now being developed for therapeutic applications. The first AAV vector to undergo clinical trials was an AAV2 vector expressing the CFTR cDNA that advanced to phase II clinical trials in CF patients [8–13]. Although testing of this CFTR vector has been discontinued more than 20 additional AAV vectors have been introduced into clinical trials for a wide variety of therapeutic and prophylactic applications (Table 6.1). In this section we describe a series of applications that are being developed with AAV vectors that either are now in clinical trials or are expected to enter clinical testing in the next several years. Most of the examples that we will discuss are chronic diseases that affect various organ systems or vaccine applications, and require different routes of delivery. These examples serve to illustrate the potential wide applicability of AAV vectors particularly for persistent gene expression in nondividing or slowly dividing cells. Most of the clinical trials have used vectors having AAV2 capsids but several more recent trials have begun testing of vectors with capsids of other serotypes such as AAV1 (Table 6.1).

6.10.1 CYSTIC FIBROSIS

CF appeared to be an attractive target for gene therapy particularly in view of the relative accessibility of the lung

for installation of delivery vectors. CF is a lethal autosomal recessive disease that is caused by mutations in the gene coding for the CFTR protein. The defect in the CFTR protein, which is a chloride ion channel expressed in epithelial cells, leads to complex biochemical changes in several organs including lung and often the exocrine pancreas. In the lung, there is a decreased mucociliary clearance, increased bacterial colonization, and a chronic neutrophil-dominated inflammatory response that leads to progressive destruction of tissue in the conducting airways. The usual cause of morbidity and eventual mortality in CF patients is a progressive loss of lung function. Thus, the goal of a gene therapy for CF is to deliver the CFTR cDNA into the epithelial cells in the conducting airways of the lung. One challenge in constructing an AAV vector expressing the CFTR protein is that the coding region requires a minimum cDNA size of 4.4 kb thus leaving very little space for a transcription promoter. In order to package this cDNA into a single AAV vector, advantage was taken of the discovery of the transcription promoter properties of the AAV ITR [84]. Thus an AAV vector expressing the CFTR cDNA was introduced into clinical trials in CF patients by delivery of the vector to the lung and the nasal epithelium [8,11–13] in addition into the maxillary sinus [9,10].

The lung is the primary target for CF gene therapy but delivery to the maxillary sinus was undertaken as a novel attempt to obtain an early indication of the potential of the AAV CFTR vector. The maxillary sinuses of CF patients exhibit chronic inflammation and bacterial colonization that is reflective of some aspects of the CF disease in the lung and in some CF patients who have undergone surgical bilateral antrostomy, the maxillary sinus is accessible to instillation of vectors and for sampling and biopsy. In an initial trial, 15 sinuses of CF patients were treated with increasing doses of the AAV-CFTR vector [9]. DNA PCR analysis of sinus biopsies showed dose-dependent delivery of the vector genome that persisted in the sinus for at least 70 days after instillation. In epithelial cell surfaces of CF patients, the transmembrane potential is hyperpolarized compared to normal patients because of the absence of a functional CFTR chloride channel. In the treated sinuses at the higher doses of vector, there was some reversal of the electrophysiologic defect, thus providing suggestive evidence for expression of the CFTR protein from the delivered vector.

A follow-up, double-blinded, randomized and placebo-controlled phase II study was performed in 23 CF patients in whom vector was administered to one maxillary sinus, while the contralateral sinus received a placebo treatment [10]. This study confirmed the safety of the AAV-CFTR vector delivered to the sinus. Additionally, the anti-inflammatory cytokine interleukin-10 showed a significant difference between vector- and placebo-treated sinuses over a 90 day period. This suggested that modulation of cytokine levels might provide a useful surrogate marker for additional trials. Because several patients had participated in the previous phase I trial, the phase II study further suggested that the vector remained safe after multiple administrations to the sinus without induction of serum neutralizing antibodies [10].

The first clinical test of administration to the lung [8] was a single dose administration, dose escalation, open label trial using a bronchoscope to install the vector into one lobe. In the same trial, a second dose of vector was administered to the nasal epithelium in a blinded, placebo-controlled manner. Administration of the vector was well tolerated but measurement of DNA and RNA molecular endpoints from biopsy samples to assess delivery and expression and *in vivo* electrophysiologic assessment of *trans* membrane epithelial potential difference (TEPD) in the nasal epithelium was difficult. Interestingly, when biopsy samples of nasal epithelium taken several days after *in vivo* administration of the vector were cultured *in vitro*, vector DNA and expressed CFTR mRNA were detected and there was some change in the TEPD [230]. This at least showed that vector administered *in vivo* could provide CFTR function when cells were subsequently tested *in vitro*.

A phase I, single administration, dose escalation trial designed to assess safety and delivery of AAV-CFTR by inhaled aerosol to the lung was carried out in 12 adult CF patients exhibiting mild lung disease. The vector was well tolerated and no apparent safety concerns were demonstrated in the study. Vector administration at the highest dose of 10^{13} genome-containing particles resulted in significant gene transfer to the airway. A clear dose-response relationship was observed in vector gene transfer over 30 days but the level of vector DNA declined over 90 days [11]. Following this study, a multidose, double-blinded, placebo-controlled, and randomized phase II trial was conducted in 37 CF patients with mild CF disease. Patients received three doses (10^{13} DRP per dose) at monthly intervals, administered by inhaled aerosol. This trial also was notable for enrolling patients down to age 12, which is important because the eventual target population to treat CF is likely to be younger patients. In this trial, the multidose vector administration was safe and well tolerated and interestingly, there appeared to be an increase in pulmonary function measured by spirometry at 30 days and a decrease of the pro-inflammatory cytokine IL-8 in the sputum [12]. A second phase IIb trial conducted in 100 CF subjects failed to confirm these effects on lung function or IL-8 [13] and highlighted an emerging general problem in many trials in CF patients. In such trials the behavior of placebo arms is unpredictable and coupled with the difficulty of evaluating gene expression in small airways this makes development of any gene therapy for CF a daunting task.

For CF clinical trials, molecular endpoint measures to evaluate gene expression have proven particularly challenging. First there is no good assay for CFTR protein. DNA and RNA PCR can be conducted on airways cells that are obtained via a brush inserted through a bronchoscope. This has several disadvantages including poor quality of the samples that often contain very few cells. Consequently, it has been possible to obtain data from DNA PCR but it has proven extremely difficult to obtain reliable RNA samples. In the clinical trials of the AAV CFTR vector in lungs of CF patients, gene transfer has been demonstrated but data on RNA expression has not been obtained. Other problematic issues are that the invasive

bronchoscopy procedure disrupts other measures of pulmonary function and inflammation. Furthermore, the bronchoscopic procedure can only provide samples from the upper airways whereas the vector needs to function in the lower airways which are the primary site of the disease. Consequently, the difficulties with molecular endpoints and the variable and unpredictable behavior of placebo arms in clinical trials currently makes clinical development of a gene therapy for CF a challenging task, with any vector, not just AAV [312,313]. Even for AAV vectors, it is therefore difficult to assess the likelihood of success for other approaches that have been suggested such as use of alternative AAV capsid serotypes [314], or a truncated CFTR cDNA thus allowing space for a larger, perhaps more efficient promoter [315].

6.10.2 HEMOPHILIA B

Hemophilia is a severe X-linked recessive disease that results from mutations in the gene for either blood coagulation factor VIII (FVIII) in hemophilia A or IX (FIX) in hemophilia B. The absence of functional FVIII or FIX leads to severe bleeding diathesis. Expression of these clotting factors at less than 1% of normal levels results in severe disease whereas levels over 5% of the normal range appear to be sufficient for normal function. Levels between 1% and 5% lead to much milder disease and prophylactic delivery of these clotting factors at these levels of 1% of the normal levels (2–10 and 50–250 ng/mL for FVIII and FIX, respectively) can decrease the risk of spontaneous bleeding into joints and soft tissues and lower the risk of fatal intracranial bleeding. However, the FVIII and FIX proteins have a short half-life and this has stimulated interest in developing gene therapy approaches in which the clotting factors may be produced more persistently. Several groups have provided evidence that FIX protein can be expressed for prolonged periods, in both murine and canine models, after delivery of AAV-FIX vectors either by portal vein injection to target the liver or by intramuscular injection [99,100,316,317]. Generally, the levels of expression, as measured by the whole blood clotting time (WBCT) assay, have indicated that at least a partial correction of the defect in both the murine and canine disease models can be achieved and suggest that accumulation of therapeutic amounts of FIX may be achievable in humans.

AAV vector delivery of the human factor IX gene into either immunodeficient or immunocompetent mice by portal-vein injection into liver resulted in prolonged expression of factor IX for up to 36 weeks at serum levels of 250 to 2000 ng/mL which is equivalent to about one fifth of the normal human level [99]. Similar portal-vein delivery of human factor IX in hemophiliac dogs resulted in expression of factor IX at about 1% of normal canine levels, an absence of inhibitors and sustained partial correction of WBCT for at least 8 months [316]. In another study by Herzog et al. [99], intramuscular injection of an AAV human FIX vector into immunodeficient mice led to prolonged expression at about 350 ng/mL in serum for at least 6 months but in immunocompetent mice there was generation of inhibitory antibody. These same investigators [317]

subsequently showed that in hemophiliac dogs, intramuscular injection of high doses of the AAV-canine FIX vector achieved expression for over 17 months and demonstrated a stable, dose-dependent partial correction of the WBCT. Moreover, at the highest dose there was a partial correction of the activated partial thromboplastin time (APTT) which may be a more reliable measure than WBCT.

Development of AAV vectors to deliver FVIII for hemophilia A faces an extra challenge in that the FVIII protein cDNA is over 7 kb which is too large to package into a single AAV vector. However, the FVIII protein is processed by excision of an internal B-domain such that the secreted protein consists of heavy and light chains. Removal of the B-domain DNA sequence reduces the size of the cDNA to about 4.2 kb which can be packaged into a single AAV vector with space to include only small regulatory elements. Because of this size restraint AAV vectors have not entered clinical development for hemophilia A.

For hemophilia clinical trials, in contrast to the CF trials, a molecular endpoint is readily available because the level of the FIX or FVIII in serum can be directly measured and the level of protein will likely be related to degree of clinical benefit. In contrast, DNA or RNA measures again would require invasive biopsy especially following portal vein delivery to the liver.

A clinical study of intramuscular injection of an AAV vector expressing human FIX in adults with severe hemophilia B was recently concluded [318,319]. This was a phase I open label dose escalation trial in a total of eight adult men with severe hemophilia B due to a missense mutation in FIX and with serum levels of FIX below 1% of normal. Three dose levels of vector, 2×10^{11} vg/kg ($n = 3$), 6×10^{11} vg/kg ($n = 3$), and 1.8×10^{12} vg/kg ($n = 2$), were administered, under ultrasound guidance to avoid large blood vessels, by injection at multiple sites in muscles of one or two legs. The treatment was generally well tolerated and there were essentially no vector-related toxicities in any of the three dose cohorts. Analysis of biodistribution in body fluids showed very little extramuscular distribution of vector and importantly no vector was detected in any semen sample over 24 weeks of the study. Analysis of muscle biopsies detected both the vector DNA and vector-specific mRNA as well as accumulation of FIX at the injection sites. Although all treated patients showed elevation of anti-capsid antibody levels in serum, the levels of gene transfer and expression in muscle did not correlate with either pre- or posttreatment levels of AAV2 capsid antibody. Importantly, there was no formation of inhibitory antibodies to FIX. However, the levels of circulating FIX in serum were disappointing and there was no dose response with only four of eight patients showing any detectable level from 1% to 1.4% at any time point over the 24 week period. There were no significant changes in clinical endpoints. Remarkably a muscle biopsy obtained from one subject 3.7 years following treatment with the highest vector dose, 1.8×10^{12} vg/kg, revealed a low level of local FIX vector DNA and FIX protein expression. This suggests that improved muscle delivery and transduction particularly of myocytes may be needed to achieve an effective

treatment [125]. Indeed, a recent study demonstrated that intravascular delivery of vector to skeletal muscle provides higher levels of circulating FIX and long-term cures in hemophilic dogs at vector doses comparable to those previously used in humans, due to widespread transduction of skeletal muscle [320]. Other strategies, such as the use of pseudotyped AAV2/1 vector and a myocyte-specific synthetic promoter to control FIX expression, have resulted in improved efficacy of AAV-mediated gene transfer to skeletal muscle in murine and canine hemophilia B models [321–323]. However, the increase in the levels of FIX expression was also accompanied by the formation of inhibitory antibodies and further studies are needed to define vector doses and treatment regimens that result in tolerance rather than immunity to FIX.

A second phase I clinical trial with the AAV2–FIX vector was initiated in patients with severe hemophilia B patients, but in this trial the vector was administered via hepatic artery infusion to target the liver which may be the natural source of FIX production. This trial was based on preclinical studies in hemophiliac dogs in which therapeutic levels of FIX were sustained over a prolonged period with a dose of vector at 10^{12} vg/kg [316–322,324]. In this open-label trial seven subjects with severe hemophilia B were treated at three vector dose levels of 1×10^{11} vg/kg, 10^{12} vg/kg, and 2×10^{12} vg/kg and there were several significant observations. Following hepatic infusion of the AAV2–FIX vector at the lower doses, patient semen samples were positive for the vector genome for several weeks [275]. However, as noted in Section 6.9, this did not represent vector in motile sperm, suggesting that the risk of inadvertent germline transmission of vector sequences after intramuscular or intravenous delivery is extremely low [276]. Two additional patients then were treated at the intermediate dose. Administration of the two lower doses of vector was safe and well tolerated and no toxicities were noted but there was also no significant therapeutic level of FIX protein produced.

Administration of the highest dose of 2×10^{12} vg/kg to two subjects resulted in several observations with regard to possible immune responses that differed from the preclinical studies [244]. Both subjects showed detectable levels of FIX expression, but expression was transient and peaked at 3% in one and 11% in the other at 4 and 10 weeks postadministration, respectively. In the latter subject, the loss of expression was accompanied by a transient rise in serum transaminase levels and in a third subject treated subsequently with slightly lower vector dose, transaminitis was again documented. Importantly, the transient therapeutic levels of FIX were achieved in subjects having low preexisting neutralizing antibody (NAB) titers to AAV2, but not in those with higher AAV2 NAB [306]. Thus a high level of preexisting NAB to AAV2 in some proportion of the human population might interfere with efficient *in vivo* gene delivery in a clinical setting [306]. The sudden loss of a level of expression of 11% accompanied with a contemporaneous transaminitis was suggestive of a CTL response and an AAV capsid-specific CD8⁺ T-cell clone was expanded from this subject and showed cytolytic activity against cells that displayed capsid antigen [306].

However, the mechanism of this is not understood [117] and it has not yet been possible to model this phenomenon in animals as discussed in Section 6.9.

6.10.3 MUSCULAR DYSTROPHY

The muscular dystrophies are a clinically and genetically heterogeneous group of disorders that show myofiber degeneration and regeneration and are characterized by progressive muscle wasting and weakness of variable distribution and severity. They are associated with mutations in genes encoding several classes of proteins ranging from extracellular matrix and integral membrane proteins to cytoskeletal proteins, but also include a heterogeneous group of proteins including proteases, nuclear proteins, and signaling molecules [325].

The most common myopathy in children, Duchenne muscular dystrophy (DMD), is a severe X-linked neuromuscular disease that affects approximately 1 of every 3500 males born, and is caused by recessive mutations in the gene for the muscle protein dystrophin. This lack of a functional dystrophin protein in DMD results in loss of muscle fiber integrity by disrupting the physical linkage between the actin cytoskeleton within the muscle fiber and the extracellular matrix. Affected boys begin manifesting signs of disease early in life, cease walking at the beginning of the second decade, and often die due to cardiac arrest or respiratory insufficiency by age 20 years [326].

An effective gene therapy for muscular dystrophy would address an unmet medical need but several major challenges must be overcome. The first challenge is that the dystrophin gene is the largest known gene with a full-length cDNA that is 14 kb. However, dystrophin can retain significant function even when missing large portions of its sequence. Large, in-frame deletions in the central-rod domain often lead to the milder Becker muscular dystrophy (BMD) [327]. The *mdx* mouse is a naturally occurring murine model that has a premature stop codon generated by a point mutation in exon 23 of the dystrophin gene [328]. Functional analysis of dystrophin structural domains in transgenic dystrophin-deficient *mdx* mice revealed multiple regions of the protein that can be deleted in various combinations to generate potentially highly functional mini-dystrophin genes [329]. Several groups have generated functional miniature versions of the human dystrophin gene that can be readily packaged into AAV vectors [330–335]. When injected into the muscle of *mdx* mice, efficient and stable expression was noted in a majority of myofibers and the missing dystrophin and dystrophin-associated protein complexes were restored onto the plasma membrane. This treatment ameliorated dystrophic pathology in the *mdx* muscle and led to normal myofiber morphology, histology, and cell membrane integrity.

Another particularly challenging problem is that widespread expression in the skeletal and cardiac muscle is a prerequisite for successful gene therapy of muscular dystrophies. But systemic gene transfer to striated muscle is hampered by the vascular endothelium that represents a barrier to distribution of vector via the circulation. One approach uses intravenous

administration of a pseudotyped AAV2/6 vector together with vascular endothelial growth factor (VEGF) to permeabilize blood vessels. In adult mice this resulted in efficient whole body muscle-specific transduction of skeletal and cardiac muscle [209]. In *mdx* mice with the microdystrophin gene expressed from a muscle-specific promoter, widespread dystrophin expression was observed throughout the skeletal muscles and resulted in partial phenotypic correction of the limb muscles that were less susceptible to contraction-induced injury [210]. A follow-up study in dystrophin-trophin double-knockout mice resulted in restoration of dystrophin protein expression in the respiratory, cardiac, and limb musculature of these mice, considerably reducing skeletal muscle pathology and extending their lifespan [211]. Similarly, extensive cardiac transduction, with microdystrophin correctly localized at the periphery of the cardiac myocytes and functionally associated with the sarcolemmal membrane was obtained following a single systemic injection of AAV2/6 carrying the microdystrophin transgene in the presence of VEGF [211]. Significantly, in this study, microdystrophin gene transfer corrected the baseline end-diastolic volume defect in the *mdx* mouse heart and prevented cardiac pump failure.

Despite the significant progress made in transduction of the mouse musculature using alternative AAV serotypes and VEGF, key safety issues to be resolved include the use of VEGF and the resulting extended biodistribution of the vector genomes in many other tissues beside the skeletal muscle, including the brain and testes. Interestingly, vectors based on the AAV8 capsid, at least in neonatal mice, can cross the blood vessels barrier and disseminate efficiently in skeletal and cardiac muscle in the absence of VEGF, and lead to prolonged transduction in these tissues [212].

Other strategies have evaluated ways to express larger dystrophins. Transcript rescue is based on the observation that exon skipping naturally occurs at low frequency during dystrophin mRNA processing and can restore the disrupted reading frame and lead to the production of rescued protein [336,337]. Persistent exon skipping that removed the mutated exon on the dystrophin mRNA of the *mdx* mouse was achieved following intramuscular injection or intra-arterial perfusion of the lower limb with a pseudotyped AAV2/1 vector expressing antisense sequences linked to a modified U7 small nuclear RNA [338]. This led to sustained production of functional dystrophin at physiological levels in entire groups of muscle and the correction of the muscular dystrophy in the absence of an immune response against the rescued dystrophin [338]. With this strategy, body-wide rescue of dystrophin synthesis and recovery of muscle strength was obtained following systemic (tail vein) delivery of a pseudotyped AAV2/1 vector-mediated antisense-U1 small nuclear RNA targeting exon 51 of dystrophin gene in *mdx* mice [339].

Larger dystrophins may also be expressed using the *trans*-splicing dual AAV vector approach (discussed in Section 6.8.3) [244,249–251]. Thus, a 6 kb mini-dystrophin gene was efficiently delivered and functionally expressed in the skeletal muscle of *mdx* mice by splitting the dystrophin coding sequence between two *trans*-splicing pseudotyped AAV2/6

vectors [340]. Furthermore, the dystrophic pathology was ameliorated and muscle strength improved in both adult, and to a lesser degree in aged mice, but in the absence of cellular immune response.

In contrast to the relative success of AAV-mediated microdystrophin gene transfer and restoration of essential muscle functions in inbred murine models of muscular dystrophy, intramuscular administration of AAV2 or AAV2/6 vectors to random-bred wild-type dogs elicited an apparent robust cellular immune responses against the AAV capsid proteins that were sufficient to largely eliminate transgene expression [341]. However, a brief course of immunosuppression shortly prior and following AAV administration to the muscle was sufficient to permit long term and robust expression of a canine microdystrophin gene in the skeletal muscle of a dog model for DMD and its expression restored localization of components of the dystrophin-associated protein complex at the muscle membrane [342].

A phase I clinical trial for the delivery of mini-dystrophin by AAV to boys with DMD is currently under way at Columbus (Ohio) Children's Hospital. In this trial, six boys with DMD will undergo injections of the AAV-mini-dystrophin gene into the biceps muscle of one arm and a placebo in the other arm in a blinded manner. The AAV serotype used in this trial is AAV2.5 which differs from AAV2 capsid at five amino acids, resulting in increased transduction efficiency. After 6 weeks, an analysis of the injected muscle tissue's microscopic appearance, as well as extensive assessment of health and strength of the trial participants, may reveal whether the treatment is likely to be safe and result in persistent production of the essential microdystrophin protein in muscle cells.

The limb girdle muscular dystrophies (LGMD) are a heterogeneous group of inherited autosomal recessive neuromuscular diseases characterized by proximal muscular weakness and variable progression of symptoms. LGMD disease is caused by mutations in a number of genes including one of the four small (cDNA < 2kb) muscle sarcoglycan genes (α , β , γ , δ) expressed predominantly in striated muscle. These transmembrane glycoproteins associate with each other in equal stoichiometry to form the sarcoglycan complex, and a deficiency of one component typically leads to partial or complete absence of all the other sarcoglycan proteins on the sarcolemma. The Bio 14.6 cardiomyopathic hamster is a naturally occurring LGMD model due to a deletion in the δ -sarcoglycan gene. Administration of AAV δ -sarcoglycan vectors to these animals either by intramuscular or intravascular administration led to genetic, biochemical, histological, and functional rescue of relatively large regions of muscle [343–345]. Mice that are null mutants for γ -sarcoglycan exhibit severe muscle pathologies that can be partly corrected if treated at less than 3 weeks of age by intramuscular injections of an AAV vector expressing the γ -sarcoglycan gene from a muscle-specific promoter [345]. Also, AAV α - or β -sarcoglycan vectors can rescue an α - or β -sarcoglycan defect in the corresponding knockout mouse model. Interestingly, while the β -sarcoglycan vector showed long-term sustained expression for more than 21 months and led to widespread biochemical and histological

rescue of the dystrophic muscle, transduction of myofibers by the α -sarcoglycan vector was transient and correlated with induction of significant immune response [346]. The transience of the latter vector was attributed to cytotoxicity resulting from over expression, by more than 100-fold over normal levels of the protein rather than due to an immune response to the transgene. In a more recent study, substitution of the very strong ubiquitous promoter with a muscle-specific promoter resulted in efficient and sustained expression of α -sarcoglycan with correct sarcolemmal localization and without evidence for toxicity following intra-arterial injection of AAV2/1- $\alpha\beta$ -sarcoglycan into the limbs of an LGMD type 2D mice [347]. Transgene expression resulted in restoration of the sarcoglycan complex, histological improvement, membrane stabilization, and correction of pseudohypertrophy. More importantly, α -sarcoglycan expression produced full rescue of the contractile force deficits and stretch sensibility and led to an increase of the global activity of the animals when both posterior limbs were injected. A phase I clinical trial of an AAV2 to deliver sarcoglycan genes to subjects with LGMD was initiated but enrolled and treated only one patient [348]. However, this is now being revisited using a pseudotyped AAV2/1 vector [346].

6.10.4 CENTRAL NERVOUS SYSTEM DISEASE

The brain is an attractive organ for gene therapy, because production of biologically active molecules within the brain might circumvent poor penetration of compounds that are delivered systemically due to a tight vascular blood–brain barrier. Treatment of most of these diseases is not easily approachable by a protein therapy because of the difficulty associated with repeated delivery of short-lived proteins to the brain. Local gene expression might also focus therapy in specific brain regions, thereby avoiding exposure of other areas to agents that might cause undesirable effects.

6.10.4.1 Parkinson's Disease

Parkinson's disease (PD) is a common progressive neurodegenerative movement disorder that affects 5% of the population over 65 years of age. In this disease there is loss of dopaminergic neurons, mainly in the substantia nigra, which leads to deficiency of the neurotransmitter dopamine (DA) in the striatum. The clinical symptoms typically appear after extensive loss of 60%–80% of the dopaminergic neurons, which is correlated with the DA deficiency. DA is synthesized from tyrosine, first through conversion to L-dihydroxyphenylalanine (L-DOPA) by tyrosine hydroxylase (TH), and then to DA by aromatic amino acid decarboxylase (AADC). L-DOPA therapy is very efficacious but response declines as the disease progresses and is complicated by adverse side effects. Thus, the different enzymes involved in DA synthesis have been targeted for gene transfer replacement therapy in order to restore dopaminergic stimulation of the striatum.

In the 6-hydroxydopamine (OHDA)-lesioned rat model of PD, a single intrastriatal infusion of an AAV2-AADC vector led to an enhanced conversion of L-DOPA to restore DA to 50% of

normal levels 12 weeks after vector administration [349] and persistence of transgene expression for at least 1 year [350]. Co-expression of TH and AADC, using two separate AAV vectors in this Parkinsonian rat model resulted in more effective DA production and more remarkable behavioral recovery, compared with the expression of TH alone [351]. Convection-enhanced delivery of the AAV2-AADC vector into six sites in the striatum of neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated monkeys restored AADC activity to levels that exceeded the normal range [352] and expression was observed for 6 years [353]. A clinical trial of an AAV2-AADC vector has been initiated in PD patients [354].

Clinical trials with AAV vectors to test a novel nondopaminergic approach to treatment of PD are under way [354,355] based on a hypothesis that re-establishment of normal brain activity within motor circuits might reverse motor deficits of PD. The strategy is to administer a mixture of two different AAV2 vectors each expressing respectively the gene for one of the two isoforms of the enzyme glutamic acid decarboxylase (GAD-65 and GAD-67) by unilateral injection into the subthalamic nucleus (STN) region of the brain. GAD catalyzes synthesis of GABA, the major inhibitory neurotransmitter in the brain. The STN has a central role in the region of the brain that is responsible for regulation of movement and becomes disinhibited in PD. The concept is that expression of GAD will cause the STN to produce γ -aminobutyric acid (GABA) and convert excitatory STN projections into inhibitory projections. This inhibitory of STN activity in turn may palliate the motor symptoms of PD. Previous studies in humans have demonstrated that reduction of subthalamic nucleus activity by electrical stimulation, lesioning, or GABA infusion could ameliorate signs of advanced PD [355], whereas animal studies indicate that AAV-GAD appears to improve brain function and signs of the disease without toxic effects [356–359]. The phase I clinical study was aimed to assess the safety and tolerability of AAV-GAD vectors in 12 PD patients over a period of 1 year, using a single-arm, open label, dose-escalation design. Patients were also assessed clinically both off and on medication at baseline and at different intervals following gene therapy. After 1 year of follow-up of all patients, there were no adverse events related to gene therapy. Importantly, significant improvements in motor scores, based on the Unified Parkinson's Disease Rating Scale (UPDRS), were noted predominantly on the side of the body that was contralateral to surgery as early as 3 months following surgery and persisted up to 12 months. Additionally, PET scans demonstrated a substantial reduction in thalamic metabolism that was restricted to the treated hemisphere, and a correlation between clinical motor scores and brain metabolism in the supplementary motor area [360]. However, caution must be exerted in interpretation of these results because there was no sham-operated control group and the placebo effect in PD clinical trials can be significant [361], especially after surgical intervention [362]. Consequently, no firm conclusions can be drawn about efficacy, despite objective improvement in motor function and functional imaging.

Another strategy for gene therapy of PD involves the use of neuronal-specific growth factors to regenerate or halt ongoing degeneration of dopaminergic neurons of the substantia nigra. Glial cell line-derived neurotrophic factor (GDNF) is a potent neurotrophic molecule for nigral dopaminergic neurons both *in vitro* [363] and *in vivo* [364]. In the 6-OHDA-lesioned rat model of PD, peri-nigral injection of an AAV vector encoding the rat GDNF, three weeks prior to a striatal 6-OHDA treatment, resulted in stable transgene expression for 10 weeks and significant protection of neurons from degeneration in the substantia nigra. However, there was no recovery of striatal TH-containing fibers and no recovery of motor function, suggesting that striatal dopaminergic recovery is necessary for functional improvement [365]. In another study, both nigral and striatal long-term transduction of up to 6 months provided significant protection of nigral DA neurons against 6-OHDA-induced degeneration. However, only the rats receiving AAV-GDNF in the striatum displayed behavioral recovery, accompanied by significant re-innervation of the lesioned striatum [366]. In both studies [365,366], AAV-GDNF was administered before or shortly after the injection of the neurotoxin 6-OHDA.

Studies of AAV-GDNF vectors have not advanced to clinical trials but clinical trials with an analogous neurotrophic growth factor, neurturin (NTN), have begun [354]. NTN is a member of the GDNF family, and is known to repair damaged and dying midbrain dopaminergic neurons. An AAV2-NTN vector exhibited both long-term efficacy and safety in pre-clinical rat and monkey models of PD [367]. In a phase I open-label study, conducted in 12 patients with advanced PD, an AAV2-NTN vector encoding the neurotrophic factor NTN was stereotactically delivered to the putamen, a region in the midbrain affected by the degeneration of dopaminergic neurons, at two different doses [354]. Patients receiving the low dose demonstrated approximately 36% improvement in UPDRS motor "off" scores by 9 months and patients receiving a fourfold higher vector dose showed similar effects 3 months earlier. This effect was maintained for at least 12 months, the final follow-up time point in the study. In addition, patients also demonstrated a 50% reduction in off time and a doubling of good quality "on" time without dyskinesias. Similarly to the AAV-GAD vector approach, these results with AAV-NTN are encouraging but require careful placebo-controlled studies to be confirmed. Consequently, a follow-up on phase II double-blind, controlled clinical trial is currently enrolling 51 patients with advanced PD. Patients will be administered AAV2-NTN to the putamen via stereotactic neurosurgery and will be followed-up for 12 months for safety and efficacy.

6.10.4.2 Canavan's Disease

A clinical trial to treat Canavan's disease, a childhood leukodystrophy, is being conducted [250]. This disease results from an autosomal recessive mutation in the gene for aspartoacylase (ASPA) that causes a toxic accumulation of the metabolite *N*-acetyl-aspartate (NAA). In this phase I safety trial up to 10 patients aged between 3 months and 6 years

received intracranial infusions via six cranial burr holes of AAV2-ASPA vector to the parenchyma of the brain at a maximum dose of 1×10^{12} vector genomes per subject. The treatment was well tolerated and only low level of immune response to AAV2 was detected in a few subjects [368].

6.10.4.3 Batten's Disease

One form of the autosomal recessive disorders known as Batten disease is late infantile neuronal ceroid lipofuscinosis (LINCL) which is caused by a mutation in the gene *CLN2* that encodes a proteolytic enzyme tripeptidyl peptidase. Absence of the enzyme leads to a lysosomal storage disorder with accumulation of lipofuscin and consequent neurodegeneration. Disease onset occurs at about age 2–4 years with progressive neurologic decline, cognitive, impairment, blindness, seizures, ataxia, and death at age 8–10. Other than symptomatic relief there is no treatment for this disease and again a protein therapy is unlikely. An AAV2 vector expressing the human *CLN2* cDNA from the CB promoter is now being tested in a clinical trial in which the vector will be administered to the whole brain via fine catheters placed at six different subcortical sites in order to obtain a wide distribution [369]. The total dose per patient is 3.6×10^{12} particles and up to ten patients, four with severe disease and then six with more moderate disease, will be treated. The primary endpoint measure is neurological assessment using the LINCL clinical rating scale and secondary endpoints involve brain imaging.

6.10.4.4 Alzheimer's Disease

Alzheimer's disease leads to progressive decline in memory and broad cognitive functions and involves multiple brain systems but the most critical for decline in memory and cognition appears to be loss of cholinergic neurons. There are several million patients in the United States and there is no treatment to prevent disease progression. There is some evidence that β -nerve growth factor (NGF) may induce a trophic response in cholinergic neurons. Consequently, a phase I/II dose escalation, randomized controlled study was recently initiated [370] to assess primarily the safety and tolerability of an AAV2-NGF vector delivered to the basal forebrain region by stereotactic injection. Additional measures will include cognitive scores and imaging analyses. The phase I portion of the trial which is ongoing will examine the safety of the vector at two different doses before proceeding to the phase II trial.

6.10.5 OPHTHALMIC DISEASE

AAV vectors may be well suited for efficient long-term treatment of ocular diseases because they efficiently and stably transduce retinal pigment epithelium (RPE) and photoreceptor cells following subretinal injection [119,371–374]. Retinitis pigmentosa (RP) comprises a group of inherited retinal degenerative diseases that lead to progressive reduction in visual field extent and impairment of visual acuity. The disease is triggered by mutations in various genes that cause degeneration and death of photoreceptors by apoptotic pathways [375].

Modulation of photoreceptor apoptosis may offer an effective therapeutic approach to RP. AAV vectors carrying various genes including those encoding for ciliary neurotrophic factor (CNTF), fibroblast growth factors FGF-2, FGF-5, and FGF-18, and glial cell line-derived neurotrophic factor (GDNF) were evaluated in rodent models of RP subretinal injections. In general, these studies demonstrated long-term expression of the transgene, delayed photoreceptor degeneration, increased rod photoreceptor survival, and functional improvement [376–380].

Other therapeutic approaches to RP are aimed at specific mutant genes. Twelve percent of Americans with the blinding disease, autosomal retinitis pigmentosa (ADRP), carry an autosomal dominant P23H mutation in their rhodopsin gene and a similar transgenic rat model of this disease is available. Delivery with an AAV vector of a ribozyme targeted at this mutation in the rodent model, protected photoreceptors from death and resulted in significantly slowing the degenerative disease for 3 months [381]. The gene *Prph2* encodes the photoreceptor-specific membrane glycoprotein peripherin-2 and mutations in this gene cause several photoreceptor dystrophies, including autosomal dominant retinitis pigmentosa and macular dystrophy. A common feature of these diseases is the loss of photoreceptor function, also seen in the retinal degeneration slow (*Prph2*^{Rd2/Rd2}) mouse. Subretinal injection of AAV-*Prph2* in these mice resulted in stable restoration of photoreceptor ultrastructure and electrophysiological function correction [382].

Control of angiogenesis in the retina is essential to the preservation of vision. Ocular neovascularization (NV) is a major threat to vision and a complicating feature of many eye diseases including proliferative diabetic retinopathy (PDR), age-related macular degeneration (AMD), and retinopathy of prematurity (ROP). Regulation of vascularization in the mature retina involves a balance between endogenous positive growth factors, such as VEGF, and inhibition of angiogenesis, such as pigment epithelium-derived factor (PEDF). Several studies examined ocular administration of AAV vectors to mice exhibiting ischemia-induced retinal NV. Expression of anti-angiogenic proteins, either PEDF or the Kringle domains 1–3 of angiostatin (K1K3), gave sustained therapeutic levels of PEDF and K1K3 in the mouse eye and significantly reduced the level of retinal NV [383,384]. Expression of a soluble VEGF receptor also led to significant reduction in the number of neovascular endothelial cells and inhibited retinal NV [385,386].

Leber congenital amaurosis (LCA) is a severe, early-onset form of retinal degeneration involving both rods and cones. LCA is caused by mutations in one of at least eight different genes, three of which are RPE-specific, the remainder being expressed in photoreceptors [387]. The largest amount of pre-clinical data assembled to date has been on the form of LCA due to mutations in the RPE65 gene. The RPE65 gene encodes a 65 kDa RPE-specific protein that is required for the conversion of vitamin A to 11-cis retinal by the RPE and thus for the regeneration of the rod visual pigment. Mutations in the RPE65 gene are responsible for approximately 10% of Leber autosomal recessive severe, infantile-onset retinal dystrophies [388].

Most patients with such RPE65 mutations present in infancy with bilateral visual impairment and severe night blindness [389,390]. Peripheral visual fields may be preserved in early childhood but later become severely constricted. Visual acuity varies from 20/60 to 20/200 in early childhood but there is gradual deterioration in vision so that by late teens or early adult life there is little residual vision.

RPE65^{-/-} knockout mice and Briard dogs do not generate adequate levels of visual pigment, have very poor vision and severely depressed light- and dark-adapted ERG responses, and thus are good models of human LCA with RPE65 mutations [391]. Several groups have demonstrated proof-of-principle for gene therapy in the *RPE65*^{-/-} knockout mice and Briard dogs following subretinal injection of AAV2-RPE65 vector which resulted in significant improvement of visual function using electrophysiology and behavioral assessments [386,392]. Stable improvement in visual function has been maintained in many animals for longer than 3 years [282]. The demonstration of long-term functional improvement following gene-replacement of RPE65 in preclinical models has supported proposals for clinical trials of recombinant AAV-mediated gene therapy for patients with LCA. Indeed, a phase I/II clinical trial has recently begun in the United Kingdom in young adults and children who have LCA (R. Ali, personal communication). In this clinical study, the RPE65 gene under the control of its own promoter is being delivered via subretinal injection of an AAV2 vector. The purpose of this clinical study is to evaluate the safety and efficacy of this approach in patients. It is anticipated that the youngest patients would be more likely to benefit the most from this treatment. Two additional clinical trials of AAV2 vectors expressing RPE65 for LCA have also obtained regulatory approval in the United States [283,284,393].

6.10.6 RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA), the most common inflammatory joint disease, is a chronic autoimmune disorder that affects approximately 1% of the population and causes significant disability [394]. The etiology of RA is largely unknown, although current evidence suggests contributions from both environmental and genetic components [395]. The chronic inflammation in the arthritic joint is characterized by recruitment of immune cells, including lymphocytes, macrophages, and plasma cells, leading to massive thickening of the synovium accompanied by release of inflammatory mediators, ultimately leading to invasion and destruction of articular cartilage and bone. At the molecular level, chronic inflammatory arthritis is characterized by diminution of T-cell factors and an abundance of cytokines and growth factors such as interleukin-6 (IL-6), tumor necrosis factor α (TNF- α), and interleukin-1 β (IL-1 β) that are produced by macrophages and synovial fibroblasts and play a major role in the progression of joint destruction [396]. IL-1 β , in particular, is a key cytokine that induces cartilage degradation, whereas TNF- α is a major cytokine involved in the joint inflammation [397].

Conventional treatment to manage the symptoms of arthritis uses general anti-inflammatory agents, including both steroidal and nonsteroidal drugs, and disease-modifying drugs such as methotrexate. However, none of these pharmacologic agents have yet proven effective in halting the progression of disease. Recent introduced biologic agents are more effective in ameliorating arthritis symptoms and slowing the disease progression. In particular, inhibitors of TNF- α and IL-1 β have proven effective in preclinical studies and in human clinical trials. Four biologic therapeutics based upon use of soluble TNF- α receptor immunoglobulin Fc (TNFR:Fc, etanercept), anti-TNF- α monoclonal antibodies (Humira, Remicade), and IL-1 receptor antagonist (IL-1Ra, Kineret) are now approved for the treatment of RA.

The use of biologics for arthritis therapy nevertheless presents several challenges. The relatively short half-life of these proteins dictates frequent, daily or weekly dosing and effective levels of the therapeutic protein may not be maintained for extended periods. In addition, therapeutic proteins are administered systemically and may have reduced bioavailability in some affected joints. Gene transfer may be an efficient means of delivery of these biological agents. Persistent transgene expression could circumvent the need for frequent repeat dosing and facilitate attainment of steady levels of the product. Furthermore, localized gene transfer might increase bioavailability in nonresponding joints.

AAV vectors encoding genes that selectively target key mediators, or that interfere with key biological processes, involved in the pathogenesis of RA have been evaluated in rodent models of inflammatory arthritis. In mice with collagen-induced arthritis (CIA), an AAV vector encoding interleukin-4 (IL-4) demonstrated protection, for up to 7 months, from articular cartilage destruction and amelioration of disease severity [398,399]. Also, an AAV vector expressing the viral interleukin-10 (vIL-10) under the transcriptional control of the regulated TetON system was evaluated following intramuscular administration to mice with CIA. Expression of vIL-10, specifically induced by doxycycline, persisted for at least 4 months and reduced significantly the incidence and severity of arthritis [399]. In TNF- α transgenic mice, intra-articular injection of AAV encoding soluble TNF receptor type I (TNFR I) significantly decreased synovial hyperplasia, and cartilage and bone destruction [400]. An AAV vector encoding IL-1Ra cDNA was evaluated in a lipopolysaccharide (LPS)-induced arthritis model in rats using therapeutic, recurrence, and preventative protocols [401]. IL-1Ra expression was upregulated by LPS-induced joint inflammation and proved efficacious in all protocols. Importantly, the IL-1Ra transgene persisted for more than 3 months and could be induced to express therapeutic levels of soluble IL-1Ra upon LPS administration. This resulted in suppression of inflammation and IL-1 β production in the treated knee joints.

In the streptococcal cell wall (SCW)-induced rat arthritis model, administration of an AAV vector encoding the rat TNFR:Fc fusion gene, either systemically (intramuscular), or locally (intra-articular), resulted in profound suppression of arthritis [402]. This was reflected in decreased inflammatory

cell infiltration, pannus formation, cartilage and bone destruction, and mRNA expression of joint proinflammatory cytokines. Moreover, administration of the vector to one joint suppressed arthritis in the contralateral joint. These studies formed the basis of a phase I dose escalation trial, to assess the safety of intra-articular delivery of AAV2 containing the human TNFR:Fc fusion gene (tgAAC94) in subjects with inflammatory arthritis who were not on concomitant systemic TNF- α antagonist therapy [403]. Eleven of the fifteen subjects enrolled in the trial were randomized to receive either one of two escalating dose levels of tgAAC94, while the other four received a placebo. The trial contained a placebo arm primarily to assess whether any adverse events were attributable to an intra-articular injection itself, as opposed to an intra-articular injection of tgAAC94. The conclusions from the analysis of trial results were that tgAAC94 was well-tolerated at doses up to 1×10^{11} DRP/mL of joint volume and that no drug-related serious adverse events were observed. The study was not powered to show efficacy but subjects administered a single dose of tgAAC94, showed some continued improvement in signs and symptoms in treated subjects ($n = 11$). Some improvement was also noted in mean tenderness and swelling scores in subjects receiving placebo.

Currently, the tgAAC94 vector is being tested in a double-blinded, placebo-controlled phase I/II clinical trial in subjects with inflammatory arthritis. In this study of 120 subjects, three dose levels of tgAAC94 are being evaluated in subjects with RA, psoriatic arthritis, or ankylosing spondylitis, who may or may not be receiving concomitant treatments of anti-TNF- α therapy, but continue to experience inflammation in one or more joints (404). In the first segment of this study, subjects are receiving a single intra-articular injection of tgAAC94 or placebo in the affected joint and are monitored until swelling in the target joint reaches predetermined criteria for reinjection. At that time, those who were injected with tgAAC94 as well as those subjects initially injected with placebo will receive an injection of tgAAC94 in the affected joint as part of the open-label segment of the study. The primary endpoint of the study is to establish the safety of higher doses and of repeat administration of tgAAC94 into the joints of subjects with and without concomitant TNF- α inhibitor therapy. Secondary endpoints include evaluation of pain and swelling, duration of response, overall disease activity following intra-articular administration of tgAAC94 into affected joints, patient and functional assessment of target joint, and joint inflammation and damage as assessed by magnetic resonance imaging.

6.10.7 OTHER DISEASES

AAV vectors have also entered into clinical trials for a number of other indications (Table 6.1). Hereditary emphysema is caused by a mutation in the gene for AAT which is normally synthesized in the liver and transported via serum to the lung where it inhibits the activity of the neutrophil elastase. The absence of AAT may lead to progressive destruction of lung tissue and premature mortality. The disease

can be treated by weekly intravenous injection of the protein AAT, but this is costly and the protein is in short supply. The general steady state level of AAT in blood is about 1 mg/mL, so relatively high expression is required from any gene therapy approach. Preclinical studies in rodents and larger animals suggest that a level of AAT protein in serum between 500 and 1000 μ g/mL can be achieved and maintained for over 1 year [124,405].

On the basis of these results, a phase I clinical trial was conducted [406]. In this trial, an AAV2-AAT vector was administered by intramuscular injection to subjects with hereditary emphysema who all had the common P1Z mutation in the AAT gene. This mutation leads to a defective salt bridge in the AAT protein. Three dose cohorts were administered with vector via intramuscular injection at doses up to 6.9×10^{13} . Most of the subjects were on systemic AAT protein therapy, and even though this systemic protein therapy was discontinued before administration of the vector, the wash-out period may not have been long enough and the serum level of the protein expressed from the vector could not be determined. A second trial, using an AAV1 is currently under way, in the hope that this serotype vector will give much higher expression in the muscle [407].

Two other clinical trials are currently being conducted with AAV1 vectors for treatment, in one case for hereditary hypertriglyceridemia caused by mutations in the gene for lipoprotein lipase (LPL) and in another case for a chronic disease, congestive heart failure (Table 6.1). For LPL deficiency one-phase I/II trial was conducted in the Netherlands in eight subjects who were administered the AAV1-LPL vector intramuscularly. Some decreases in serum levels of triglycerides were observed but there was no evidence of expression of the LPL transgene. A second phase II trial is currently being conducted in a population of LPL deficient subjects in Quebec, Canada. One characteristic of chronic heart failure is a progressive loss of contractility of the heart muscle and thus decreased ejection volume. Cycling of calcium plays a critical role in the cardiac contraction-relaxation cycle. In particular, the sarcoplasmic reticulum calcium ATPase pump (SERCA2a) is required in cardiac myocardium to recycle calcium back into the sarcoplasmic reticulum during each diastolic period. Subjects with chronic heart failure exhibit a progressive loss of activity of SERCA2a in their myocardium. Consequently, a clinical trial is currently under way to deliver the gene for this enzyme using an AAV1 vector, which is particularly efficient in cardiomyocytes, via infusion through the coronary artery.

6.10.8 VACCINES

Early reports on administration to animals of AAV vectors expressing some neo-antigenic transgenes demonstrated the long-term durability of transgene expression in the muscle and showed that the use of AAV vectors did not result necessarily in an immune response against the vector-encoded transgene [70,71,316,408]. However, other studies in mice showed that under certain conditions both humoral and

antigen-specific T-cell responses to the transgene protein could be observed. Production of these immune responses probably depends upon several parameters that include the nature of the neo-antigen and its level of expression and localization within transduced cells, the mouse strain used, and the vector dose. Transgene-specific immune responses have been observed in mice following administration of AAV vectors expressing genes encoding *Escherichia coli* β -galactosidase [301,302,409], ovalbumin [298], HSV-2 glycoproteins B (gB) and D (gD) [303], influenza virus hemagglutinin (HA) and HIV-1 Env [409–411], human α -1-antitrypsin (hAAT) [124], and clotting factor IX [305].

The ability to elicit immune responses implies that there is no general mechanism by which AAV blunts the immune system. While the mechanism of antigen presentation following administration of recombinant AAV vectors to the muscle is not clear, one report suggests that activation of T-cells in the draining lymph nodes occurs exclusively through cross-presentation by antigen-presenting cells rather than by direct transduction of dendritic cells (DC) [301]. Whether cross-presentation is a phenomenon that occurs for all transgenes in the context of recombinant AAV vectors is unknown but it suggests a possible role for these vectors as vehicles for prophylactic or therapeutic vaccines. For example, one study demonstrated that a recombinant AAV vector expressing a secreted HSV-2 gB led to the activation of gB-specific CTL, which were most likely activated via cross-presentation of the secreted protein by DC [264]. In contrast, mice injected intramuscularly with an AAV vector expressing ovalbumin developed a robust humoral response to the transgene product but only a minimal ovalbumin-specific CTL response [298].

The use of AAV to stimulate an anti-human immunodeficiency virus (HIV-1) response has been tested in mice. A single, intramuscular injection of an AAV vector encoding the HIV-1 *env*, *tat*, and *rev* genes (AAV-HIV) induced robust, long-term production of HIV-1-specific serum IgG and MHC class I-restricted CTL activity [411]. HIV-specific cell-mediated immunity was enhanced strongly by co-administration with an AAV vector encoding interleukin-12, while boosting with AAV-HIV resulted in rapid and strong HIV-1-specific humoral responses. When AAV-HIV was administered orally, a strong systemic and regional HIV-specific humoral immunity and MHC class I-restricted CTL response was induced which significantly reduced viral load after intrarectal challenge with a recombinant vaccinia virus expressing the HIV-1 *env* gene [412].

In rhesus macaques a single dose, intramuscular administration of an AAV vector expressing the simian immunodeficiency virus (SIV) major structural genes resulted in long-term CD8⁺, antigen-specific CTL responses against multiple SIV protein epitopes that were similar to responses observed in monkeys directly infected with pathogenic SIV. Neutralizing antibody responses were also robust and persisted for more than 1 year. More recent studies to examine the efficacy of AAV-SIV vaccines in an macaque-SIV challenge model showed that immunized macaques were able to significantly lower replication of a live, virulent SIV after intravenous challenge

at peak (2 weeks) and set-point (10 weeks) compared with mock-vaccinated control animals [413,414].

An HIV vaccine candidate, tgAAC09, that utilizes an AAV2 vector to deliver genes encoding the HIV proteins gag, protease and reverse transcriptase, is currently being tested in clinical trials. In a phase I, double-blind, placebo-controlled, dose-escalation safety study of tgAAC09, 80 healthy volunteers in Europe and India received a single intramuscular injection of tgAAC09 at different doses. Additionally, 21 of the 50 European volunteers received a booster vaccination of either tgAAC09 at the highest dose tested, or placebo. The vaccination with tgAAC09 was safe and well tolerated and stimulated a modest immune response against gag. HIV gag-specific T-cell responses were observed in 20% of participants receiving the highest dose of tgAAC09 tested. A phase II clinical study of tgAAC09 currently under way at multiple sites in South Africa, Zambia, and Uganda is being conducted to evaluate the impact of a higher dose of tgAAC09 and boost vaccination on the strength and duration of immune responses.

6.11 SUMMARY

The work summarized in this chapter illustrates the increasingly rapid progress that is now being made in developing therapeutic applications of AAV vectors. The early clinical testing of AAV vectors for the treatment of CF was extremely important in initiating the regulatory environment for AAV vectors and demonstrating the inherent good safety profile of AAV vectors. As more groups have extended investigations to additional *in vivo* models, the potential utility of AAV vectors as therapeutic gene delivery vehicles has gained more widespread interest. The level of clinical activity in testing many additional AAV vectors has been accelerated in recent years. The development of more sophisticated production systems for AAV vectors has enhanced both the quantity and quality of vectors that can be produced. Additional work to modify the transduction efficiency by judicious choice of serotype for the capsid or by modification of the capsid structure may expand the use and potency of AAV vectors. In addition, further understanding of the intracellular metabolism of AAV vectors also increase the sophistication with which these vectors can be deployed.

7.1 INTRODUCTION

7.1.1 GENERAL OVERVIEW

Successful gene therapy requires not only the identification of therapeutic genes but also the design and construction of suitable vehicles for delivery and expression of these genes to target tissues *in vivo*. Identification of genes with therapeutic potential and engineering effective gene transfer vectors are rapidly proceeding, suggesting that gene therapy is likely an imminent clinical reality. Following inevitable setbacks in any innovative approach, gene therapy researchers have spent considerable time and effort in the engineering of safe and effective gene transfer vectors. Combining the natural traits of the desired vector system with the disease specific attributes will significantly increase the likelihood of efficacious gene transfer. For example, use of a neurotrophic vector

system for gene transfer to the nervous system likely increases the odds for success. Similarly, use of a gene product naturally involved in pain relief, such as preproenkephalin that directs production of opioid peptides, also increases the likelihood of success. Combining the natural biology of the disease with the natural biology of the gene transfer vector is not only intuitive, but we have found it is also effective.

With considerable progress in vector design, the number of gene therapy clinical trials has been steadily increasing. Several successful gene therapy clinical trials have recently re-invigorated gene transfer research and have begun fulfilling the promise for creating a new age of molecular medicine in which genomics and proteomics merge with genetic diagnostics and therapeutic gene transfer. We speculate that the age of efficacious gene therapy will soon be upon us.

In order to overcome technical hurdles, the development of strategies for vector targeting, modifications to increase

transgene stability, regulation of gene expression, an circumvention of undesirable immune responses and effects of vector integration remain at the forefront of gene therapy research. Delivery of transgenes into target cells can be accomplished using either viral or nonviral vectors, with viral strategies remaining the most prevalent in human clinical trials. Virus-mediated gene delivery requires efficient methods for vector construction, vector production, and target cell infection. In this chapter, the relative merits and potential applications of replication-defective genomic herpes simplex virus type 1 (HSV-1) vectors are discussed. In the context of vector development, the natural history of HSV infection in the host is reviewed, highlighting unique features of the virus biology. Recent advances in therapeutic gene transfer to the nervous system using HSV-based vectors are also discussed.

7.1.2 ADVANTAGES OF HSV VECTORS

Successful therapeutic gene transfer will require construction of vectors tailored to specific applications, often utilizing the natural attributes of the base virus. The human herpesviruses naturally reside within the peripheral nervous system (PNS), an attribute we take advantage of by targeting PNS disease. Replication-defective HSV-based vectors represent promising candidate vectors for several types of gene therapy applications that include neuropathological disorders, cancer, pain control, autoimmune syndromes, and metabolic diseases.

Herpesviruses, large DNA viruses with the potential to accommodate multiple transgene cassettes, have evolved mechanisms that allow lifelong persistence in a nonintegrated latent state without causing disease in an immune-competent host. Among the herpesviruses, HSV-1 is an attractive vehicle for gene transfer to the nervous system because natural infection of humans results in a usually benign, lifelong persistence of viral genomes in neurons. This latent state is characterized by the absence of lytic viral protein expression and the presence of these latent genomes does not alter nerve cell function or survival. The HSV-1 genome contains a unique, neuron-specific promoter complex that remains active during latency, the latency active promoter (LAP). This promoter can be adapted to express therapeutic proteins without compromising the latent state or stimulating immune rejection of transduced cells. The establishment of latency does not appear to require the expression of viral lytic functions. Essential genes required for expression of the viral lytic functions can therefore be deleted to create completely replication-defective vectors that nonetheless effectively establish a latent state, but cannot cause disease or reactivate from latency. Experimental HSV infection is not limited to neurons; the virus is capable of infecting most mammalian cell types, and does not require cell division for infection and gene expression. Accordingly, HSV may be generally useful for gene transfer to a variety of non-neuronal tissues, particularly where short-term transgene expression is required to achieve a therapeutic effect.

Considerable technical progress has been made in developing HSV-1 into a practical gene transfer vector, including

the development of efficient methods for vector construction and high-titer vector production. Recombinant HSV vectors expressing a multitude of gene products have been applied to models of human disease with a great degree of efficacy and without overt safety concerns. The obstacles requiring satisfactory resolution in order to realize the full potential of these vectors include (1) elimination of residual vector toxicity, (2) design of promoter cassettes that provide for sufficient level and duration of transgene expression, and (3) targeting of transgene expression to specific cell populations through the use of tissue-specific promoters, or by altering the virus host range through modifying receptor utilization for attachment and entry. This chapter concentrates on the design, production, and utilization of replication-deficient genomic HSV vectors.

7.2 VECTOR DESIGN STRATEGIES

7.2.1 BIOLOGY OF THE VIRAL LYTIC CYCLE

HSV-1 is a double-stranded DNA virus whose capsid is surrounded by a dense layer of proteins, the tegument, which is contained within a lipid bilayer envelope (Figure 7.1A). Glycoproteins embedded in the viral envelope mediate infection of the host cell, which takes place in two identifiable stages: (1) attachment to the cell surface and (2) fusion with the cell membrane, resulting in virus penetration. The envelope of HSV-1 contains at least 10 glycoproteins (gB, gC, gD, gE, gG, gH, gI, gJ, gL, and gM) and 4 nonglycosylated integral membrane proteins (products of the UL20, UL34, UL45, and UL49.5 genes). Of the 10 glycoproteins, gB, gD, gH, and gL are essential for viral infection [1–4], whereas gC, gE, gG, gI, gJ, and gM are dispensable for infection *in vitro* [5–7] yet can contribute to the replication and spread of the virus *in vivo* in the nervous system.

Attachment of the viral particle is mediated by several glycoproteins [5,6,8]. The sequential attachment steps in infection result in fusion of the viral envelope with the cell surface membrane and entry of the viral capsid into the cell cytoplasm. Even though the molecular events of penetration are not well understood, it is clear that multiple viral glycoproteins are required (e.g., gB, gD, gH/gL) [2,4,9–11]. In addition, following new virion assembly, viral glycoproteins are also involved in a less well-defined process of egress and release of mature particles from the infected cell membrane. Recent work has now shown a link between the viral envelope proteins and the capsid via several of the tegument proteins that explains the formation of active centers of virus assembly. In particular, the VP1/2 and UL37 inner tegument proteins have been shown to associate with intranuclear capsids [12] and that the outer tegument layer proteins VP16, VP22, and UL11 can bind to the cytoplasmic tails of gD, gE, and gH [13–15], thereby providing a framework within the infected cell where particle assembly occurs. The redundancy in these interactions explains previous data where deletion of single glycoprotein or tegument protein genes did not result in decreased virus release and overall titer, however, the deletion

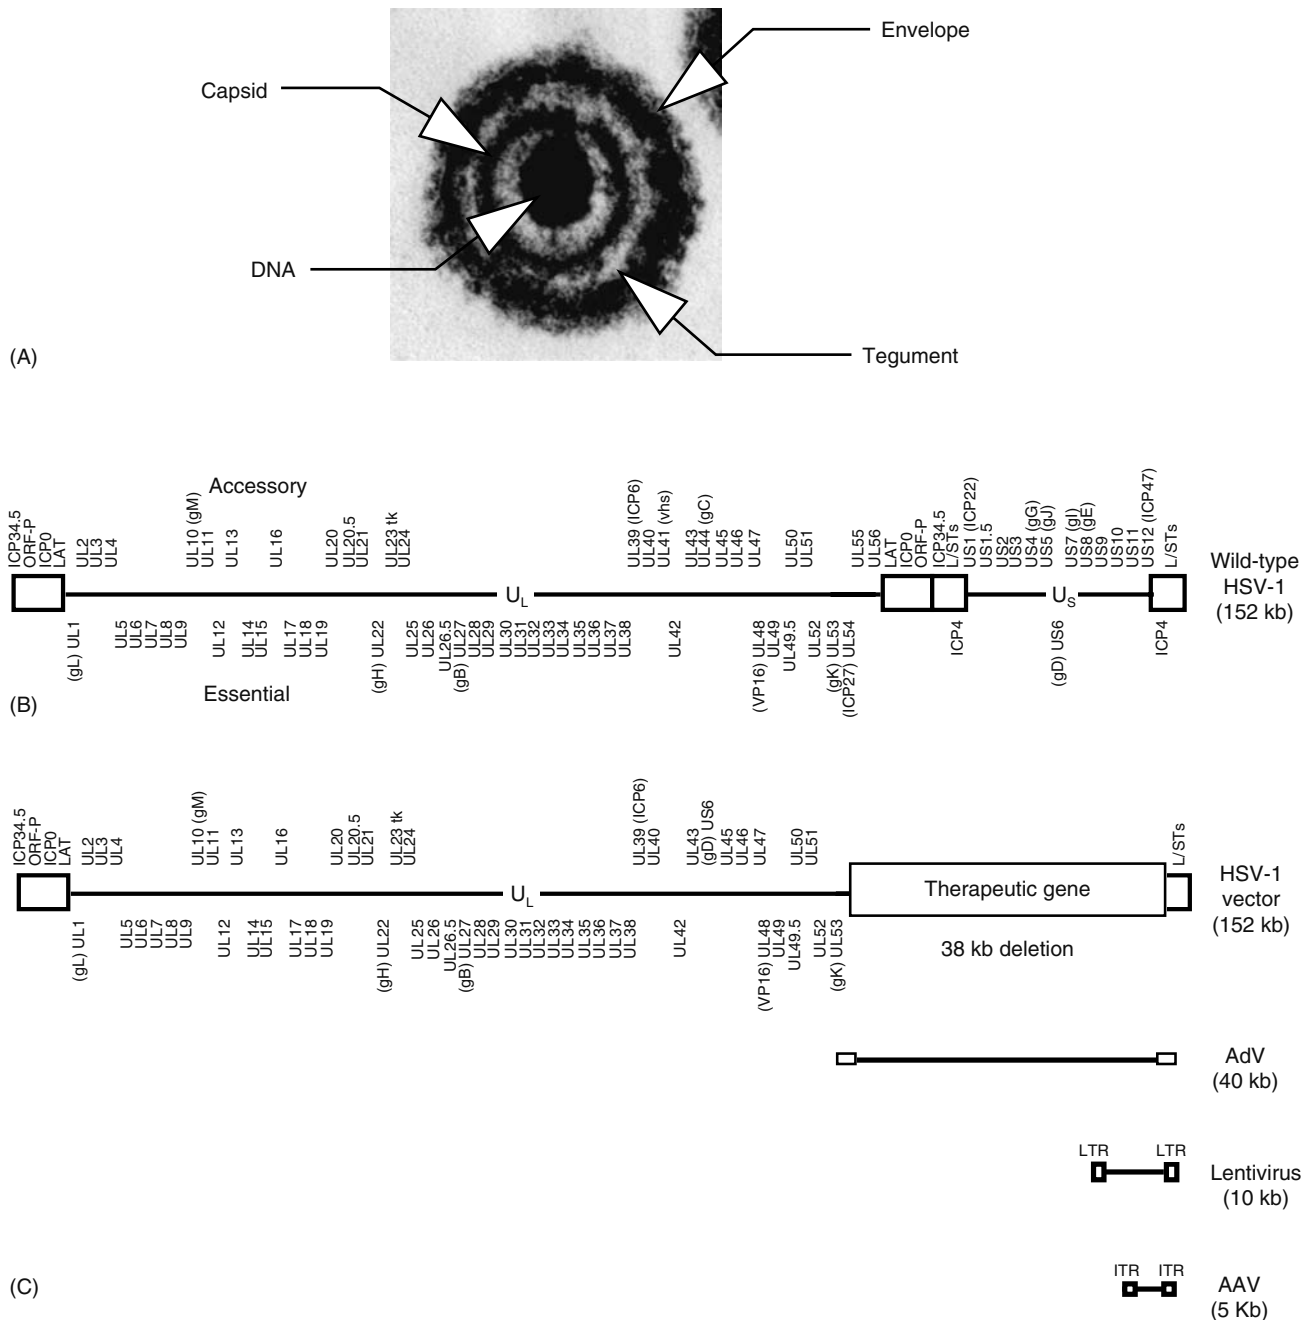

FIGURE 7.1 HSV-1 virion structure, genome organization, and comparison of viral vector payload capacities. (A) Electron micrograph of the HSV particle showing the capsid, tegument, and glycoprotein-containing lipid envelope. (B) Schematic representation of the HSV genome showing the unique long (UL) and unique short (US) segments, each bounded by inverted repeat (IR) elements. The location of the essential genes, which are required for viral replication *in vitro*, and the nonessential or accessory genes, which may be deleted without affecting replication *in vitro*, are indicated. (C) Schematic diagram of various viral vector genomes currently in use for gene transfer and therapy studies, including the overall size of the entire vector genome. The HSV-1 vector, which contains a 38 kb deletion of sequences comprising the joint region and the entire US segment of the viral genome (ICP4⁻, ICP22⁻, ICP27⁻), can accommodate foreign transgene sequences that are larger than lentivirus or AAV vectors and equivalent in size to the complete adenoviral (AdV) genome.

of multiple functions has greatly impaired virion assembly [16]. Viral particles are also capable of spreading from cell to cell across cell junctions, a process requiring the functional activities of several glycoproteins that are not required for

initial infection (e.g., gI/gE) [17,18] and also the function of at least some tegument proteins [19,20].

The genome structure of HSV can be divided into viral genes that are essential or accessory for replication in cell

culture (Figure 7.1B). The accessory functions may be deleted without significantly hampering virus growth in culture. However, removal of essential genes necessitates the use of complementing cell lines that express the essential products in order to propagate these viral recombinants. In human infections, HSV binds to and enters epidermal cells following direct contact with an infected individual that is shedding virus or has an active lesion. Following virus attachment, the viral capsid penetrates the surface membranes of epithelial cells of the skin or mucosa and is transported to the nuclear membrane where viral DNA is injected through a nuclear pore (Figure 7.2A). Once inside the nucleus, the viral DNA is circularized and transported to nuclear domain 10 (ND10) structures

[21,22], where the immediate early (IE) genes are expressed as part of the sequential cascade of lytic gene synthesis [23] (Figure 7.2B). Transcription of the five IE genes (ICP0, ICP4, ICP22, ICP27, and ICP47) does not require de novo viral protein synthesis. Expression of the IE genes is controlled by promoters that contain one or more copies of an enhancer element responsive to the viral tegument protein VP16 (aka Vmw 65 or TIF), a transactivator that is transported into the nucleus along with viral DNA [24–26]. The essential IE genes ICP4 and ICP27 encode products required for expression of the early (E) and late (L) genes [27–30]; the former (E) gene class specifying primarily enzyme functions required for viral DNA synthesis and the latter (L) comprising primarily virion structural

FIGURE 7.2 HSV-1 life cycle in the host. (A) Lytic infection. Primary lytic infection of epithelial or mucosal cells results from the attachment and penetration of HSV particles to host cells, a complex process involving many HSV surface glycoproteins. Following transport of the capsid to the nuclear membrane and injection of linear dsDNA into the nucleus, the genome circularizes and begins to express the lytic HSV gene functions in a highly regulated sequential cascade, yielding the expression of proteins involved in viral DNA synthesis and virion structural components. Following assembly of newly synthesized particles within the nucleus, virion maturation results in the egress of these virions from the infected cell. (B) Schematic diagram of the sequential cascade of lytic gene expression. The five IE or α genes are expressed immediately upon infection through transactivation by the VP16 tegument protein. The ICP4, ICP27, and ICP0 IE gene functions are responsible for the activation of the early or β genes that are primarily involved in viral DNA synthesis. In addition, ICP4 acts to shut-off expression of the IE genes. Following viral DNA replication, ICP4, ICP22, and ICP27 participate in the activation of true viral late or γ genes, which mainly encode virion structural components. (C) Latent infection. When virion particles encounter and bind to axonal termini that innervate the site of primary infection, viral capsids are transported in a retrograde manner to the nerve cell body. At this point the circular viral genome can persist as an episomal molecule in a latent state within the neuron, wherein viral lytic gene expression is silenced and a series of latency-associated transcripts (LATs) are produced. (D) Gene expression during latency. The major 2.0kb LAT arises from the large 8.3 kb polyA⁺ through a splicing event that yields an unstable 6.3 kb LAT and a circular LAT lariat of 2.0 kb. The location of the LAP regions LAP1 and LAP2 relative to the LATs is depicted.

components. ICP4 regulates viral promoter function [31], whereas ICP27 affects the processing and transport of viral RNA [32–34]. The IE gene products ICP0 and ICP22 contribute to viral gene transcription but are not essential to virus replication in cultured cells [35–38]. ICP0 is a promiscuous transactivator that exerts its effect prior to the transcription initiation event; it is not a DNA-binding protein [39]. ICP22 has been found to regulate the level of ICP0 expression [40]. ICP47 does not affect transcription but rather has been reported to interfere with the transporter of antigen presentation (TAP) that is responsible for loading major histocompatibility (MHC) class I molecules with antigenic peptides [41–43]. Expression of late genes is dependent on both viral DNA synthesis and IE gene functions [29,31,44,45]. Following translation of the late gene products, which become viral structural components of the capsid, tegument, and envelope, genome-length copies of viral DNA are packaged into the newly assembled capsids. Tegument proteins accumulate around the capsid and the immature particle buds through the inner nuclear membrane followed by progressing through the transgolgi network where the viral glycoproteins are localized. Double-membrane-enveloped virus containing virus-encoded glycoproteins modified by the Golgi apparatus enzymes fuse with the cell membrane forming a mature, extracellular virus particle with a single membrane bilayer [46]. The infectious particles can infect neighboring cells by cell-to-cell transmission or can be released for infection of distal cells. With the exception of sensory neurons, cell lysis accompanies productive viral infection.

7.2.2 COMPLEMENTATION OF ESSENTIAL GENES AND ELIMINATION OF CYTOTOXICITY

Because HSV genes are expressed in a sequential cascade during lytic infection [23], removal of the single essential IE gene ICP4 severely inhibits the expression of later E and L genes [27], resulting in a defective vector incapable of producing virus particles. In addition, the IE gene products, with the exception of ICP47, are individually toxic to most cell types when expressed at high levels by transfection [47]. The elimination of multiple IE genes reduces the cytotoxicity of HSV-based vectors for cell lines and primary neuronal cell cultures [48–52] (Figure 7.3A and B). Cytotoxicity of a genomic HSV vector deleted for ICP4, ICP22, and ICP27 in cultured Vero cells is reduced compared with a virus-only deficient for ICP4 [52]. Such mutants are also less toxic to primary neurons [49] or undifferentiated cells such as umbilical cord blood-derived stem cells [53] which may involve the ability of these cells to regulate the activity of ICP0 or the downstream effects of ICP0, as the protein is less stable in primary neurons than other cell types [54], or may relate to the antiviral state of the target cell.

Interestingly, ICP0 appears to be the key regulatory protein encoded by the virus that determines vector-associated toxicity and controls the level of transgene expression from the viral genome. The role of ICP0 in infection pertaining to gene expression and toxicity can be evaluated in mutant viruses lacking the various IE genes. A virus defective for the expression

of all five IE genes was developed and demonstrated to be completely nontoxic at all multiplicities of infection tested [55]. However, transgene expression from this virus was very low in most cells, suggesting that expression of ICP0 is essential for high levels of transgene expression from such depleted viruses. It was also determined that the expression of ICP0 in the absence of the other IE proteins has profound effects on infected non-neuronal cells [52]. However, infected cells did not divide or synthesize DNA. Curiously, and unlike all previously generated HSV mutants, the infected cells did not round up, but remained metabolically active for several days in a state conducive to high-level transgene expression. Additional published studies demonstrated that both the prolonged high-level transgene expression and the induction of cell cycle arrest were functions of ICP0 [55,56]. Subsequently, published studies have demonstrated that the expression of ICP0 from defective viruses results in a cellular gene expression profile consistent with cell cycle arrest at G1/S [57–59] or G2/M [60,61]. Therefore, residual toxicity in non-neuronal cells of a vector lacking all IE genes except ICP0 is due to the expression of ICP0. ICP0 has been shown to be a potent transactivator of viral and cellular promoters in transient assays [39,62] and provides for efficient viral gene expression and growth *in vitro* and *in vivo* [63,64]. Several activities have been described for ICP0 but the functional relevance of these remains to be clarified. ICP0 localizes to and disperses complex nuclear structures called ND10s/PODs/NBs/Kr, which are thought to be involved in the proliferative state of the cell [21,65] and are involved in acting as a storing house for cellular factors that are stimulated in response to a variety of cellular insults such as DNA damage due to irradiation or chemicals, as well as participating in the IFN response to virus infection. Two E3 ubiquitin ligase domains have been identified in ICP0 [66–68] which may explain the ability of ICP0 to induce the proteosomal degradation of many of the ND10 components such as PML and Sp100 [67,69,70], CENP-A [61], CENP-C [71], CENP-B [72], DNA-PK [73,74], and p53 [66]. It has also been shown to associate with a 135-kDa ubiquitin-specific protease USP7 [75,76], and other ubiquitin components such as cdc34 [68], and also UbcH5a and UbcH6a [66,67,74] where it is believed that its association with USP7 blocks its ability to ubiquitinate itself thereby leading to its own degradation by the proteosomal machinery [77]. In addition, it associates with the BMAL-1 transcription factor [78] and the p60 protein [79]. It also interacts with molecules involved in translation [80] and cell cycle regulation such as CyclinD3 [81] and binds to HDACs [82,83] and plays a role in dissociating HDACs from the HDAC1/2:REST:Co-REST complex [84], which is thought to play a major role in activating gene expression. ICP0 also modulates the innate response to the virus by altering the IFN response to HSV through IRF3, CBP, and p300 [85,86] that may also enable the cell to repress expression from the viral genome. Recent evidence using PML, IFN α R, and STAT1 knockout mice has shown that STAT1 and the IFNs play a role in repression while PML does not [87]. Therefore, ICP0 has the potential to alter many aspects of host cell metabolism. However, neurons regulate and process ICP0 differently and

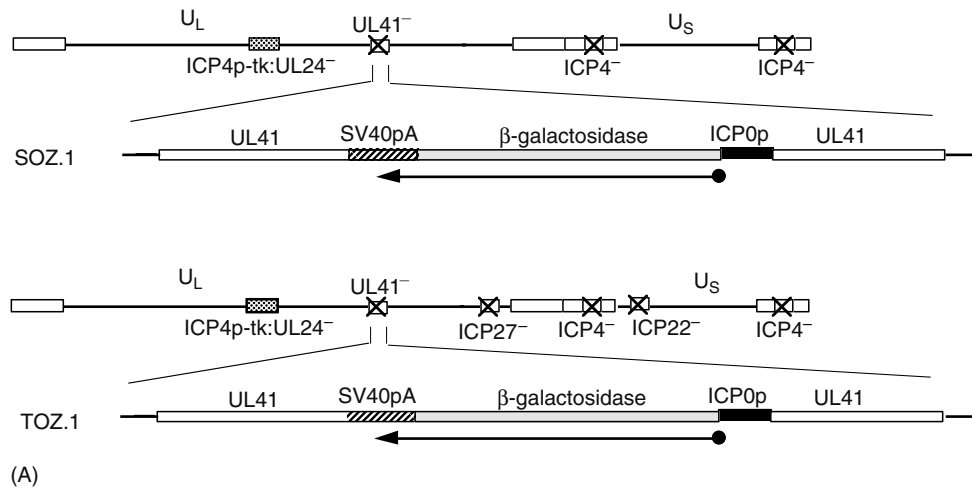

FIGURE 7.3 Reduced toxicity following infection of primary dorsal root ganglia neurons. (A) Schematic representation of the first-generation SOZ.1 (ICP4⁻, UL41⁻:ICP0p-lacZ:UL24⁻:ICP4p-tk) and the third-generation TOZ.1 (ICP4⁻, ICP22⁻, ICP27⁻, UL41⁻:ICP0p-lacZ, UL24⁻:ICP4p-tk) replication-defective vectors displaying the lacZ transgene inserted into the UL41 locus under the control of the ICP0 promoter using the SV40 polyadenylation signal. (B) Number of primary dorsal root ganglion (DRG) neurons undergoing apoptosis was determined at various times following infection with either SOZ.1 or TOZ.1. Even at an MOI of 30, TOZ.1 was less toxic than the first-generation vector (SOZ.1) at the lower MOI (3.0).

are not dramatically affected by ICP0 expression [54] since they lack ND10 structures. Moreover, proteasome inhibitors affect ICP0 degradation in neurons and other cells that tie with ICP0s function as an E3-Ubiquitin ligase [66–68]. The decreased half-life of ICP0 in neurons also contributes to the overall decreased toxicity in these cells.

We engineered numerous mutant background vectors for gene therapy applications that require short-term, high-level expression by deleting multiple viral functions, including the IE genes ICP4, ICP22, ICP27, and ICP47. We chose to remove the ICP47 gene in some vectors to avoid interference with antigen presentation in applications intended for induction of specific immunity, but we did not delete the ICP0 gene because this gene product improves transgene expression and permits

efficient construction of recombinant vectors [56,88]. In these mutant backgrounds, we eliminated the virion host shut-off function (vhs) encoded by UL41 because this virus tegument component indiscriminately interferes with translation of mRNA in infected cells [89–91]. A similar vector background has been used to express transgenes for up to 21 days in cultured primary neurons without causing neuronal cell death [49]. For applications involving infection of cancer cells *in vivo*, the transient arrest of cell division offered by ICP0 and subsequent recovery of cell growth at high multiplicity of infection should prove advantageous because transduced cells produce high levels of transgene product prior to induction of cell death. For other applications in non-neuronal targets, it may be necessary to delete ICP0 or employ a modified form of the gene that

enables sufficient therapeutic gene expression from the viral backbone in the absence of observable vector-related cytotoxicity. We are currently investigating numerous approaches in a matrix deleting these gene products in combinations.

7.2.3 VECTOR TRANSGENE CAPACITY

The treatment of monogenic diseases typically requires only limited vector capacity, but complex applications may require the delivery of large or multiple independent genetic sequences. A comparison of the genome structure and capacity of several current vector systems is shown in Figure 7.1C. The overall size of the HSV-1 genome (152 kb) represents an attractive feature for employing the vector for the transfer of large amounts of exogenous genetic sequences. Approximately one-half of the HSV-1 coding sequences are nonessential for virus replication in cell culture and therefore may be deleted to increase transgene capacity without blocking viral replication (Figure 7.1B). The latency region of the virus genome represents approximately 8 kb of sequence that can be removed and the joint region of the virus is composed of 15 kb of redundant sequence that can be eliminated without compromising virus replication [92]. In one line of experiments we removed in excess of 26 kb of the HSV-1 genome (Wolfe, D., unpublished data, 2007). At least 44 kb of HSV sequence can potentially be removed and vectors propagated in cells engineered to complement just three viral functions (ICP4, ICP27, and gD). Transgene expression cassettes can also be inserted into deleted essential gene loci to avoid transfer of foreign sequences to wild-type virus by recombination that could potentially occur between the vector and wild-type genomes *in vivo*. We have observed that some nonessential genes (e.g., IE genes ICP0 and ICP22) are toxic to some cell types, yet the products of these genes are required for high-titer vector production. The toxicity of these products makes it difficult to produce a complementing cell line carrying these genes. However, it is possible to engineer the promoters for these genes in a manner to make their function dependent on viral IE genes present only in complementing cells [52]. By the judicious selection of viral gene deletions and promoter alterations, high-titer vectors can be produced with minimal complementation.

We have developed a panel of novel HSV-1 vectors with a background suitable for expression of multiple transgenes using a rapid gene insertion procedure [93]. To take advantage of the reduced cytotoxicity resulting from the deletion of ICP4, ICP22, and ICP27 genes [49,51], we designed a single vector in which nine viral genes were deleted, removing a total of 11.6 kb of viral DNA that was replaced with multiple transgenes under control of different promoters. These HSV multigene vectors were constructed with either four or five independent transgenes at distinct loci [94] with all the transgenes simultaneously expressed for up to 7 days. These multigene vectors demonstrate the potential for using HSV-1 vectors for the expression of complex sets of transgenes that have coordinated or complementary functions.

Recent work inserting bacterial artificial chromosome (BAC) elements into large viruses including HSV promises to

increase the speed of recombinant construction as well as allow the creation of extensively modified vectors without the necessity of creating complementing cell lines. We have introduced the BAC elements into multiply defective HSV vectors and propagated them in *Escherichia coli* (Wolfe, D., 2007, unpublished data). Transfection of HSV:BAC DNA purified from bacteria into complementing cells is much more efficient than using viral DNA purified from mammalian cells. Infectious virus produced can be recovered back into *E. coli* for further modification. Several methods have been used to modify the viral genome in bacteria with high frequencies of recombinant production in a greatly shortened time frame. We have further modified vector genomes and have constructed recombinant replication-defective BAC vectors that have been used to incorporate cellular cDNA libraries using recombineering (Wolfe, D., 2007, unpublished data) as well as engineering additional methods for recombinant engineering in bacteria.

7.2.4 AMPLICONS AS AN ALTERNATIVE VECTOR SYSTEM

Often referred to as “defective” HSV-1 vectors, amplicons are plasmids engineered to contain both an HSV origin of replication and packaging signals as well as a bacterial origin of replication [95]. Amplicons are propagated in bacteria and then cotransfected with a defective HSV “helper” virus to create a mixed population of HSV particles containing either the defective HSV helper genome or concatemers of the plasmid packaged within an HSV capsid. In concept, the production of virion-packaged amplicons uses transient complementation of the entire HSV genome to provide the needed replication machinery and viral structural components. A comparison of replication-defective genomic HSV vectors and helper virus-free amplicons is shown in Figure 7.4A and B. Amplicons have been used to express reporter genes [96–102] or biologically active peptides [103–112] transiently in tissue culture systems.

In vivo, a prolonged expression of both a *lacZ* reporter gene [100,113–117] and of the TH gene [113] following amplicon injection into brain has been reported. However, the production of amplicons requires repeated passaging of the amplicon/helper virus preparation, which results in the emergence of recombinant wild-type virus that, although estimated to occur at the low frequency of 10^{-5} [113,114], results in the death of 10% of infected animals in experiments *in vivo* [113]. The production of true helper virus-free amplicon preparations using multiple restriction fragments of the helper virus genome that lack packaging signals has recently been reported [118]. However, the maximal yield obtained with that method has remained low ($<10^7$ pfu/mL), and expression *in vivo* has not been fully tested [118]. The presence of cytotoxic helper virus and the generation of replication-competent contaminants represent technical hurdles to the effective production and use of amplicons in human patients. Helper-free amplicons will likely require the development of new helper systems to make their use practical enough for human applications.

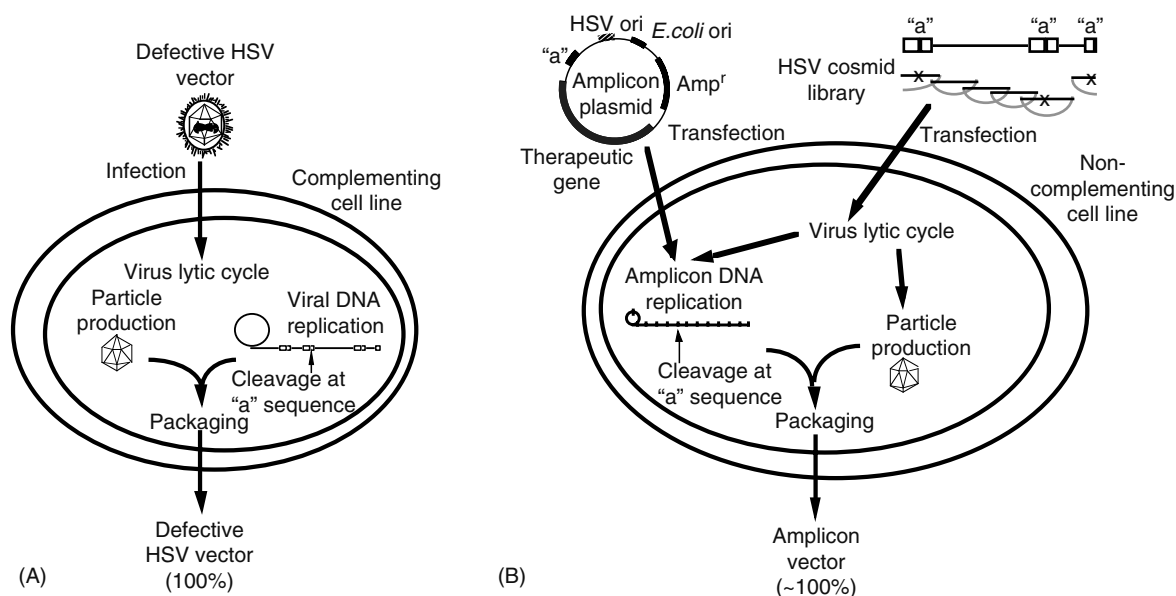

FIGURE 7.4 Strategies for HSV-1 vector design. (A) The production of defective full-length genomic HSV vectors is carried out in cell lines engineered to provide the deleted essential genes *in trans*. These vectors can be produced in high titers, are capable of long-term persistence in neurons *in vivo*, can accommodate large or multiple transgenes, and are incapable of replicating in neurons or other cells because of the missing essential genes. (B) Helper-free amplicons can be readily propagated in bacteria using the bacterial origin of replication (*E. coli* ORI), and then transfected into a noncomplementing cell line along with five cosmids that encompass the entire HSV genome. Unlike the standard amplicon system in which the final preparation consists either of a mixture of amplicon concatemers and defective HSV particles, only amplicon concatemers get packaged into new virus particles because the overlapping cosmids lack the HSV packaging sequence ("a" sequence). The helper-free amplicon preparations suffer from low titer yields, decreased stability of the amplicon DNA, and decreased transgene payload.

Improvements in the amplicon-packaging system using Cre-lox [119] among other methods have resulted in preparations that are less immunogenic when injected into the CNS of rodents [120] that represents a drastic improvement in the use of the amplicon system. With these modifications, amplicons still continue to be used for *in vivo* delivery to the CNS to deliver neurotrophin-3 (NT-3) or the NMDA receptor [121] or ATM [122] or to treat cancer [123,124]. Recently, they have been employed as a vaccine vector with some success [125–128] as their lower overall titers and immunogenic nature compared to the genomic replication-defective HSV vectors prove to be an advantage for vaccine approaches.

Hybrid amplicon vectors have been produced with either AAV [129] or EBV [130] that allow rep-mediated site-specific integration of the transgene cassette (AAV) [131,132] or enable long-term plasmid DNA maintenance in cells of non-neuronal origin (EBV). Finally, as mentioned previously, HSV:BAC constructs [133,134] have now been employed to incorporate either large transgene cassettes containing larger natural promoters and full-length eukaryotic genes [135] or for the introduction of cDNA libraries (Wolfe, D., 2007, unpublished data).

7.3 REDIRECTING VECTOR INFECTION

One method to achieve cell-specific expression of the therapeutic gene is targeting vector recognition and infection of cells to unique receptors present principally on target cells.

Targeted viral infection requires (1) the identification of cell-specific surface receptor(s) to which viral binding/entry can be directed and (2) the modification of viral glycoproteins to recognize novel receptors while eliminating the binding of these viral ligands to native receptors, a process that ideally should be accomplished without compromising infectivity.

Initial binding of HSV particles to cell surface heparan sulfate (HS) and other glycosaminoglycans (GAGs) [9,143–149] is mediated by exposed domains of glycoproteins C [150–154] and B [145,151], as evidenced by (1) diminished cell attachment of gC and gB mutants, (2) interference with cell attachment by pretreatment with anti-gB or anti-gC antibodies, (3) reduced attachment of virus after enzymatic removal of cell surface GAGs, and (4) competition studies using heparin. The role of gB is complex as this glycoprotein functions both in the initial binding of virus to the cell surface (nonessential for cell entry) and in later stages in the virion-cell fusion program (essential for cell entry). Molecular dissection of the domains of gB that are responsible for each distinct process has allowed for the generation of a gB mutant that exhibits a reduced capacity for binding to GAGs without a loss of its fusogenic activity [151]. This mutant, generated by deletion of a positively charged lysine-rich region within gB (designated gBpK⁻), is an important resource in the generation of viral vectors with targeted cell binding

and preserved entry (Figure 7.5). The initial gB/gC-HS/GAG-mediated cell attachment greatly enhances but is not essential for subsequent events in the cell entry cascade; thus, cell attachment represents a reasonable target for strategies aimed at effecting restricted cell entry.

Attachment of HSV-1 to cell surface HS is followed by gD-mediated attachment to a second cell receptor. Work by several labs has identified gD cognate receptors utilized for

both virus attachment and penetration. The first herpes virus entry mediator (HVEM or HveA), a member of the tumor necrosis factor- α (TNF- α)/nerve growth factor (NGF) receptor family, was identified by screening a cDNA expression library in HSV-1 resistant CHO cells for clones that enabled virus infection [155]. Domains of gD that contribute to HveA binding have been identified in virus infection inhibition studies using monoclonal antibodies that recognize residues 11–19

FIGURE 7.5 Targeted binding of HSV-1 particles expressing gC:EPO fusion molecules to EPO receptor (EPO-R)-bearing cells. (A) Diagram of the KOS wild-type HSV-1 genome depicting the location of the two HSV glycoproteins (gB and gC) involved in HS binding. The HS-binding domain of gB consisting of a series of polylysine (pK) residues is shown in greater detail. (B) The KgBpK-gC⁻ recombinant virus deleted for binding to HS was constructed by deleting the pK region from the essential gB gene and deletion of the nonessential gC gene by insertion of an HCMV IEp-lacZ expression cassette into the gC locus. (C) The gC:EPO2 recombinant (KgBpK-gC^{EPO2}) was constructed by introducing EPO into the gC gene, replacing aa# 1–162 in the KgBpK-gC⁻ recombinant virus, which could readily be purified by X-gal staining.

FIGURE 7.5 (continued) (D) The percentage of radiolabeled wild-type HSV-1 (KOS), the recombinant deleted for HS-binding (KgBpK-gC⁻), and the EPO-expressing (KgBpK-gCEPO2) viruses that bound to K566 cells bearing the EPO-R was determined and is expressed compared with input virus. These data demonstrate that the KgBpK-gCEPO2 recombinant virus binds to the EPO-R and this binding conferred increased infectivity of the KgBpK-gCEPO2 virus for cells bearing the EPO-R (K566).

and 222–252 [156]. Further insight into the interacting domains of gD and HveA was acquired upon the crystallization of gD bound to HveA. Data acquired from these studies identified critical amino acids primarily within the amino termini of HveA and gD that are critical for gD-HveA complex formation [157–160]. In addition to the HveA receptor, a number of other gD entry mediators have been identified, including HveB (nectin-2) [161], 3-O-sulfated HS [162], and HveC (nectin-1) [163,164]. HveC is ubiquitously expressed on most cells, including epithelial and neuronal cells, and is generally considered to be the main HSV-1 entry receptor. HveC is a member of the immunoglobulin superfamily and has no structural relation to HveA [164]. A type I integral membrane protein, HveC contains a variable (V) domain and two constant (C) domains, but attachment of HSV-1 via gD to only the V domain is necessary and sufficient to initiate fusion of the virus with the cell [165]. Recently, we and other laboratories discovered the first mutants of gD that do not bind to HveC, but can still mediate virus entry through an interaction with HveA [158,166–168].

The consequence of the sequential attachment steps in infection is fusion of the virus envelope with a cellular membrane and subsequent virus entry [5,6]. A role for gD in virus penetration is supported by evidence that attached virus can be neutralized by anti-gD antibody and virus mutants deleted for gD attach to cells but do not penetrate [4,10,11]. Mutants deleted for gH/gL [169,170] or gB [1,171] are also blocked in virus penetration but are not defective in attachment. Both gB and gD are capable of inducing syncytia if expressed on the cell surface at low pH, supporting a possible role for both molecules in fusion [172]. Fuller and Lee proposed that entry involves a cascade of events in which gD initiates the fusion process [9]. According to their hypothesis, a fusion bridge is most likely formed by the action of gB followed by extension of the bridge and virus release requiring the fusogenic activities

of gH/gL. Recent data suggest that, while gB, gH, and gL are all required for fusion, the order of glycoprotein activation is gD-gH-gL, which form a hemifusion intermediate before gB completes the fusion process [173,174]. In addition to external entry, HSV-1 is also capable of infecting neighboring cells by moving transcellularly across cell membranes. This process, referred to as cell to cell or lateral spread, can be distinguished from infection by exocytosed particles through its ability to occur in the presence of virus neutralizing antibodies as well as by deletion of certain accessory envelope glycoproteins (e.g., gI/gE) which prevents lateral spread but not initial infection [17,18].

Entry of HSV-1 can occur through fusion of the viral envelope with the plasma membrane [5,6,175] or an internal endosomal/phagosomal membrane depending upon the cell type [176–179]. Regardless of the mode of entry, after fusion of the viral envelope with a cell membrane, HSV-1 virions are deposited into the cell cytoplasm and the viral DNA is ultimately delivered to the nucleus where transcription and replication of the viral genome ensues.

In early studies designed to alter the cell attachment properties of HSV, we focused on the elimination of GAG-binding by removing the GAG-binding domains from the virus envelope, while leaving intact the viral determinants that mediate cell entry. We hypothesized that vector targeting may be achieved by replacement of the HS-binding domains with ligands that specifically recognize and bind alternate cell receptors. A double-mutant virus, KgBpK⁻gC⁻, was derived from wild-type KOS strain (Figure 7.5A and B). In this mutant, the coding sequence for the nonessential gC gene was removed from the viral genome and the wild-type gB sequence replaced by the gB:pK⁻ mutation [180] (Figure 7.5B). The resulting virus demonstrated an 80% reduction in binding to Vero cells compared with wild-type virus. By replacing the HS-binding domain of gC with the coding sequence of erythropoietin (EPO) in the background of the

KgBpK-gC⁻ mutant virus (Figure 7.5C), we demonstrated that the gC:EPO fusion protein was incorporated into the budding virion and that recombinant virus was specifically retained on a soluble EPO-receptor column [180]. The gC:EPO virus demonstrated a twofold increase in infection of K562 cells (Figure 7.5D), which express the EPO receptor. The EPO-expressing particle also stimulated the proliferation of FD-EPO cells [180], an EPO-dependent cell line, indicating that virus binding to the EPO-receptor had occurred.

In a similar fashion, HSV-1 was also engineered to bind to hepatocytes through the expression of preS1 and a preS1 peptide from hepatitis B virus [181]. Expression of these molecules from an HSV-1 recombinant increased entry into hepatocytes compared to the parental virus that was impaired in binding to GAGs. However, while this recombinant displayed increased entry kinetics on hepatocytes, wild-type HSV-1 entry was even more efficient than the recombinant indicating that the preferred mode of entry in these cells was mediated by an interaction of gD with one or more of the natural receptors. Grandi et al. replaced the HS-binding domain of gC with a His-tag sequence and showed that this vector exhibited a fourfold increase in binding to 293T cells expressing a pseudo-His-tag receptor [182,183]. Collectively, these data showed that HSV-1 vectors can be generated that bind to cells expressing an alternate receptor without disrupting the fusogenic properties of HSV-1.

The next step in the development of redirected HSV vectors was the replacement of HveA- and HveC-binding domains within gD with targeting molecules that could effectively redirect the tropism of HSV vectors. The first data showing that this strategy was a feasible one was reported by Zhou et al. who retargeted an HSV-1 recombinant to IL-13R α 2-expressing cells by insertion of an IL-13 ligand into gC and gD [184]. Virus binding to GAGs was significantly reduced through elimination of the HS-binding domains of gB and gC, and the insertion of IL-13 into the N-terminus of gD destroyed the ability of this recombinant to bind the HveA receptor, but binding to HveC remained intact. This HSV recombinant was shown to efficiently enter and replicate in cells that only express the IL-13R α 2 receptor. These results showed that, in addition to elimination of most of the HS binding, the HveA-binding domain of gD could be altered without affecting virus entry. However, this recombinant was not impaired for entry on cells bearing the HveC receptor. In a subsequent study, the same group inserted the urokinase plasminogen activator (uPA) into the same position of gD and showed that this recombinant could enter cells that express the uPA receptor [185]. Taken together, these data showed that different ligands could be inserted into the amino terminus of gD and effectively retarget the virus. In a recent report, these authors showed that a mutation of amino acid 34 of gD (V34S) in the IL-13R α 2-retargeted virus enabled this recombinant to exclusively enter cells bearing the IL-13R α 2 receptor [186].

Menotti et al. showed that, in addition to ligand insertion, single-chain antibodies against alternate receptors could also be used to redirect HSV tropism. In their study, a single-chain antibody that recognizes the Her2-neu receptor, which is

highly expressed on breast tumor cells, was inserted into gD at the same location as the IL-13 and uPA ligands [184–186]. Recombinant viruses harboring the scFv were able to enter cells bearing only the Her2-neu receptor, but could also infect cells expressing nectin-1. These data showed that scFvs, which are relatively large constructs, could be accommodated by HSV and used to target HSV to alternate receptors.

An alternative approach to introducing novel ligands into viral glycoproteins for targeted HSV entry involves the development of soluble adapter molecules designed to interact simultaneously with a cell-specific receptor and virion gD. In our model study [187], the gD-binding V-domain of HveC was fused to a single-chain antibody (scFv) to the EGF receptor in an effort to target EGFR-bearing cells. The adapter molecule enabled HSV-1 entry into naturally non-permissive CHO cells expressing the human EGFR [187], but not into CHO cells lacking the receptor, and entry was not observed when the antibody portion of the adapter was replaced with that of a different specificity. The degree of EGFR-scFv-adapter-mediated entry increased with viral dose, reaching approximately 65% of the cells at an MOI of three compared to 75% infection of HveC-bearing CHO cells at the same MOI in the absence of adapter. Adapter-mediated virus entry into CHO-EGFR cells was inhibited in a dose-dependent manner by antibodies to gD, EGFR, and the HveC V domain as well as by soluble gD and soluble V domain, establishing its dependence on accessible EGFR, adapter V domain, and viral gD. Moreover, efficient adapter-mediated entry required the presence of cellular GAGs. Together, these results showed that a bi-specific adapter molecule can efficiently redirect HSV infection using a process that does not require the generation of a new recombinant HSV vector for each retargeting attempt.

7.4 VECTOR TRANSGENE EXPRESSION

7.4.1 LYTIC GENE PROMOTERS

We have utilized many divergent viral and cellular promoters in the background of replication-defective viral vectors [49,53,94,188–190]. Typically, lytic viral gene promoters display transient activity in both neuronal and non-neuronal cells. Thus, these viral IE promoters are effective for applications that require only transient transgene expression. Alternatively, the use of transient promoters can allow the design and application of these vectors in clinical trials in order to minimize unforeseen effects of long-term gene expression. Following success in initial clinical trials, long-term promoters may be substituted to allow extended therapeutic benefit from a single-vector application. The human cytomegalovirus (HCMV) IE gene promoter produced vigorous transgene expression for up to 21 days postinfection *in vivo* and in neuronal cell cultures in the background of a vector deleted for ICP4, ICP27, and ICP22 [49]. Studies in rabbits and primates demonstrated transgene expression under control of the HCMV promoter for at least 1 year following infection of rabbit joints, although this result is not typical and may have been influenced by the biological activity of the NGF transgene [191]. Other promoters, such as those

from SV40 and various retroviral LTRs, are also transiently active [192,193] following infection of brain. Cellular promoters such as the muscle-specific muscle creatinine kinase (MCK) enhancer support muscle-specific expression in myotubes in culture [188]. Several reports have described long-term transgene expression from similar promoters in neurons [194–197], but expression declined significantly after the first week and may represent activity of aborted reactivation events. However, many therapeutic applications will require prolonged transgene expression from latent genomes. For this purpose, we and other laboratories have studied the native latency gene promoters in considerable detail.

7.4.2 BIOLOGY OF LATENCY AND THE LAP

Following infection of epithelial cells of skin or mucous membrane, viral particles come into contact with sensory neuron axon terminals in which the particle is transported along microtubules to the nerve cell body where the viral DNA enters the nucleus [198,199] (Figure 7.2C). Although the virus can express lytic functions in sensory neurons [200–202], lytic gene expression is curtailed through a set of largely undefined molecular events and the virus enters a latent state. Latency is typified by expression of a series of LATs from the repeat regions flanking the long unique segment (U_L) of the viral genome partially antisense to and overlapping the 3' end of the ICPO mRNA [203–205] (Figure 7.2D). Two colinear, non-polyadenylated (poly A⁻) LAT RNA species of 2.0 and 1.5 kb [206,207], which accumulate in the nuclei of latently infected neurons [208], are stable nonlinear intron lariats derived from a large, unstable 8.3 kb polyadenylated primary transcript [209–213]. It has recently been demonstrated that this region of the genome remains transcriptionally active while transcription from the remainder of the genome is repressed due to histone deacetylation [214,215] and that a CCTC element within LAP2 may be responsible for this difference in chromatin structure [216,217] as we had previously suggested [218,219]. The virus can remain latent for the life of the individual, although sporadically viral genomes may reactivate in response to a variety of stimuli including immune suppression, ultraviolet light, fever, and stress [199,220].

The promoter/regulatory region that controls LAT expression is of interest to gene therapy applications because that promoter remains active during latency when all other viral promoters are silenced. LAT expression is differentially directed by two independent LAPs, LAP1 [221–224] and LAP2 [219,222,225]. LAP1, predominantly responsible for LAT expression during latency [222,223], is located 5' proximal to the unstable 8.3 kb LAT. LAP2 is primarily responsible for LAT expression during lytic infection, but is also capable of driving low-level expression of LAT in the absence of LAP1 during latency [222] and is located immediately upstream to the 2.0 kb LAT intron [219,222,225]. Deletion of both LAP1 and LAP2 completely eliminates expression of detectable levels of LAT during latency *in vivo* in animals [222], demonstrating that both promoters contribute to LAT expression during latency in neurons *in vivo*.

The continuous expression of the LAT region of the HSV genome during neuronal latency suggests that it should be possible to exploit the LAT promoter to express therapeutic genes from latent viral genomes in neurons. Both LAP1 and LAP2 have been employed to achieve long-term transgene expression from the HSV vector genome during latency. For example, a LAP1- β -globin recombinant produced transgene expression in murine peripheral neurons during latency [223], but the level of product decreased over time [226]. Other examples include recombinants with LAP1 driving expression of β -glucuronidase [227], NGF [226], β -galactosidase [225,226,228], or murine α -interferon [192] that either displayed a similar expression pattern or were not active in latently infected animals [192,196,226]. These data suggest that LAP1 may lack the *cis*-elements required for long-term transgene expression in the context of the HSV viral genome. However, long-term transgene expression in PNS neurons or neurons of the spinal cord was achieved when LAP1 was juxtaposed to the Moloney murine leukemia virus (MoMLV) promoter [229–232], unlike recombinants employing either LAP1 or the LTR alone, suggesting that the elements responsible for extended expression lie elsewhere within the LAT promoter/regulatory region. These *cis*-acting elements may be complemented by elements within the MoMLV promoter, thus allowing transgene expression to continue during latency. When LAP2 was added to the LAP1-reporter cassette in the ectopic site within the genome, long-term expression within PNS neurons was restored although the transcription start site was not determined [231]. The LAP1–LAP2 complex was capable of driving long-term transgene expression when a lacZ reporter gene cassette was introduced into the LAT intron in the native LAT locus [233] or when a LAP2-lacZ expression cassette was present in an ectopic locus within the viral genome [219]. We have also shown that a LAP2-NGF cassette present either in the tk (Figure 7.6A and B) or Us3 loci of the vector expressed this gene product in latently infected rodent neurons both in culture and *in vivo* [234–236], and that expression of the therapeutic gene was sufficient to block toxic insult *in vitro* or in diabetic animals. Recently, we have been able to use LAP2 alone to direct expression of NGF [237] or in conjunction with the HCMV IE promoter to drive expression of NT-3 [237,238] to achieve long-term neuroprotection in the PNS of rodents that correlated with functional recovery. While LAP2 activity in CNS neurons appears somewhat weaker than in PNS neurons, we are easily able to achieve therapeutic levels of GDNF expression that result in a change in rotational behavior of LAP2-GDNF vector-injected 6-hydroxydopamine (6-OHDA) treated animals even when the vector was injected 6 months prior to treatment of the rats with 6-OHDA, whereas animals treated with the HCMV IEp-GDNF vector were only capable of restoring behavior when injected 1 week prior to toxic insult [239]. This demonstrates the overall utility of LAP2 for therapeutic gene expression in neurons of the PNS, CNS, and spinal cord. Of interest, we have shown that both the HCMV IE gene promoter and LAP2 are capable of long-term NGF expression in rabbits following intra-articular injection with a replication-defective HSV

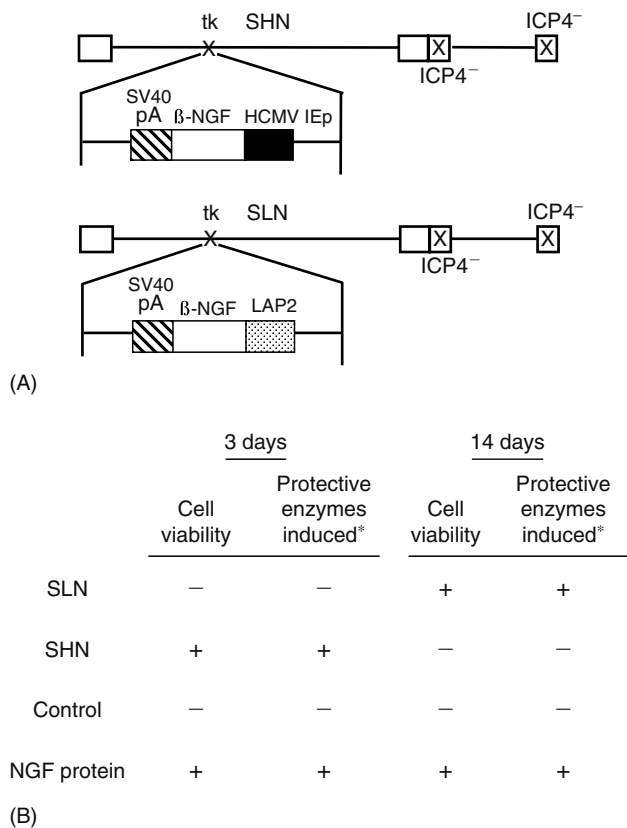

FIGURE 7.6 HSV vector-mediated expression of NGF protects neurons from peroxide toxicity. (A) Vectors SHN and SLN are replication-defective due to a deletion of the essential IE gene ICP4. SHN expresses NGF from the HCMV IE promoter from within the HSV-TK locus while SLN utilizes the latency-active promoter, LAP2, to drive NGF expression. (B) Transduction of primary DRG neurons with SHN induces cellular enzymes that protect neurons from peroxide toxicity at three days postinfection but not at 14 days. Conversely, SLN expression of NGF takes several days to accumulate until protection is evident at 14 days postinfection. Using these divergent promoter systems we are able to direct expression of neuroactive gene products at high levels for a short term (HCMV) or at somewhat lower levels long term (up to one year).

vector [191] and in rabbit fat tissue explants and subcutaneous adipose tissue following direct injection of vector into the rabbit fat-pad [240]. These results have uncovered two important findings: First, that the HCMV IE promoter can remain active long term although we do not fully understand the mechanism behind this activity; and second, that LAP2 is active in cells other than neurons such as adipose cells and cells of the ligaments. These findings will be important for designing treatment regimens where continuous therapeutic protein production will be required to achieve a therapeutic outcome in tissues other than those of the nervous system.

7.4.3 DRUG-REGULATED PROMOTERS

For many applications, it may be desirable to regulate expression of a therapeutic transgene *in vivo*, either to limit

toxic effects from high-level expression or more closely resemble physiological expression profiles. We created a viral vector with regulatable transgene expression using an autoregulatory loop that consisted of a promoter with 5 tandem copies of the 17-bp Gal4 DNA recognition element that could be transactivated by vector-encoded chimeric Gal4/VP16 protein (Figure 7.7A), based on the ability of the chimeric protein to transactivate promoters containing this site [241–243] despite the repressive presence of nucleosomes [244,245]. The constitutive Gal4/VP16 transactivator was able to induce transgene expression from a Gal4-sensitive minimal promoter in the background of the virus [189]. Regulation was achieved by replacing the constitutive transactivator with a chimeric molecule consisting of the hormone-binding domain of the mutated progesterone receptor fused to the transactivation domain of VP16 and DNA-binding domain of Gal4 [246,247]. In the presence of the progesterone analog RU486, the inactive chimeric transactivator assumes a conformation allowing it to bind to and transactivate the Gal4 recognition site-containing promoter driving transgene expression. Compared with control (Figure 7.7B), completion of the autoregulatory loop following administration of RU486 (Figure 7.7C) resulted in substantial enhancement of expression of the transgene in the CNS [189] (Figure 7.7D). Following infection of the rat hippocampus with the regulatable virus, levels of viral vector-derived transgene expression are stimulated by administration of the inducing agent RU486 [248].

7.5 APPLICATIONS

7.5.1 HSV GENE TRANSFER FOR NEUROPATHY AND PAIN

The PNS, specifically the sensory neurons with cell bodies in the DRG and peripheral axonal terminals in the skin, represents a natural target for the therapeutic use of HSV-mediated gene transfer. Recombinant replication-defective HSV-based vectors, like the parental wild-type virus, target with high efficiency to DRG neurons from skin inoculation, in part because sensory nerve terminals expresses high amounts of the HveC HSV receptor [249]. Following fusion of the viral envelope with the cell membrane, specific interactions between viral capsid proteins and the cytoplasmic motor ATPase dynein along with its multisubunit cofactor dynactin ensure efficient retrograde axonal transport along microtubules to the nucleus [250,251] where the viral DNA is injected through a nuclear pore. Because our recombinant vectors are incapable of replication, the recombinant viral genome is forced into a pseudo-latent state as an intranuclear but extrachromosomal element that may persist for the life of the host.

There are two major conditions of peripheral nerve that are particularly well suited for treatment by HSV-mediated gene transfer. The first is peripheral polyneuropathy, a condition resulting from degeneration of peripheral sensory neurons.

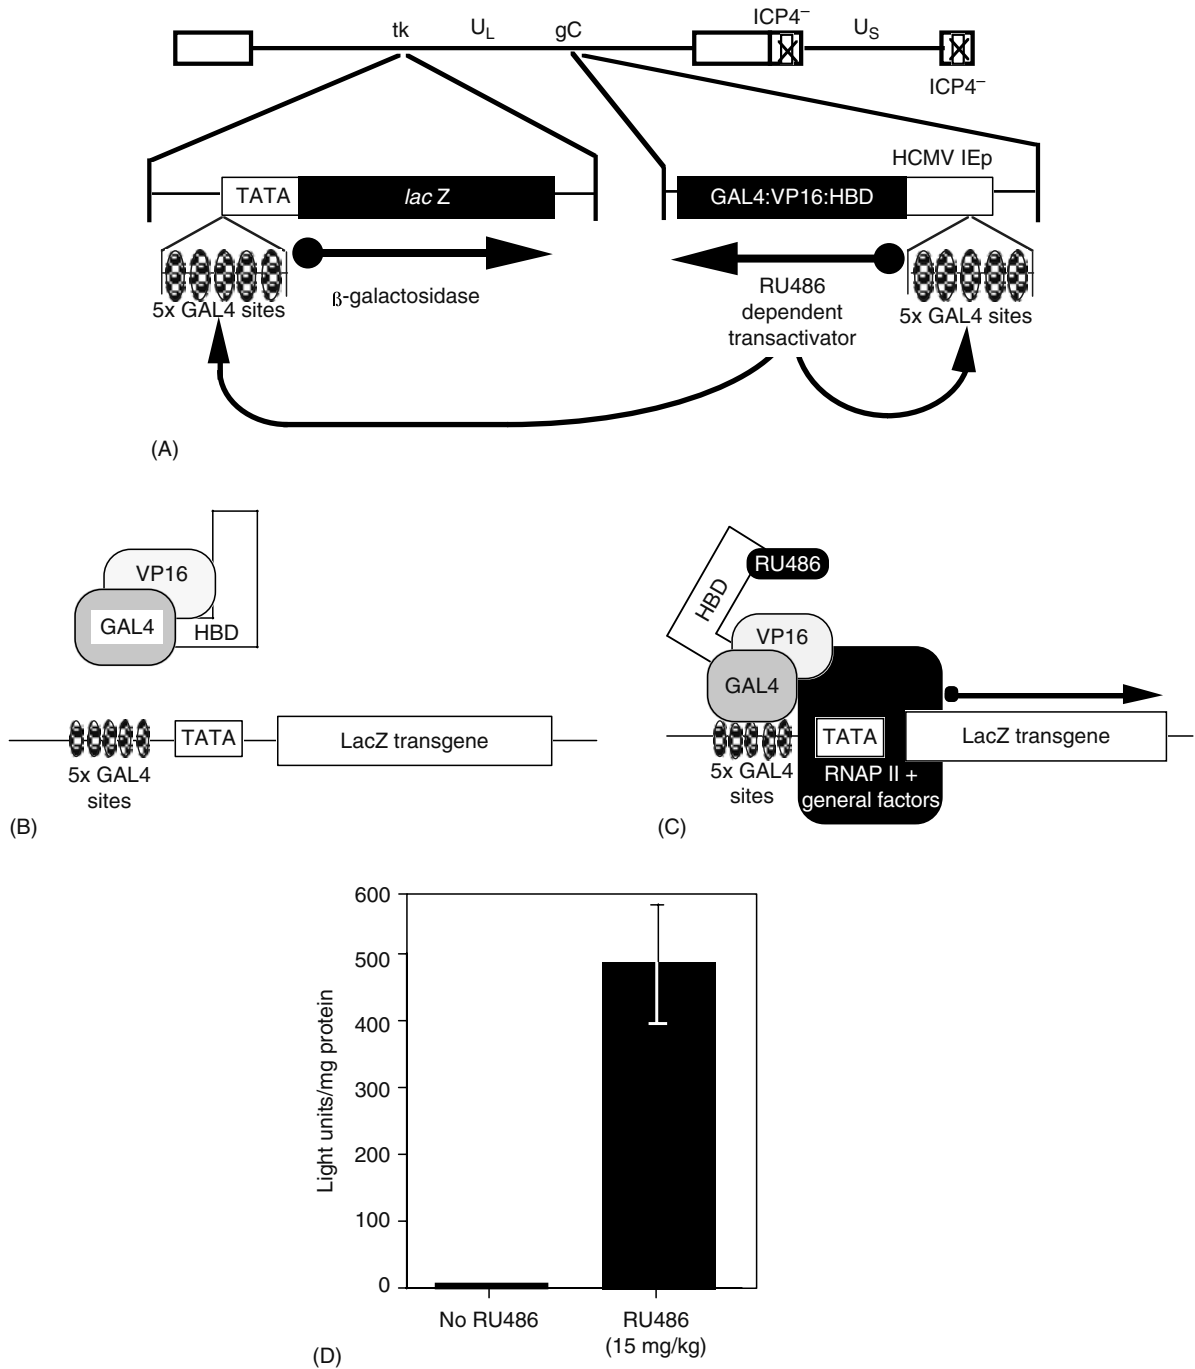

FIGURE 7.7 *In vivo* regulated transgene activation from HSV vectors by drug-inducible recombinant transactivator (RTA). (A) GLVP RTA vector contains the inducible chimeric transactivator GAL4:VP16:HBD, composed of the yeast GAM DNA-binding domain fused to the HSV VP16 transactivation domain fused in frame to a mutant form of the progesterone receptor hormone-binding domain, which can be activated by RU486. In addition, the vector contains a promoter-reporter cassette (GAL4TATA-lacZ) that is responsive to activation by the transactivator (RTA). (B) In the absence of the drug, the GAL4:VP16:HBD RTA cannot bind to the GAL4 sites in the minimal TATA box promoter, resulting in no expression of the β-galactosidase transgene. (C) Following administration of RU486, the tripartite transactivator undergoes a conformational change that allows the RTA to bind to the GAL4-binding sites to yield β-galactosidase expression. (D) Quantitation of β-galactosidase transgene expression in the presence of RU486 displays activation of the transgene promoter by the inducible transactivator following injection of the vector into rat CNS.

The most common cause of neuropathy in the developed world is diabetes; diabetic polyneuropathy is a very common condition 100 times more prevalent than Parkinson's disease, Alzheimer's disease, and multiple sclerosis combined and a cause of substantial morbidity. The second condition that may be approached using HSV-mediated gene transfer is chronic pain. In both polyneuropathy and chronic pain, therapeutic peptides of proven efficacy have been identified. For example, polyneuropathy can be prevented in animal models by treatment with neurotrophic factors; pain can be substantially ameliorated by the delivery of opioid peptides. However, it is difficult to deliver these short-lived peptide factors in adequate doses to achieve therapeutic effects without causing intolerable side effects that result from the widespread expression of the receptors for these peptides throughout the nervous system and in non-nervous structures in the body. Theoretically, targeted gene delivery to the DRG using HSV vectors can be used to express a neurotrophic factor to prevent neurodegeneration, or to express a pain-relieving peptide to modify nociceptive neurotransmission at the spinal level, while avoiding the off-target effects that are engendered by systemic administration of these same agents.

7.5.1.1 Neuropathy

The initial proof-of-principle studies of HSV-mediated gene transfer to treat neuropathy examined the effect of vector-mediated expression of NT-3 in neuropathy caused by pyridoxine (vitamin B6). Pyridoxine overdose causes a selective degeneration of large DRG neurons that are known to express the Trk C high affinity NT-3 receptor, and previous work had demonstrated that daily subcutaneous co-administration of NT-3 (5–20 mg/kg) with pyridoxine prevented the development of neuropathy [252]. Using an identical paradigm of pyridoxine intoxication we demonstrated that subcutaneous inoculation of a replication-incompetent HSV vector expressing NT-3 prevented the degeneration of large myelinated fibers characteristic of neuropathy as measured by electrophysiologic, morphologic, and behavioral outcomes [253]. In this model, neuropathy develops subacutely over the course of 2 weeks. In a subsequent study, we demonstrated that with appropriate choice of promoter, a prolonged neuroprotective effect can be achieved. Rats inoculated subcutaneously with a nonreplicating HSV vector containing the NT-3 coding sequence under the control of the HSV LAP2 element [219] protected against the neurotoxic effects of pyridoxine administered five and a half months after vector inoculation [237], using the same measures examined in the subacute intoxication paradigm.

We subsequently examined the effect of HSV-mediated expression of NGF or NT-3 in the clinically relevant model of neuropathy caused by administration of a chemotherapeutic drug. Peripheral sensory polyneuropathy is a dose-related predictable off-target effect of many chemotherapeutic agents like cisplatin [254] that are used to treat cancer, and the effect on peripheral nerve either limits the use of these agents or results in toxicity that impairs quality of life. Subcutaneous

inoculation of nonreplicating HSV vectors expressing either NGF or NT-3 three days prior to the onset of treatment with cisplatin prevented the development of neuropathy assessed by standard electrophysiologic, behavioral, and histologic parameters [255].

HSV vectors have similar neuroprotective effects in protecting against the development of diabetic polyneuropathy. Administration of streptozotocin (STZ) to mice results in degeneration of beta cells, and the resultant hypoinsulinemic state serves as a model of type 1 diabetes. These animals develop a mild predominantly sensory neuropathy characterized by reductions in sensory nerve amplitude, and distal axonal degeneration that can be characterized by the loss of sensory fibers in the skin peripherally and a loss of neuropeptide containing afferent terminals in the spinal cord centrally. In initial studies we demonstrated that subcutaneous inoculation of an NGF-expressing HSV vector 2 weeks after the onset of diabetes protected against the development of neuropathy measured 4 weeks later [256]. We subsequently demonstrated that similar neuroprotective effects could be achieved using an HSV vector engineered to express the vascular endothelial growth factor (VEGF) in DRG neurons *in vivo* [257]. More recently, we have shown that subcutaneous inoculation 2 weeks after the onset of diabetes of an HSV vector expressing NT-3 under the control of the LAP2 element is effective in preserving sensory nerve function measured by electrophysiologic and histologic parameters [238]. Interestingly, in these experiments we found that HSV-mediated expression of NT-3 protected small-diameter fibers expressing substance P (SP) and calcitonin gene-related peptide (CGRP) despite the fact that these fibers are conventionally thought of as expressing predominantly the high affinity NGF receptor TrkA. This observation is congruent with our previous observation that HSV-mediated expression of NGF protects large diameter (predominantly TrkC-expressing) DRG fibers from the toxic effects of pyridoxine overdose [253], and suggests that local continuous expression of these trophic factors may provide more potent effects than would be anticipated from studies of bolus peptide administration.

In each of the experimental models described above, the HSV vector was inoculated prior to the onset of neuropathy. We have not examined whether the vectors might be used to enhance recovery from neuropathy, but achieving prevention alone would be a major advance in the treatment of neuropathy. Most sensory neuropathies develop gradually over a period of months to years; patients with diabetes, for example, characteristically present with loss of sensation in their toes, but there is no available therapy that will prevent progression of neuropathy. Gene transfer at that stage, if it prevented the development of a severe sensory neuropathy, would represent a substantial advance in our therapeutic armamentarium. Neuropathy caused by chemotherapeutic drugs represents one model in which the onset of neuropathy is temporally defined and pretreatment is possible, so that this category of neuropathy may serve as a convenient model for the first human trials of HSV gene therapy for neuropathy.

7.5.1.2 Pain

Using HSV vectors that express either inhibitory neurotransmitters or anti-inflammatory peptides, an analogous approach using HSV-mediated gene transfer can be employed to modify nociceptive neurotransmission. Wilson and colleagues first reported that a replication-competent HSV-based vector engineered to express preproenkephalin could be injected subcutaneously into the dorsum of the foot to transduce DRG and produce an antihyperalgesic effect as demonstrated by an increased latency to withdraw the foot from noxious heat after sensitization of C-fibers by application of capsaicin, or sensitization of A δ -fibers by application of dimethyl sulfoxide [258]. These investigators subsequently demonstrated similar effects on nociceptive neurotransmission in primates [259].

We and others extended these results to models of chronic pain using a nonreplicating HSV vector engineered to express enkephalin. We demonstrated that subcutaneous inoculation of the vector reduced spontaneous pain behaviors in the delayed phase of the formalin test of inflammatory pain [260], and in the selective spinal nerve ligation (SNL) model of chronic neuropathic pain [261]. The effect of vector-mediated enkephalin production was continuous over time, and was reversed by opiate antagonists naloxone or naltrexone. Transduction of DRG with the enkephalin-expressing vector enhanced the effect of morphine. Uninoculated animals with neuropathic pain responded to intraperitoneal morphine with an ED₅₀ of 1.8 mg/kg but animals inoculated with the enkephalin-expressing vector demonstrated a reduction in the ED₅₀ of morphine to 0.15 mg/kg [261]. In addition, expression of the delta opioid receptor agonist enkephalin from the vector continued to produce analgesic effects in animals that had been rendered tolerant to the analgesic effect of morphine [261].

Pain resulting from cancer metastatic to bone has features of both inflammatory and neuropathic pain. To evaluate the potential therapeutic effect of HSV-mediated gene transfer and expression of preproenkephalin (PE) in pain due to cancer, we tested the vector in the osteogenic sarcoma model in the mouse. Tumor-injected mice demonstrated spontaneous pain, increasing to 2 weeks after tumor inoculation and remaining at the same level up to 4 weeks postinoculation. Subcutaneous inoculation of the enkephalin-expressing vector 1 week after tumor implantation resulted in a substantial and significant reduction in spontaneous behavior recorded 2 and 3 weeks after tumor implantation (1 and 2 weeks after vector inoculation), an effect that was reversed by intrathecal naltrexone.

Taken together, the results of studies demonstrate that a nonreplicating genomic HSV vector expressing PE is antinociceptive in models of neuropathic pain, inflammatory pain, and pain resulting from cancer in rodent models. A proposal for the first human trial employing these vectors in the treatment of intractable pain resulting from cancer metastatic to a vertebral body was presented to the Recombinant DNA Advisory Committee at the National Institutes of Health in June 2002. In the near future, we should be able to determine

if this approach will be as successful in treating the human disease as it has been in the animal models.

In addition to expression of preproenkephalin in various animal models of pain, we have successfully constructed and utilized numerous other HSV-based vectors expressing a variety of genes in several different pain models, two of which will be briefly reviewed below. We engineered a vector to express glutamic acid decarboxylase (GAD) in DRG following peripheral footpad inoculation (Figure 7.8A). In the SNL model of neuropathic pain, the HSV-GAD vector effectively reversed both the resultant thermal hyperalgesia as well as mechanical allodynia (Figure 7.8B). These effects, which also suppressed c-Fos induction in the spinal cord, lasted at least 6 weeks. Importantly, these antinociceptive effects were effectively re-established by reinoculation of the vector without loss of effect or development of tolerance (Figure 7.8B). This ability to effectively re-administer vector and re-establish the therapeutic effect is a very important attribute and is in contrast with most other gene transfer vector systems.

Another use of the GAD vector is to address the large unmet need for therapies focusing on pain due to spinal cord injury. Spinal cord injury pain is, in general, not effectively treated with standard opioid drugs leading to the large unmet need for this indication. Delivery of HSV-GAD vector by peripheral footpad inoculation leads to constitutive γ -amino butyric acid (GABA) release in the spinal cord. GABA, a major inhibitory neurotransmitter, is involved in regulation of neuronal activity and mimicked by Baclofen that has shown some positive effects in clinical trials for spinal cord injury pain. Both thermal hyperalgesia and mechanical allodynia associated with a T13 hemisection were alleviated with HSV-GAD. Spinal CGRP levels were attenuated by GAD treatment and these antinociceptive effects were antagonized by bicuculline or phaclofen. We are currently evaluating specific indications and market potential for a GAD-based therapeutic prior to human clinical trials.

Processed enkephalin binds with high affinity to the δ -opioid receptor while the widely used acute pain drug morphine, as well as most other common pain medications, binds to the μ -opioid receptor. Recently, endomorphins have been identified from brain homogenates and may represent endogenous μ -receptor ligands [262,263]. The endomorphins are carboxyamidated tetrapeptides that have been found to be effective in several animal models of pain. However, while the peptide is present in nervous tissues from vertebrates, the corresponding gene has not been identified in the genome nor has any transcript been identified. In order to improve potential endomorphin approaches to pain management, we engineered a tripartite gene product to direct the synthesis, processing, amidation, and regulated secretion of endomorphin-2 (EM-2) with the amino acid sequence of YPPF-NH₂ [264]. This synthetic EM-2 gene was recombined into a replication-defective HSV vector and EM-2 expression confirmed by HPLC-mass spectroscopy and radioimmunoassay following *in vitro* and *in vivo* transduction, respectively. The EM-2 vector was found to effectively

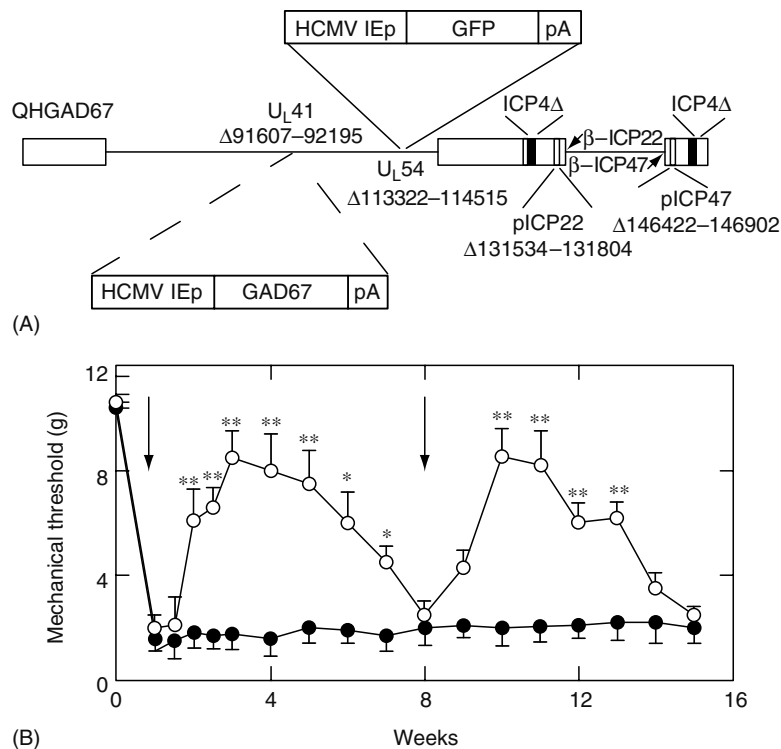

FIGURE 7.8 HSV-mediated GAD delivery for neuropathic pain therapy. (A) Schematic diagram of the replication-defective HSV vector engineered to express GAD67 as well as the marker gene GFP. The GAD expression vector is defective for both essential IE genes ICP4 and ICP27 (U_{L54}). In addition, deletion of the TATGARAT element within the promoters for ICP22 and ICP47 restricts their expression to ICP4 complementing cell lines. The GAD67 cDNA is driven by the HCMV IE promoter from within the U_{L41} locus while GFP is expressed from the U_{L54} (ICP27) locus. (B) Ligation of the L5 spinal nerve in rats caused a significant decrease in the threshold to tactile stimulation, which persisted for more than 4 months and was unaffected by inoculation of control vector (arrow; closed circles). Subcutaneous inoculation of the GAD expression vector (arrow; open circles) produced an antiallodynic evidenced by an increase in the mechanical threshold required to stimulate a pain response. Seven weeks after vector administration the antinociceptive effect diminished. Upon reinoculation (second arrow) the antiallodynic effect was re-established that lasted for an additional 7 weeks.

reverse thermal hyperalgesia and mechanical allodynia, hallmarks of SNL induced neuropathic pain [264]. This effect was reversed by intrathecal CTOP administration, a μ -opioid receptor specific antagonist.

In summary, we have utilized the innate aspects of our replication-defective HSV vector platform and the natural biology of pain transmission to develop several avenues toward a novel pain therapeutic. Using our platform, we are able to achieve relatively long-term effects (several weeks/dose) with the HCMV promoter and extended (months/years) using our LAP2 system. Importantly, with this platform, we are able to re-establish the therapeutic effect by reinoculation. Moreover, with the genetic flexibility of our HSV platform, we are able to include several distinct approaches, for example, GABA receptor agonism with the GAD gene and the δ -opioid receptor agonism with the enkephalin gene, into a single vector; an approach we are currently evaluating.

7.5.2 CANCER

Cancer gene therapy may offer a treatment modality to patients who have exhausted all other standard treatment

regimens such as surgery, chemotherapy, and radiation therapy. There are a number of considerations in applying gene therapy to the treatment of cancer that include the selection of the appropriate therapeutic gene(s), the specific effect or mechanism, target tissue, and method of gene delivery. The overriding problem is that cancer is generally a systemic disease, and thus, even if gene transfer is effective in destroying a tumor locally, metastases will promote continued disease.

Strategies to treat cancer by gene therapy can be considered in three categories: (1) tumor cell destruction using conditionally replicating viruses that selectively replicate in and kill tumor cells [265,266] compared with the surrounding normal tissue, (2) tumor cell destruction by expression of transgenes whose products induce cell death, or sensitize the cells to chemo-[267] or radiation therapy [268], and (3) tumor vaccination through expression of transgenes whose products recruit, activate, or costimulate immunity or provide tumor antigens. The latter approach is more likely to be effective in treating metastatic disease. Because these strategies are complementary, it has also been suggested that they can be used in combination. Examples of these various approaches include the use of (1) prodrug-activating genes such as thymidine

kinase (TK) or cytosine deaminase (CD) [269]; (2) cytokines such as TNF- α , γ IFN, and various interleukins [270]; (3) MHC products such as costimulatory molecules (B7.1) [271–273]; (4) allotypic class I or class II molecules [271–274]; and (5) tumor antigens [275,276], which together may assist in the recruitment and activation of nonspecific inflammatory responses [277] or the induction of tumor-specific immunity.

The first strategy involves the use of vectors that are replication competent, but depend on attributes unique to the tumor cell to support viral growth. For example, E1b-deficient AdV vectors can replicate in tumor cells mutant for p53 but generally not in normal cells [265,278–280]. Thus, the intent of this strategy is to provide a mechanism for virus spread locally in the tumor to increase the number of infected tumor cells. However, this treatment is limited to p53-defective tumors. Similarly, HSV vectors have been engineered that replicate in dividing cells, such as tumor cells, but not in normal neurons. The use of conditional replication-competent viruses could in theory allow for spread in tumor tissue without damaging normal brain, thereby increasing the specificity and effectiveness compared with nonreplicating vectors that express transgenes that augment tumor cell killing. HSV vectors of this type include mutants lacking the γ 34.5 gene, which is required for growth specifically in neurons [281–283]. Deletion of this gene alone (1716), or in combination with the UL39 ribonucleotide reductase (RR) large subunit (G207), creates viruses that are highly compromised for their ability to replicate in and kill neuronal cells, yet that retain the ability to replicate in and kill dividing tumor cells.

Although these vectors were originally used to treat animal models of malignant glioma [284–288] they have now been employed to treat breast [289,290], lung [291,292], head and neck [293], melanoma [294,295], colorectal [296–298], prostate [299–302], ovarian [303,304], peritoneal [305–307], bladder [300,308], renal [309], cervical [310], and gallbladder [311] tumors in various animal models, demonstrating their utility. In addition, they have also been used in conjunction with suicide gene therapy (SGT) [312], low-dose ionizing radiotherapy [298,310], and chemotherapeutic agents like cisplatin [292,313].

The second approach to treat cancer involves SGT for the treatment of cancer in experimental animals and in phase I human clinical protocols [267,314–318]. This strategy uses the bystander destruction of tumor cells mediated by a variety of mechanisms other than virus spread, including the recruitment of natural killer (NK) cells by expressing the appropriate cytokines, the activation of anticancer drugs at the tumor site that kill multiple tumor cells in addition to those transduced by the vector, and the use of antigens and cytokine-expressing genes to elicit specific antitumor immunity. Transfer of the HSV gene TK into tumor cells results in tumor cell death when combined with the antiviral drug ganciclovir (GCV). TK has been shown to convert the prodrug into a toxic nucleoside analog that, upon incorporation into nascent DNA, results in the interruption of DNA replication by chain termination. A uniquely powerful characteristic of the TK-GCV approach is that only a small fraction of the tumor cells need to be

transduced with the suicide gene to result in significant anti-tumor activity, an activity known as the “bystander effect” [315,317–320]. It has been demonstrated that cell-to-cell transfer of activated GCV via gap junctions between transduced tumor cells and untransduced neighboring cells is a major mechanism of the bystander effect [321–324]. A variation on this strategy is to introduce cell lines into the tumor site that produce TK-expressing retroviruses that then infect tumor cells locally. Although setting up virus production factories in this manner is logical, the practice of this strategy has been disappointing because the xenogeneic producer cell lines induce rapid inflammatory processes that lead to brain swelling and little detectable gene transfer [325]. Although these TK-GCV SGT strategies suffer from limitations, approaches of this nature are under evaluation for efficacy in phase I–II clinical trials for patients with brain tumors; however, they have met with limited success.

In our initial experiments using replication-defective HSV vectors expressing HSV-TK for SGT, we employed both vectors deleted for single (ICP4⁻) and multiple (ICP4⁻/ICP27⁻/ICP22⁻) essential IE genes that expressed the TK gene from an HSV IE promoter to ensure its expression from the replication-defective virus backbone (Figure 7.9A). We tested the ability of these TK overexpressing replication-defective HSV vectors to act as a treatment for established tumors in rodent glioma models and demonstrated significant increases in survival following administration of the HSV-TK vector and GCV [326,327]. However, the magnitude of the bystander effect was inversely proportional to the overall toxicity of the vector. Thus, more cytotoxic vectors like the ICP4 deletion mutant resulted in the cytotoxic death of the transduced tumor cells before they were able to produce and release significant levels of modified GCV, thereby dampening the overall bystander-mediated killing [326]. We have now seen similar results using vectors that express CD alone or in combination with HSV-TK [328], suggesting that further modifications will be required to achieve more effective tumor cell killing.

To augment the cell killing seen in SGT we have taken two approaches. In the first approach, we attempted to augment the bystander effect by altering the make up of tumor cell gap junction complexes. Connexins are the major components of gap junctions [329] that play a major role in intercellular communication to control homeostasis and cell proliferation. Reduced intercellular communication through gap junctions has been regularly observed in transformed cells [330–332] and may be due to reduced connexin expression. Retrovirus-mediated introduction of the connexin 43 (Cx43) gene limited the growth of transformed cells that shared the characteristic of reduced gap junctional activity [333], and other studies have reported similar findings supporting the suggestion that connexins alone have tumor-suppressor activity [334–337]. Gap junctions also play a critical role in the HSV-TK/GCV bystander effect by enabling the transfer of activated GCV from TK-positive to neighboring TK-negative cells [321,338–341]. Tumor cells having reduced gap junction formation are less susceptible to the bystander effect [341], suggesting that transfer of connexin genes into

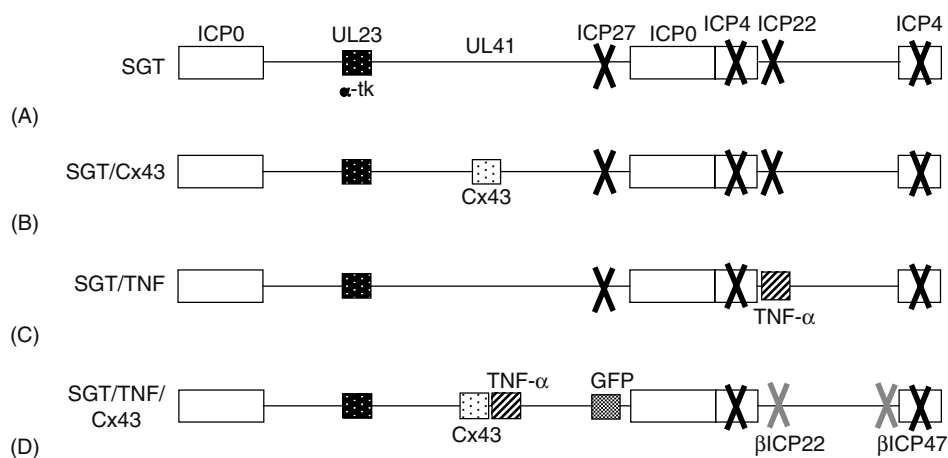

FIGURE 7.9 HSV-vector mediated tumor cell killing. Diagrams of replication-defective HSV-1 expression vectors for expressing (A) HSV-TK (SGT), (B) HSV-TK and connexin 43 (SGT/Cx43), (C) HSV-TK and TNF- α (SGT/TNF), and (D) HSV-TK, connexin 43, and TNF- α (SGT/TNF/Cx43). All vectors express ICP0 from both copies of the IR element flanking the UL segment of the HSV genome, and TK as an IE gene from a copy of the ICP4 IE promoter replacing the native TK promoter in the UL23 gene locus. All vectors have the ICP4 and ICP27 genes deleted, and all but the SGT/TNF/Cx43 vector have inactivating deletions in ICP22. This vector has the IE genes ICP22 and ICP47 turned into early genes by deletion of the TAATGARAT promoters element converting these to early (β) genes. The SGT/Cx43 vector contains the Cx43 gene driven by the ICP0 IE promoter inserted into the U_L41 locus. The SGT/TNF vector has TNF inserted into the ICP22 gene locus under control of the HCMV IE promoter. The SGT/TNF/Cx43 vector has both the ICP0p-Cx43 and HCMV IEp-TNF expression cassettes inserted into the U_L41 locus. The ability of these vectors to destroy tumors and effect animal survival in the immunocompetent rat 9L tumor model was evaluated by intratumoral vector injection 3 days following implantation of the 9L tumor cells into the frontal lobe of Fisher rats. Animals received i.p. injections of GCV at the time of vector injections for 10 consecutive days and gamma-knife radiosurgery (GKR) at 2 days postvector injection.

these cells to restore or augment intercellular communication would improve the effectiveness of HSV-TK/GCV therapy. Indeed, it has been demonstrated both *in vitro* and *in vivo* that the bystander effect can be potentiated by the expression of connexin [340,342,343]. The bystander effect requires

connexin expression not only by the TK-positive GCV-activating cell, but also by the TK-negative recipient cell [341]. This suggests that gene therapy approaches aimed at codelivery of connexin with HSV-TK to mediate an enhanced bystander effect may not be extremely effective against

tumors that express no connexin at all as a study of 17 cell lines measuring bystander effects and gap junctional activity [339] demonstrated. Furthermore, overexpression of connexin in the transduced cells will increase transfer of activated GCV, providing even limited connexin expression in neighboring cells.

We tested the potential benefit of coexpressing connexin with HSV-TK for the treatment of glioblastoma [344]. Human U-87MG tumor cells express detectable amounts of Cx43 and are sensitive to bystander killing *in vitro*, but this effect is not sufficient to control tumor formation with TK-transduced cells and GCV treatment alone [330]. Replication-defective vectors (ICP4⁻/ICP27⁻/ICP22⁻) that we engineered to express Cx43 (Figure 7.9B) were able to enhance TK-GCV tumor cell killing in cultures of U-87MG tumor cells that express Cx43 [344]. Thus, although U-87MG cells already showed a good bystander effect, the expression of additional Cx43 in a fraction of the population further enhanced the effectiveness of GCV treatment. We also were able to demonstrate a pronounced bystander effect with L929 cells [344] that did not show a bystander effect when infected with a TK-expressing vector, in agreement with recent findings by others [341]. This indicated that vector-directed connexin expression enabled bystander killing among these otherwise bystander-resistant cells. Together, these results suggested that vector-directed Cx43 expression should be beneficial regardless of whether the target cells express significant levels of connexin.

These *in vitro* assays were extended to animals using an *ex vivo* flank tumor model and *in vivo* using animals bearing U-87MG tumors in the CNS [344]. Dramatically, all animals implanted with Cx43 vector-infected cells and treated with GCV were tumor free 1 week after cessation of GCV administration, whereas no other animal was tumor free at this time, including animals treated with Cx43 vector alone or the TK-expressing vector plus GCV. Moreover, all animals in this treatment group were alive at the end of the observation period (72d), whereas no animals in any of the other groups survived past day 41. Encouraged by these promising results, experiments were initiated to test the effectiveness of combined Cx43/TK gene delivery *in vivo* because the *ex vivo* approach enables one to infect every tumor cell that does not readily mimic the actual situation in human patients with glioblastoma. In the *in vivo* experiments, virus was injected directly into the tumor mass 3 days following tumor cell implantation and GCV was administered for 10 days after vector inoculation. In these studies, all animals in every treatment group died by day 50, whereas 50% of the Cx43-expression vector-treated animals survived past 50 days and one-third were still alive at the end of the study (70d), indicating a beneficial effect of connexin/TK gene codelivery *in vivo*.

In the second approach to augment SGT, we created vectors that express cytokines in the hope of stimulating a host response to the tumor. There has been a considerable amount of recent interest in using cytokine genes, costimulatory molecules, tumor antigens, and recruitment molecules to enhance the immune response to the tumor. Antitumor immunity should prove effective in treatment of metastatic cancer. The

development of antitumor immunity could circumvent the need for replication-competent vectors because tumor-specific cytotoxic T lymphocytes (CTLs) constantly move through the brain parenchyma searching for target cells. A growing body of literature suggests that local expression of cytokines can enhance CTL activation at least in animal model systems and these bear testing in human brain cancer. HSV offers the potential for combinational gene therapy in this regard because multiple immunomodulatory genes can be recombined into the virus and comparatively tested [94].

TNF- α has been demonstrated to possess an array of antitumor activities, including potent cytotoxicity exerted directly on tumor cells [345], enhancement of the expression of HLA antigens [346] and ICAM-1 [347] on tumor cell surfaces, enhancement of interleukin-2 receptors on lymphocytes [348], and stimulation of such effector cells as NK cells, lymphokine-activated killer cells, and CTLs [348–351]. However, despite this promising antitumor profile, the clinical use of TNF- α has been constrained by the toxicity of systemic TNF- α delivery [349,351]. This problem could be minimized by local production of TNF- α at the site of tumor growth, which may allow for effective use of this cytokine as an antitumor agent. Furthermore, TNF- α has a radiosensitizing ability that could optimize its antitumor effects. In an effort to augment the effectiveness of HSV-TK-mediated SGT, we created the replication-defective, triple IE gene-deleted HSV vector (ICP4⁻, ICP27⁻, ICP22⁻) that expresses HSV-TK and TNF- α (Figure 7.9C).

In vitro studies demonstrated that high levels of TNF- α could be detected in the media of vector-infected cells during the first 24 h period, but this was followed by a precipitous decline in production on day 2 and subsequent days with the protein being no longer detectable on day 7 [327]. The bioactivity of TNF- α produced in this experiment was tested by exposure of cultured TNF- α -sensitive L929 fibrosarcoma cells to medium collected after the first day of infection. A dramatic reduction in cell viability was observed for cells treated with medium from TNF vector-infected cells, and this reduction was essentially identical over time to that seen with unconditioned medium supplemented with 10 ng recombinant TNF- α protein [327]. These results demonstrated that TNF- α produced by the TNF vector was biologically active and comparable in specific activity to recombinant TNF- α . We then determined that intracellular production of TNF- α could enhance HSV-TK/GCV-mediated cell killing of both the TNF- α -sensitive L929 cell line, as well as the TNF- α -resistant U-87MG cell line. Although the mechanism is unclear, this enhancement indicated that the combination of vector-directed TNF- α expression and HSV-TK expression with GCV treatment could be beneficial not only against TNF- α -sensitive tumor cells such as L929, but also against TNF- α -resistant tumors.

To determine if the increased effectiveness of combination gene treatment evident *in vitro* could also be observed *in vivo*, we first tested the effect of intratumoral vector injection followed by GCV treatment on established L929 tumors (TNF- α sensitive) in the flanks of immune-competent mice

[327]. Tumor treatment with the TNF vector plus GCV resulted in significantly greater growth inhibition and extended animal survival compared with all other treatments. These results demonstrated the promise of combination TNF/TK gene therapy for the treatment of TNF-sensitive tumors and added an incentive to test the same treatment against TNF-resistant tumors. However, the results in the U-87MG TNF- α -resistant intracerebral tumor model in immunodeficient mice were not as significant as those observed with the L929 model, although 2 of 14 animals in the TNF/GCV treatment group survived past 80 days [327]. This reduced response in the U-87MG model may be due to the fact that the tumor cell killing mediated by TNF is only the result of the cytotoxic effects of TNF expression intracellularly and is not augmented by its immunomodulatory ability. Together, these results suggest that combined HSV-TK/TNF therapy is beneficial, but that a more effective strategy may be required.

Fractionated radiotherapy has been shown to confer a small but significant survival benefit to patients with glioblastoma. Unfortunately, the dose of radiotherapy that may be tolerated by the brain (about 60 Gy) is inadequate for tumor eradication. To circumvent inherent toxicity problems, techniques have been developed that allow radiation focused to the tumor bed, allowing a higher dose to be delivered (radiosurgery). This enables eradication of the central portion of the tumor, but does not allow delivery of an augmented radiation dose to the tumor periphery. GKR allows for precise delivery of a single high dose of radiation to brain tumors without opening the skull. In this technique, tumors are targeted by the application of a tightly focused high-energy radiation field, which results in minimal collateral damage to the surrounding normal tissue. Radiosurgery has been used for boost irradiation of patients with malignant glial tumors, in addition to conventional wide-margin fractionated radiotherapy [352,353]. Unfortunately, glioma cells are often seen invading the normal tissue surrounding the tumor, often migrating along normal white matter tracts [354,355]. This feature of glioma is largely responsible for the inability to achieve a surgical cure by resection and the correspondingly poor prognosis. We have therefore examined ways in which the response to radiotherapy may be enhanced by gene delivery. One such approach involves selectively sensitizing tumor cells to radiotherapy. This would confer a major advantage, in that the sensitized cells could be effectively killed by a low dose of radiotherapy that is not toxic to surrounding brain tissue. In this strategy, we combine GKR with the injection of replication-defective HSV vectors expressing HSV-TK, Cx43, and TNF.

In the first series of experiments, we used GKR in conjunction with vector-mediated TNF expression because TNF has previously been shown to have a synergistic effect with ionizing radiation when delivered as a recombinant protein [356–362], by plasmid-based delivery [363–366] or using an AdV vector [367–371]. Moreover, the TNF- α approach has proven safe and shown some efficacy in human phase I clinical trials [371,372]. Experiments were carried out to determine whether HSV-TK/TNF gene transfer along with GCV treatment was more effective in the presence of low-dose

gamma-knife radiation. Both the TNF/TK vector and GKR alone were effective in protecting a proportion of animals from tumor growth and animal death when used in the U-87MG model of glioblastoma in nude mice [373]. The results using the TNF/TK vector with SGT and GKR demonstrated that the combination of TNF, GCV, and GKR was superior to other treatments, such that 89% of the animals in that treatment group surviving for the length of the study (75 days) and 67% of the animals were found to be tumor free at 75 days [373].

We then extended these results to an immunocompetent tumor model that may more closely mimic the human disease by carrying out survival studies comparing the efficiency of HSV-TK, TNF, and Cx43 in combination with GCV, with and without radiosurgery using the 9L gliosarcoma model in immunocompetent Fisher 344 rats [374]. In this study, GKR was found to enhance the survival of 9L intracranial tumor-bearing rats compared with the control (Figure 7.9E); however, treatment resulted in an overall survival of 15%, similar to what has been reported in human patients [352,375,376]. Combining the TNF and Cx43 genes in an HSV-TK/ICP0 vector (Figure 7.9D) further improved animal survival (Figure 7.9E). Eleven of fifteen animals treated with the HSV-TK/TNF/Cx43 vector, GCV, and GKR survived for more than 150 days compared with 7 of 15 treated with TNF, GCV, and GKR. These results demonstrate that our most effective current strategy for the treatment of animal brain tumors involves the multigene vector, which simultaneously expresses TNF- α , Cx43, HSV-TK, and HSV-ICP0, combined with radiosurgery and GCV treatment. This combination approach employs genes whose products that are tumoricidal (HSV-TK, TNF), augment this process by increasing the bystander effect (Cx43), sensitize tumor cells to radiation (TNF), and stimulate the host immune response to the tumor (TNF). This combination approach may also prove to be effective against metastatic disease, but remains to be tested in these animal models.

7.6 SUMMARY AND FUTURE DIRECTIONS

This overview of HSV biology and gene transfer has focused on the use of highly defective HSV genomic vectors that are blocked very early in the virus lytic cycle. These vectors express few viral functions and are highly reduced in vector toxicity, even for primary neurons in culture that are readily killed by less-defective HSV vectors. Moreover, these vector backgrounds are suitable for expression of multiple transgenes or single large genes (e.g., dystrophin) in applications where expression of single- or multiple-gene products are required to achieve a therapeutic outcome (e.g., tumor cell killing, vaccination). Expression of these transgenes can be coordinated, even sequentially, using strategies similar to those employed by the virus to regulate its own genes. Expression can also be controlled by drug-sensitive transactivators, which may prove to be important for regulating the timing and duration of transgene expression. HSV vectors may be most suited for expression of genes in the nervous system where the virus has

evolved to remain lifelong in a latent state. The highly defective viruses deleted for multiple IE genes are able to efficiently establish residence in neurons and serve as a platform for long-term gene expression using the LAP2 system. These mutants are unable to reactivate from latency and cannot spread to other nerves or tissues following cell transduction. Delivery of these vectors requires direct inoculation of tissue to achieve direct contact with neurons. Ideally, HSV vectors would be most effective if infection could be targeted to specific cell types using enveloped particles defective for their normal receptor recognition ligands, but modified to contain novel attachment and entry functions. This area of research is still very early in development, and it remains to be determined to what extent this will be feasible. Finally, it should be emphasized that current viral delivery systems may each become reduced to highly defective transfer vectors, retaining only those elements required for vector DNA maintenance and transgene expression. Fortunately, the natural biology of many persistent viruses, including HSV-1, indicates that long-term vector maintenance will be possible and we continue to learn from the highly evolved biology of persistent and latent viruses in order to mimic their strategies for gene transfer and therapy.

8.1 INTRODUCTION

Although the treatment of most cancers has improved steadily, metastatic solid tumors remain incurable. Despite frequent responses, refractory clones often emerge rapidly and the disease becomes refractory to available treatment modalities. Although chemotherapeutic agents and radiation therapy target various cellular structures and pathways, the majority of them kill cancer cells through induction of apoptosis and selectivity is based mostly on more rapid replication of tumor cells in comparison to normal cells. As malignant cells are characterized by an ability to adapt to the environment, apoptosis-resistant clones frequently develop following standard treatment. Furthermore, during subsequent treatment regimens, resistance factors are shared and therefore loss of response typically occurs more rapidly, and there is a tendency for cross-resistance between agents. Therefore, new agents with novel mechanisms of action and lacking cross-resistance to currently available approaches are needed.

Due to safety concerns, gene therapy approaches have usually been based on viruses that are unable to replicate in infected cells. Although replication-deficient viruses expressing therapeutic transgenes have provided high *in vitro* and *in vivo* preclinical efficacy and good clinical safety data, trials have demonstrated that the utility of these agents may be limited when faced with advanced and bulky disease [1]. Viruses that replicate and spread specifically inside the

tumor have been suggested as a way to improve penetration of and dissemination within solid tumor masses [2–4]. Oncolytic viruses used in various cancer gene therapy approaches take advantage of tumor-specific changes that allow preferential replication of the virus in target cells (Figure 8.1). The viral replication cycle causes oncolysis of the cell, resulting in the release of newly generated virions and subsequent infection of neighboring cells. Normal tissue is spared due to lack of replication. Thus, the antitumor effect is delivered by the actual replication of the virus. Therefore, a transgene is not necessarily required, but can be used for additional efficacy. Importantly, the viral replication cycle allows dramatic local amplification of the input dose, and in theory, the oncolytic process continues as long as target cells persist, and vascular dissemination can also occur to distant sites.

8.2 HISTORY OF ONCOLYTIC VIROTHERAPY

Oncolytic virotherapy originates from the beginning of the last century and is based on observations of tumor regressions in cancer patients contracting a viral infection. In 1904, a patient with chronic myelogenous leukemia had a dramatic decrease in white blood cells during a “flu-like” illness. During the 1950s–1980s, further examples were reported: varicella-induced remission of acute lymphoblastic leukemia [5] and measles-induced regressions of leukemias [6], Burkitt’s

FIGURE 8.1 Principle of oncolysis viruses. Replication kills tumor cells while features engineered into the virus genome prevent replication in normal cells.

lymphoma [7] and Hodgkin’s lymphoma [8]. A chicken farmer’s gastric cancer responded following occupational exposure to Newcastle disease virus [9].

Similar responses occurred following purposeful vaccination of cancer patients. In 1912, a cervical carcinoma responded following inoculation of an attenuated rabies vaccine [10]. This led to an experiment in 1920 by Levaditi and Nicolau, who documented vaccinia oncolysis of murine tumors [11]. Subsequently, a human trial was performed in 1940 by using an attenuated rabies virus against melanoma [12]. By 1950s, Southam et al. were treating patients suffering from various types of cancers and frequent remissions were reported [13,14]. A long-lasting benefit was reported in a patient with chronic lymphocytic leukemia, who sustained a complete response lasting over 3 years following systemic vaccinia virus dissemination from a vaccination site in the

skin [15]. In the 1980s, measles virus vaccination was associated with responses in two patients with Hodgkin’s lymphoma [16,17]. An overview of historical trials with oncolytic viruses has been listed on Table 8.1.

8.3 ONCOLYTIC VIRUSES

An oncolytic virus considered for treatment of cancer should have several important properties. Virus must be able to infect, replicate in, and kill human tumor cells including nondividing cancer cells [2–4]. From a safety standpoint, the parental virus should cause only mild, well characterized human disease. Further, a nonintegrating virus would decrease the risk of acquiring unwanted changes to the host genome. Viral replication in normal tissues might be preventable by genetic engineering or by utilizing agents that are capable of inactivating virus if necessary [18]. Also, a genetically stable virus that can be easily purified to high titers according to current good manufacturing practices (cGMP) is desirable.

There are various approaches for achieving selective viral replication in tumor cells. As the cellular changes induced by viral infection are often similar to changes acquired during tumor development, it is not surprising that some viruses (measles, vesicular stomatitis, and Newcastle disease viruses), have inherent selectivity for cancer cells. However, many popular oncolytic viruses (adenovirus, herpes simplex, and vaccinia viruses) are genetically modified to minimize toxicity to normal tissues and to maximize the tolerated dose.

One way to restrict replication to malignant tissues is to use tumor-specific promoters (TSPs). Another strategy involves engineering deletions in viral genes critical for efficient replication and cytotoxicity in normal but not in cancer cells. This may seem complex but is facilitated by the intriguing similarities between carcinogenesis and cellular takeover by DNA viruses. This may pertain to general cellular physiology: There are a handful of central growth control pathways that need to be overcome, regardless of whether the purpose is immortal growth or utilization of the cell for virus production. As an alternative, or better yet, to complement

TABLE 8.1
Historical Oncolytic Virus Trials

Type of Virus	Patients	Responses	Safety	Year	References
Sera or tissue extract containing Hepatitis B virus	22	4 reductions in tumor size, 7 clinical improvements	14 got hepatitis, 1 died of hepatitis	1949	[142]
Glandular fever sera	5	3 brief remissions	Good	1952	[143]
Egypt 101 (West Nile)	34	4 brief tumor regressions	2 encephalitis, fever and nausea in other patients	1952	[13]
Adenovirus	30	65% of injections caused local tumor necrosis	Good, vaginal hemorrhages from necrotic tumors	1956	[144]
Mumps	90	37 good responses (>50% reduction in tumor size), 42 PR (<50% reduction in tumor size)	Good, in 7 patients bleeding and fever	1974	[145]

transcriptional targeting such as described above, transductional modification of viral coat proteins can be genetically or chemically performed to alter virus tropism for more effective gene delivery to tumor cells and less transduction of normal cells.

Here, some of the most popular oncolytic virus platforms will be reviewed. Emphasis is placed on agents that have clinical data available and central pieces of that data will also be presented.

8.3.1 ADENOVIRUS

Adenoviruses are nonenveloped, double-stranded DNA viruses whose native pathogenesis typically involves mild upper respiratory tract, ocular, and gastrointestinal infections. The icosahedral virus capsid encapsulates an up to 38 kb linear DNA genome whose main structural components include hexon, fiber, and penton [19]. Penton units are located at each of the 12 vertices of the capsid, and the receptor binding fibers protrude from the penton bases. Infection by serotype 5 (Ad5), which is most commonly used for gene therapy, starts by binding of the fiber knob domain to the primary receptor, the coxsackie-adenovirus receptor (CAR) [20]. Binding is followed by internalization of the virus, mediated by the interaction of a penton base Arg-Gly-Asp (RGD) motif and cellular $\alpha_5\beta_1$ integrins, which triggers endocytosis of the virion via clathrin-coated pits [21]. Thereafter, viral DNA is transported to the nucleus through a rather poorly understood microtubule-mediated process, and viral genes are expressed. These processes are best understood *in vitro*. *In vivo*, it is conceivable that the fiber may have important interactions with blood factors, with implications on biodistribution, at least in mice [22,23].

Adenovirus is an attractive vector for gene therapy due to its high efficiency of infection of both dividing and quiescent cells, ease of high titer production, and stability *in vivo* [3,4]. Adenoviral DNA does not integrate into the host genome, resulting in a low risk of mutagenesis in humans. Additionally, the molecular biology of adenovirus has been well characterized and its safety has been demonstrated in a large number of clinical trials [4]. The limited duration of viral gene expression may render adenoviruses less desirable for the treatment of hereditary diseases, where long-term expression is needed, but is adequate for cancer gene therapy, where the purpose is to kill the target cells.

The first cancer trials with replicating adenoviruses were done already in the 1950s [24]. Ten different serotypes of wild-type adenoviruses were applied intratumorally, intra-arterially, by both routes, or intravenously into patients with cervical carcinoma. No significant toxicity was reported. A "marked to moderate local tumor response" was reported in over half of the patients. However, systemic responses were not detected and all patients eventually had tumor progression. Although these clinical studies were not performed according to current clinical research standards and therefore should be interpreted with caution, they suggest that replication competent or even wild-type adenoviruses can be safely

administered to humans and that viruses can replicate in tumors for therapeutic effect.

8.3.1.1 Type I Oncolytic Adenoviruses

With type I oncolytic adenoviruses, tumor-specific replication is achieved by introduction of loss-of-function mutations to the virus genome that requires specific cellular factors to compensate for the effects of these mutations. Most approaches are based on deletions in immediately-early (*E1A*) or early (*E1B*) adenoviral genes resulting in mutant E1 proteins unable to bind cellular proteins necessary for viral replication in normal cells, but not in cancer cells, because of transcomplementation in the latter [4].

The first and most widely studied oncolytic adenovirus *dl1520* (ONYX-015) carries two mutations in the gene coding for the E1B-55 kDa protein [25]. One purpose of this protein is binding and inactivation of p53 in infected cells, for induction of S-phase, which is required for effective virus replication. Thus, this virus may have selectivity for cells with an aberrant p53-p14^{ARF} pathway, a common feature of human tumors. Initial studies suggested that this agent replicates selectively in cancer cells lacking functional p53 [25–28]. However, contradicting studies have suggested that cells with functional p53 also support *dl1520* replication [29,30]. It has become clear that factors independent of p53 play critical roles in determining the sensitivity of cells to *dl1520*. Loss of function of p14^{ARF}, which normally stabilizes p53, can result in inactivation of p53 [31]. Adenoviral proteins other than E1B-55 kDa, including E4 or F6, E1B-19 kDa, and E1A, have effects on p53 function [32]. Further, the functions of E1B-55 kDa are not limited to p53 binding, but include also mRNA transport [33], and therefore the virus replicates inefficiently compared with the wild-type adenovirus. Nevertheless, taken together, these data seem to suggest more effective replication of *dl1520* in tumor cells in comparison to normal cells. Importantly, this has later been confirmed in humans and one reason may be the relative protection from the immune system offered by the tumor environment [34].

Ad5- $\Delta 24$ and *dl922–947* are closely related viruses that carry a 24 bp deletion in the constant region 2 (CR2) of the E1A gene [35,36]. This domain of the E1A protein is responsible for binding of the retinoblastoma tumor suppressor/cell cycle regulator protein (Rb) for induction of S-phase entry. Therefore, viruses with this type of deletion have reduced ability to overcome the G1-S checkpoint and replicate selectively in cells deficient in the Rb-p16 pathway, including most if not all cancer cells [37]. These agents are promising anti-cancer agents as they are not attenuated in comparison to wild-type viruses and some reports suggest that they may be even more oncolytic than wild type in tumor cells [36]. It should be noted, however, that Rb is phosphorylated in rapidly replicating normal cells which could allow a degree of replication of $\Delta 24$ generation agents. Further, their safety has not yet been demonstrated in human trials, although they are expected to begin soon [4,38].

8.3.1.2 Clinical Experience with *dl1520* and Closely Related Viruses

The safety and antitumor efficacy of *dl1520* type viruses has been tested in numerous phase I/II/III clinical trials with various tumor types and several routes of administration, with and without concomitant conventional treatments (Table 8.2). The goal has been to sequentially increase systemic exposure to the virus after safety with localized delivery has been shown. Following demonstration of safety and biological activity by the intratumoral route, trials were sequentially

initiated to study intracavitary, intra-arterial, and eventually intravenous administration of *dl1520* [34].

Intratumoral delivery of *dl1520* has been most extensively studied in the context of head and neck cancer [39–43]. Treatment has been well tolerated without dose-limiting toxicity and virus has been shown to replicate in tumor cells but not in peritumoral tissue. Antitumor activity has been demonstrated by shrinkage of tumors. In a phase II study of intratumorally administered *dl1520* to 40 patients, 3 complete and 2 partial responses were reported [42]. However, the most encouraging results were seen in a phase II combination trial

TABLE 8.2
Trials with *dl1520* and H101

Cancer Type	Phase	Patients	Safety	Responses	References
Recurrent head and neck cancer	I	22	Good	No objective responses, 5 MRI detected necrosis at injection site	[39]
	II	37 (30 evaluated)	5 patients experienced grade 4 adverse effects	8 CR, 11 PR lasting over 5 months	[40]
	II	14 (9 evaluated)	No SAE, 2 grade 3 mucositis	3 CR, 1 MR, 3 PR, and 2 SD	[146]
	II	37	Good	2 CR, 3 PR, 3 MR, 9 SD, and 7 PD	[41]
	II	40 ^a	Good, serious adverse effects probably related to treatment in 5 patients	Standard therapy: 2 CR, 2 PR, 2 MR, 10 SD, and 13 PD Hyperfractionated therapy: 1 CR, 1 MR, 3 SD, and 2 PD	[42]
Refractory primary and secondary liver tumors	I	9	Good	6 SD and 1 PD	[147]
Pancreatic cancer	I	23	Good	No objective responses	[45]
Solid tumors with metastasis	I	10	Good	1 MR, 9 SD	[55]
Liver metastasis of colorectal carcinoma	I	11	Good	1 PR	[52]
Recurrent epithelial ovarian cancer	I	16	No SAE, 1 grade 3 abdominal pain and diarrhea	No objective responses	[49]
Hepatocellular carcinoma	I/II	5	Good	1 PR, 4 PD	[47]
Gastrointestinal carcinomas metastatic to liver	II	27	No SAE, grade 3/4 hyperbilirubinemia in 2 patients, grade 4 systemic inflammatory response	3 PR, 4 MR, 9 SD, and 11 PD	[53]
Pancreatic carcinoma	I/II	21	Good	2 PR, 2 MR, 6 SD, and 11 PD	[46]
Hepatobiliary carcinoma	II	20 (16 evaluated)	Grade 3 adverse effects including 3 hepatic toxicity, anemia, infection and atrial fibrillation	1 PR, 1 SD and 8 patients had >50% decrease in tumor markers	[148]
Metastatic colorectal cancer	II	18	Good	No responses	[56]
Premalignant oral dysplasia	I/II	22 (19 evaluated)	Good	7 histologic resolutions, 1 improvement in dysplasia grade	[51]
Late stage cancers	II	50	No SAE, one grade 4 hepatic dysfunction and hematologic toxicity	3 CR and 11 PR	[149]
Recurrent malignant glioma	I	24	Good	1 SD, 23 PD	[50]
Advanced sarcomas	I/II	6	Good	1 PR	[150]
Refractory metastatic colorectal carcinoma	II	24	Good	2 PR, 11 SD, treatment of 8 patients was stopped due to progression	[54]

Note: CR, complete response; MRI, magnetic resonance imaging; MR, minor response; PD, progressive disease; PR, partial response; SD, stable disease; SAE, serious adverse effects.

^a 30 patients received 1 injection daily (standard therapy) and 10 patients received 2 injections daily (hyperfractionated therapy).

of intratumorally delivered *dl1520* with 5-fluorouracil (5-FU) and cisplatin to 37 patients with recurrent head and neck cancer [40]. Treatment resulted in 27% and 36% complete and partial responses, respectively.

Recently, intratumoral injection of H101, an oncolytic adenovirus quite similar to *dl1520*, was evaluated in a phase III trial against squamous cell cancer of head and neck or esophagus [43,44]. Combination treatment with 5-FU and cisplatin resulted in a response rate of 78.8% (41/52) versus 39.6% (21/53) with chemotherapy alone ($P < .0001$). Virus injected patients had more mild flu-like symptoms and injection site reactions but severe toxicity was not increased. This is a landmark trial in several regards. It is the first randomized demonstration of safety and efficacy of oncolytic viruses in humans. Also, a doubling of the response rate represents a magnitude of improvement rarely seen in oncology, which allowed a highly significant result in a relatively small trial. The oncology and gene therapy communities eagerly await confirmation of the results in further trials performed also outside China. Nevertheless, these data and response rates are well in accord with an earlier independent phase II trial performed in the United States [40], which supports the validity of the H101 trial.

Intratumoral administration of *dl1520* has been utilized in nonrandomized trials with several other cancer types including pancreatic cancer [45,46], hepatocellular carcinoma [47], and oral carcinoma [48]. However, results from these trials have been less promising as responses to treatment have been rare.

Intracavitary administration of *dl1520* has been tested in patients with recurrent ovarian cancer [49], recurrent malignant glioma [50], and premalignant oral dysplasia [51]. A phase I ovarian cancer trial with intraperitoneal delivery of *dl1520* resulted in grade 3 abdominal pain and diarrhea in one patient but the maximum tolerated dose was not reached, and the “maximum affordable dose” was 10^{11} pfu [49]. Disappointingly, there were no clinical or radiological responses in any patients.

After the safety and preliminary efficacy of intratumoral *dl1520* had been established, phase I/II hepatic artery infusion trials were carried out among patients with colorectal liver metastases who had failed first-line chemotherapy. Although the treatment was well tolerated, no objective responses were seen after single-agent treatment [52,53]. However, more promising results were obtained when *dl1520* was given via hepatic artery in combination with intravenous 5-FU and leucovorin to patients who failed to respond to *dl1520* alone. One patient demonstrated a partial response and 10 had stable disease. A recent study demonstrated that this combination resulted in prolonged stable disease in nearly half (48%) of the patients [54]. The first intravenous trial with *dl1520* resulted in no evidence of antitumor activity in patients with advanced carcinoma metastatic to the lung [55]. In another intravenous study, stable disease was seen in some patients with metastatic colorectal cancer but only for a few months [56]. In both reports, *dl1520* was rapidly cleared from the circulation.

In summary, *dl1520* has been well tolerated even at the highest doses that could be administered (2×10^{12} – 2×10^{13} pfu) by any route of administration. The lack of clinically significant toxicity in the liver or other organs has been remarkable. Flu-like symptoms have been the most common toxicities and have been more frequent in patients receiving intravascular treatment. Viral replication has been documented in head/neck and colorectal tumors following intratumoral or intra-arterial administration. Heretofore, single-agent antitumoral activity has been limited to head and neck cancers. However, favorable and potentially synergistic interaction with chemotherapy has been discovered in multiple tumor types and by multiple routes of administration [4,57,58].

8.3.1.3 Type II Oncolytic Adenoviruses

With type II oncolytic adenoviruses, tumor-specific promoters replace endogenous viral promoters to restrict viral replication to target tissues expressing the TSP. Usually, a TSP is placed to control *E1A*, but alternatively or in addition, other early genes can also be regulated. Various promoters have been used to limit viral replication to desired tissues, including α -fetoprotein [59,60], DF3/MUC1 [61], midkine [62], cyclooxygenase-2 [63,64], human telomerase reverse transcriptase [65,66], and secretory leukoprotease inhibitor [67–69].

Human prostate specific antigen (PSA) and rat probasin promoters have been utilized for prostate cancer-specific replication. CG7060 has the PSA promoter and enhancer controlling *E1A* expression [70]. In a phase I trial of locally recurrent prostate cancer, CG7060 was well tolerated following intraprostatic injection to 20 patients and resulted in dose-dependent reductions in PSA in some patients [71]. Similar results were obtained in a phase I/II dose-escalation trial with intraprostatic CG7870 [72], which has the rat probasin promoter controlling *E1A* and the PSA promoter and enhancer driving *E1B* [73]. In contrast to CG7060, this virus has an intact E3 region. CG7870 was recently delivered intravenously to 23 patients with hormone-refractory metastatic prostate cancer [74]. Although PSA levels decreased in some patients, neither partial nor complete formal PSA responses were observed.

Oncolytic adenoviruses combining both type I and type II approaches have been constructed [75,76]. Such double control of viral replication seems advantageous over a single control approach, because it seems to be possible to gain specificity without loss of efficacy.

8.3.2 HERPES SIMPLEX VIRUS

Herpes simplex virus type 1 (HSV-1) is an enveloped, double-stranded DNA virus that frequently causes recurrent oropharyngeal or genital cold sores [77]. HSV-1 is an attractive vector for gene therapy as up to 30 kb of the 152 kb viral genome can be replaced with transgene cassettes. HSV-1 has natural tropism for neuronal tissue and therefore clinical applications have mainly focused on treating brain tumors and neurodegenerative diseases. Pathogenicity of HSV-1 can

be reduced by mutating one or more of the crucial virulence genes resulting in selective replication competence in dividing cells.

G207 is an HSV-1 mutant that carries deletions in both loci of neurovirulence gene $\gamma 34.5$ and an inactivating insertion in the *UL39* gene [78]. Although originally designed for brain tumor therapy, the virus has shown efficacy against various solid tumors *in vitro* and *in vivo* [77]. Intratumoral G207 was evaluated in a phase I dose-escalation study for recurrent malignant glioma [79]. No shedding of G207 was detectable and no toxicity or encephalitis was reported even with the highest dose 3×10^9 pfu. Phase II trials with G207 are now ongoing.

HSV1716 is another $\gamma 34.5$ deleted oncolytic HSV-1 that has been evaluated in phase I clinical trials against malignant glioma [80–82] and melanoma [83]. The virus has been successfully delivered at relatively low doses (1×10^3 – 1×10^5 pfu) without evidence of adverse events. In addition to glioma and melanoma, HSV1716 is currently in clinical trials for treatment of head and neck cancer and mesothelioma.

NV1020 is a genetically engineered HSV-1 containing a deletion of one copy of $\gamma 34.5$, *UL24*, and *UL56*. The deleted region has been replaced with a genome fragment derived from HSV-2. NV1020 was initially developed as a herpes vaccine but it has also been used as an oncolytic agent against various tumors [77]. In a phase I trial, NV1020 was administered via the hepatic artery to patients with colorectal carcinoma liver metastases [84,85]. The treatment was well tolerated and the virus is currently in phase II trials.

OncoVex^{GM-CSF}, a $\gamma 34.5$ deleted HSV-1 strain expressing a human immunostimulatory molecule GM-CSF, has shown promising antitumor effects both *in vitro* and *in vivo* [86], and has been tested in a phase I trial against cutaneous or subcutaneous metastasis of various cancer types. Side effects related to treatment were mostly mild, and shrinkage or no progression of injected lesions were seen [87].

8.3.3 VACCINIA VIRUS

Vaccinia virus is a member of the poxvirus family [88]. It is related to smallpox, and has been used as a smallpox vaccine in millions of humans. Vaccinia is typically a mild pathogen in humans, and it may cause rash, fever, and body aches. It is an enveloped, double-stranded DNA virus with a genome of approximately 200 kb. The large genome allows insertion of large transgenes for virotherapeutic purposes.

Intratumoral treatment with vaccine strains of vaccinia has resulted in significant and reproducible antitumor efficacy in numerous clinical trials. Vaccinia-induced responses have often been durable, complete, and distant from the site of injection [89–92]. Also systemic efficacy following intravenous delivery has been suggested [91,93]. Objective tumor responses occurred in the lungs of two patients with widely metastatic adenocarcinoma. A third patient with multiple myeloma had an objective serologic response.

The clinical use of vaccinia as an anticancer agent has traditionally focused on the induction of an antitumor immune

response, since the virus is highly immunogenic [92,94–97]. However, conditionally replicating deletion mutants have been recently developed [88]. Most genetically modified vaccinia viruses have the thymidine kinase (TK) gene deleted, which might help to give selectivity for dividing cells. This deletion makes the virus dependent on host cell nucleotides, high amounts of which are available in dividing cells. TK-deficient vaccinia virus mutants were shown to replicate selectively in tumor cells [98]. To further enhance tumor-specificity, a combined TK and vaccinia growth factor (VGF) deleted virus was generated [99]. In murine tumor models, the TK/VGF double-deletion mutant displayed higher tumor-targeting capacity and potent antitumor activity with reduced viral pathogenicity. Also other viral genes such as SP-1 and SP-2, have been successfully deleted for improved tumor selectivity [100]. These genes encode serine protease inhibitors homologous to proteins known to be upregulated in cancer cells. Therefore, they may be dispensable for replication in tumor cells but are required in normal cells. Additional tumor selectivity may result from the size of the virus. Leaky tumor vasculature may allow preferential extravasation in comparison to intact normal vessels.

8.3.4 MEASLES VIRUS

Wild-type measles virus is a negative-strand RNA virus causing rash, fever, cough, and conjunctivitis. Although the disease is usually mild, it causes almost 1 million deaths of children each year worldwide [101]. Wild-type measles does not propagate in cells derived from human neoplasms. However, certain members of the Edmonston vaccine lineage (MV-Edm) are selectively oncolytic against various types of human malignancies, probably due to mutations enhancing the ability of virus to interact with CD46, a receptor highly expressed by tumor cells. Thus, due to altered receptor-specificity, attenuated pathogenicity, and ability to selectively replicate on cancer cells, MV-Edm is a promising agent for cancer gene therapy.

Attenuated MV-Edm has shown potent antitumor activity against a variety of human malignancies *in vivo* [101]. Initially, there was no convenient way to evaluate the replication and persistence of the virus *in vivo*, and the oncolytic potency of MV-Edm in different human tumor xenograft models was deemed highly variable. Therefore, MV-Edm-derived oncolytic measles viruses expressing either soluble marker peptide carcinoembryonic antigen (CEA) (MV-CEA [102]) or thyroidal sodium iodide symporter (NIS) (MV-NIS [103]) were developed. Currently, intraperitoneal delivery of MV-CEA and systemic administration of MV-NIS are under evaluation in phase I clinical trials against recurrent human ovarian cancer and myeloma, respectively. Progress in the former trial has been presented in an intermediate report [104]. Out of the first 12 patients, 5 have displayed stable disease for 2–8 months, while significant CA125 decreases have been seen in 3 patients. No serious side effects have been seen and dose escalation continues.

8.3.5 NEWCASTLE DISEASE VIRUS

Newcastle disease virus (NDV) is a negative-strand RNA virus that causes severe respiratory and central nervous system diseases to fowl [101]. However, to humans it is usually a mild pathogen causing conjunctivitis. Tissue culture-adapted strains of the virus show reduced virulence towards normal cells but oncolytic activity in human cancer cells, possibly due to cancer-specific defects in the interferon signaling pathway.

The first promising report of efficacy with NDV was published in 1964 [105]. A patient with myelogenous leukemia responded to intravenous NDV treatment. Subsequently, various naturally attenuated NDV strains have been reported useful in the treatment of neoplastic diseases. The oncolytic potency of NDV strain 73-T has been demonstrated in several human cancer xenografts and in clinical trials [101]. A follow-up of stage III melanoma patients treated with 73-T oncolysate in 1975 reported a 55% overall 15 year survival [106].

MTH-68/H is an *in vitro* passaged NDV strain administered initially by inhalational to patients with advanced solid tumors [107]. Objective responses were reported in 55% of patients. Intravenous MTH-68/H was given to 15 glioblastoma patients [108]. Daily infusions were associated with tumor shrinkage in seven patients, although interpretation is complicated by concomitant treatments.

Oncolytic NDV strain PV 701 has been evaluated in a phase I clinical trial in patients with advanced solid cancers [109]. Seventy-nine patients were treated with single or multiple intravenous doses of PV 701. The maximum tolerated dose was 1.2×10^{10} pfu/m² with the most common adverse effects being flu-like symptoms that occurred mainly after the first dose and were decreased in number and severity with each subsequent dose. Desensitization with a lower dose enabled the utilization of a higher dose 1.2×10^{11} pfu/m². Objective responses occurred at higher dose levels, and progression-free survival ranged from 4 to 31 months. A recent phase I study utilized a two-step desensitization approach (two low doses followed by higher dose) to successfully improve patient tolerability to PV 701 treatment [110]. Another phase I study sought to improve patient tolerability to PV 701 treatment by slowing the intravenous infusion rate. This regimen diminished adverse effects and tumor responses were reported [111].

Systemic delivery of lentogenic NDV-HUJ strain was recently tested in a phase I/II trial in patients with recurrent glioblastoma multiforme [112]. The maximum tolerated dose was not reached but a complete response was seen in one patient.

8.4 FUTURE DIRECTIONS

In summary, although preclinical studies utilizing oncolytic viruses for treating neoplastic diseases have been mostly promising, data from clinical trials is less convincing (Tables 8.2 and 8.3). Overall, the safety of these approaches has been very good, but objective antitumor responses following intravascular

delivery have been rare thus far. Nevertheless, transduction of tumor cells or secondary viral burst has been demonstrated in many cases. Many reports confirm that if intratumoral injection can be performed, responses can be seen regularly. Furthermore, many viruses (including adenovirus, vaccinia, reovirus, and NDV) can achieve tumor transduction following systemic delivery. Nevertheless, the available clinical data implies that transduction efficacy continues to be the limiting factor for clinical benefit. Several strategies are currently being explored to improve transduction of tumor cells and effective penetration of solid tumors (Figure 8.2). In particular, spreading within the tumor can be limited by physical barriers such as stromal cells and matrix, necrotic, hypoxic, or hyperbaric regions. Also, methods for increasing bioavailability following intravenous delivery seem appealing.

In the context of oncolytic adenoviruses, all published trials rely on CAR for entry into cells. It has been demonstrated that a major determinant of the oncolytic potency of replicating agents is their capability of infecting target cells [113]. Unfortunately, concurrent studies have suggested that expression of CAR is frequently dysregulated in many types of advanced cancers [3]. Various strategies have been evaluated to genetically modify adenovirus tropism in order to circumvent CAR deficiency, for increased transduction of tumor cells and reduced normal tissue tropism.

Ad5- Δ 24RGD is Rb-p16 pathway selective oncolytic adenovirus featuring an integrin binding RGD-4C modification in the HI-loop of the fiber knob [114]. Fiber pseudotyping has also been evaluated. Substitution of the knob domain of Ad5 with the corresponding domain of serotype 3 (Ad3) allows binding and entry through the Ad3 receptor, which is expressed to high degree on ovarian cancer cells [115,116]. Ad5/3- Δ 24 is another Rb-p16 pathway selective oncolytic adenovirus that contains a chimeric fiber featuring a serotype 3 knob [117]. Recent studies have demonstrated that these both agents deliver a powerful antitumor effect to many types of cancer cells *in vitro*, to clinical cancer specimens fresh from patients, and in orthotopic models of ovarian cancer, and both viruses are now proceeding towards clinical testing on ovarian cancer patients [117–119].

Although pretargeting with adaptors requiring conjugation prior to infection is perhaps not optimal for replicating agents, secretory adapter molecules (produced in conjunction with replication) could be more useful for allowing targeting of viral progeny. Coinfection of a replication-deficient virus coding sCAR-EGF with Ad5- Δ 24 resulted in enhanced oncolysis [120]. sCAR is a secretory variant of the adenovirus receptor, while the other end of the fusion molecule binds to the epidermal growth factor receptor (EGFR), which is often highly expressed on advanced tumors. However, when this approach was tested in a single-component oncolytic virus, D24sCAR-EGF, efficacy was not increased [121]. This suggested that the expression of biologically active adapter proteins can interfere with virus production and oncolysis. In contrast, van Beusechem et al. introduced a bispecific single chain (csFv) antibody 425-S11, which recognizes EGFR and

TABLE 8.3
Modern Trials with Other Oncolytic Viruses

Name	Virus Type	Tumor Selectivity	Phase	Patients	Safety	Results	References
CV706	Adeno	Prostate	I	20	Good	5 PSA reductions of $\geq 50\%$	[71]
Ad5-CD/TKrep	Adeno	—	I	15	No SAE, 2 patients had grade 3 lymphopenia	Mean PSA half-life was significantly shorter in patients who were administered >1 week of prodrug therapy than in patients who received prodrugs for 1 week ($P < .02$).	[125]
CG7870	Adeno	Prostate	I	23	One serious grade 3 fatigue, 2 grade 3 fevers	No response	[74]
NDV-HUJ	NDV	—	I/II	14	Good	1 CR	[112]
PV 701	NDV	—	I	79	SAE included fever, diarrhea, leucopenia, thrombocytopenia, fatigue, dehydration, and were mostly related to the first cycle of treatment	1 CR, 1 PR, and 7 MR	[109]
PV 701	NDV	—	I	18	No SAE, transient grade 4 rise in liver enzymes and pain at tumor site	1 CR, 3 PR, and 2 MR	[111]
MTH-68/H	NDV	—	—	14	Good	4 CR, 4 patients still alive (2004) after 5–9 years from the beginning of the therapy	[108]
MV-EZ	Measles	—	I	5	Good	1 PR, 2 SD, and 2 PD	[151]
G207	HSV-1	—	I	20	No SAE, hemorrhages at injection site and weakness	14 patients had a decrease in the enhanced mass measured by MRI	[79]
HSV1716	HSV-1	—	I/II	12	Good	2 SD, 10 died for progressive disease	[82]
OncoVex-GM-CSF	HSV-1	—	I	30	No SAE, more grade 3/4 side effects in single-dose group	3 SD, no progression, or shrinkage of injected lesions were observed	[87]
NV1020	HSV-1	—	I	12	No SAE, grade 3 diarrhea, leukocytosis and liver enzyme elevation in 3 patients	2 MR, 7 SD, 3 PD	[85]
Vaccinia/GM-CSF RV	Vaccinia	—	I	7	Good	1 CR, 1PR	[92]
rV-PSA	Vaccinia	—	I	33	Good	14 SD for 6 months, 9 SD for 11–25 months, 6 SD at the completion. Responses were measured as PSA levels in 3 successive monthly determinations.	[95]

Note: CR, complete response; HSV-1, herpes simplex virus 1; MRI, magnetic resonance imaging; MR, minor response; NDV, new castle disease virus; PD, progressive disease; PR, partial response; PSA, prostate specific antigen; SAE, serious adverse effects; SD, stable disease.

fiber knob, into the *E3* region of Ad5- $\Delta 24$. This secretory retargeting moiety increased oncolytic potency on CAR-deficient glioma cells [122].

For further potentiation, replication competent viruses can be armed with therapeutic transgenes such as cytokines, suicide genes, fusogenic, proteolytic, or antiangiogenic moieties [123]. For example, Ad5-CD/TKrep contains a fusion suicide gene expressing both *Escherichia coli* cytosine deaminase (CD) and herpes simplex virus thymidine kinase (TK) which can convert systemically administered prodrugs 5-fluorocytosine and ganciclovir into toxic agents. The activated

drugs can also spread into surrounding cells delivering a powerful bystander effect. In a phase I study with recurrent prostate cancer patients, Ad5-CD/TKrep treatment appeared safe and also resulted in frequent decreases in PSA levels [124,125].

A powerful approach for increasing efficacy is utilization of oncolytic viruses in combination with conventional anticancer therapies in a multimodal antitumor approach. Oncolytic tumor killing differs from conventional anticancer therapies, providing a possibility for additive or synergistic interactions. Further, the toxicity profiles may be different,

FIGURE 8.2 Ways to improve oncolytic viruses.

which could result in enhanced efficacy without significantly increased adverse effects. There are several studies suggesting enhanced cell killing activity when oncolytic viruses have been combined with chemotherapeutic agents [26,40,60,126–132] or radiation [71,72,133–137].

Finally, the biodistribution of many viruses may not be optimal for systemic delivery. For example, adenovirus has strong liver tropism, at least in mice. Intriguing approaches for improving the bioavailability of oncolytic viruses include ablation of hepatic Kupffer cells [138], using carrier cells [139,140] or coating of viruses with synthetic molecules such as polyethylene glycol [141]. Further, preliminary evidence suggests that certain blood factors such as platelets or members of the coagulation cascade may be of important determinants of the fate of intravascular adenovirus [23]. These aspects may be relevant for other oncolytic viruses as well, but much work needs to be done before those viruses are understood as well as adenovirus.

8.5 CONCLUSIONS

In summary, oncolytic viruses have emerged, or in fact reemerged, as promising developmental agents for treatment of cancer refractory to more conventional treatments. Only one phase III trial has been completed thus far, demonstrating that field is still in its infancy. Nevertheless, the only completed trial was a positive one with regard to safety and efficacy. Uniquely, oncolytic viruses face much more complex regulatory, production and intellectual property issues than other novel, but more conventional therapeutics such as small molecular inhibitors and monoclonal antibodies. Overlapping patents, lay concerns over gene delivery, and standardization

of biological production systems may be more challenging obstacles than any of the scientific ones mentioned above. Nevertheless, the complexity and capacity for adaptation exhibited by advanced cancers suggests that all new cancer drugs will eventually have an opportunity for demonstrating their potency. The single most impressive feature of oncolytic viruses may be their outstanding capacity for rapid killing of tumor cells. In a world where most new cancer drugs are cytostatic or stabilizing by nature, the ability to kill cells and concurrently mount a protective immune reaction may well prove valuable for avoiding resistance and relapse.

9.1 INTRODUCTION

Lentiviruses are a genus of the family *Retroviridae* (retroviruses) [1] that have been modified to be used as gene transfer agents. “Lenti-,” from the Latin for “slow,” refers to the well-known properties of these viruses as human and animal pathogens that are characterized by long incubation periods and persistent infection. Members of the lentivirus genus have garnered much attention from both scientists and the public at large since the early 1980s, when the then-phenomenon and now-pandemic of AIDS introduced the world to the most well-known and feared lentivirus: human immunodeficiency virus type 1 (HIV).

Although HIV is still the most well publicized and widely studied of the lentiviruses, there are other members of this

group. All are pathogenic, but during the last decade these viruses have held specific interest for researchers not only in their capacity as infectious agents but now as promising tools (vectors) for the delivery of genetic material. Lentiviruses possess several features, such as capacity for a large (up to 9 kbp DNA) genetic payload and a minimal immune response, that make them attractive as gene transfer agents. The singular attribute, however, that most distinguishes this class of virus from other viral vectors (particularly from conventional retroviral vectors) is their ability to transduce and permanently modify nondividing cells. This property was initially demonstrated in cell culture but has since been reproduced in many experiments *in vivo*. The excitement generated by these results has fostered a large amount of research, some of which has recently led to the first use of these vectors in human

trials; an encouraging step towards the ultimate goal of utilizing the unique properties of lentiviral vectors in the clinical therapeutic setting.

This chapter is written for readers with at least a basic understanding of molecular biology and its methods. It aims to provide an overview of the historical development, design features, and production of these vectors as well as the opportunities and obstacles surrounding their use. The references provide examples and leads for further information, and are not meant to be exhaustive.

9.1.1 BIOLOGY OF THE LENTIVIRUSES: LIFE CYCLE AND GENETIC GEOGRAPHY

A good portion of this chapter is dedicated to understanding the construction and manipulation of lentiviral vectors. It is difficult to consider manipulation of a vector, however, without first having a comprehension of its components. There, it is necessary to first discuss the life cycle and genomic architecture of the native lentiviruses that are the template for all of the lentiviral vectors.

Lentiviruses, like all retroviruses, are enveloped RNA viruses that fuse with the membrane of a target cell and deposit a viral core within. Once inside, viral core particles reverse transcribe their RNA genome into duplex DNA and then integrate it into the host cell genome (see Figure 9.1B for details of life cycle). Following integration, long-terminal repeat (LTR)-driven RNA transcription occurs, such that viral proteins are translated and progeny virions are assembled, budded, and released to infect other cells [1,2]. This life cycle makes lentiviruses attractive vectors for gene therapy because it means that they are able to carry therapeutic sequences within their genomes and then integrate the DNA (including the therapeutic sequence) into that of the host cell. This ability to alter the host cell genome by inserting genetic sequences of interest is one essential aim of gene therapy and these modifications can be tailored by manipulation of the vector genome.

The proviral genome of HIV is shown in Figure 9.2, as are those of several other lentiviruses (feline immunodeficiency virus [FIV], equine infectious anemia virus [EIAV], simian immunodeficiency virus [SIV], and bovine immunodeficiency virus [BIV]) that have been used to construct vectors. The features of HIV and HIV-based vectors will be considered more extensively here than other lentiviral vectors, since efforts at developing vectors based upon HIV have thus far dominated the field.

A working knowledge of the HIV genome is vital for an understanding of both normal viral gene function and vector design. When approaching the relatively complex genome of HIV, it may be helpful to first functionally divide it into the two broad categories of *cis* and *trans* components, which can then be individually considered. The *cis* functions of HIV are carried out by segments of RNA or DNA that serve important functions, without being translated into protein. Important *cis*-acting elements of HIV include the LTRs, donor and acceptor splice sites, Rev responsive element (RRE), and packaging

signal (Ψ) [4]. The LTR is a regulatory sequence of DNA found at both the 5' and 3' ends of the provirus that acts as a promoter of transcription for the viral genome. The RRE is a structured RNA element within the *env* gene (see the following paragraph) which, when bound by the HIV protein Rev, allows an RNA transcript to be exported unspliced from the nucleus. Ψ consists of two short sequences on either side of the major splice donor site that form structured RNA elements that allow recognition and selective packaging of viral genomic RNA into the viral capsid (CA) before viral assembly and membrane budding [5,6].

The *trans*-acting components of the HIV genome are composed of nine open reading frames (Figure 9.2). Three of these can be considered to make up the “backbone” of the virus, since they are essential for replication and are shared among all retroviruses. These three open reading frames contain the conserved genes encoding the polyproteins Gag, Pol, and Env (shown shaded in diagonal lines, Figure 9.2). These three polyproteins are posttranslationally cleaved into the structural and enzymatic proteins that perform the vital functions necessary to the life cycle of any retrovirus: Env is cleaved into two structural proteins, SU (surface or gp120) and TM (transmembrane or gp41) which together make up the outer membrane envelope protein gp160. Gag is proteolytically cleaved into matrix (MA), CA, NC (nucleocapsid), and p6. Collectively, these four structural components aggregate to form the proteinacious core which houses the virus' RNA genome. Pol is also cleaved into the three essential viral enzymes PR (protease), RT (reverse transcriptase), and IN (integrase) which are responsible for proteolytic cleavage of most viral polyprotein precursors, reverse transcription of the viral RNA genome into DNA, and integration of viral DNA in the host cell genome, respectively [7].

The remaining six open reading frames contain encode genes that are not found in simple oncoretroviruses and that distinguish HIV as a lentivirus. Two of these genes, *tat* and *rev* (shown shaded with horizontal lines, Figure 9.2), code for regulatory proteins. Tat plays a critical role in producing large quantities of mRNA transcripts from the integrated proviral genome by acting as a transactivator of transcriptional elongation. Specifically, Tat forms a complex with the cellular proteins cyclin T1 and CDK9 which hyperphosphorylates the carboxyterminal domain of RNA polymerase II [8–10]. This modification increases the processivity of RNAPII, resulting in a 100- to 500-fold enhancement in the transcription of the HIV genome [11].

Rev, the other regulatory protein of HIV, is responsible for allowing unspliced or singly spliced species of messenger RNA to exit the nucleus intact. This function is crucial to viral replication, since the cell's default pathway is to splice all nascent mRNA transcripts as part of the nuclear processing required before export of mature mRNAs through nuclear pores. If all transcripts of the HIV genome were treated in this manner, there would be no full-length mRNA transcripts of the genome to be packaged into progeny virions. Unspliced and singly spliced mRNAs are also necessary for the proper translation of Gag/Pol and some HIV accessory proteins. Rev is

FIGURE 9.1 (A) Life cycle of generic lentiviral vector (replication-defective). (B) Simplified life cycle of HIV (replication-competent). Released virus is infectious and capable of infecting other cells.

able to overcome the cell's default splicing mechanism by multimerizing along the RRE, a structured RNA element within the intron shared by Tat and Rev. Cellular factors bind to a nuclear export signal within Rev and these complexes (containing the unspliced RNA) are exported from the nucleus [12].

The final four genes code for the so-called accessory proteins, which are also unique to lentiviruses: Vif, Nef, Vpr, and Vpu (shown in speckled shading, Figure 9.2). These proteins are not strictly necessary for viral replication *in vitro*, but all

play one or more roles in disease progression or pathogenesis in man. Vif has recently been found to play an important role in rendering cells susceptible to HIV infection by causing the proteasomal degradation of APOBEC3 proteins, which normally restrict retroviral replication by mutating or degrading viral cDNA [13–15]. The *in vivo* importance and exact function of the other accessory proteins are less clear, although it has been established that they modulate multiple host cell processes [7,16]. For example, Nef is a protein produced from a fully spliced mRNA that augments viral infectivity and rates

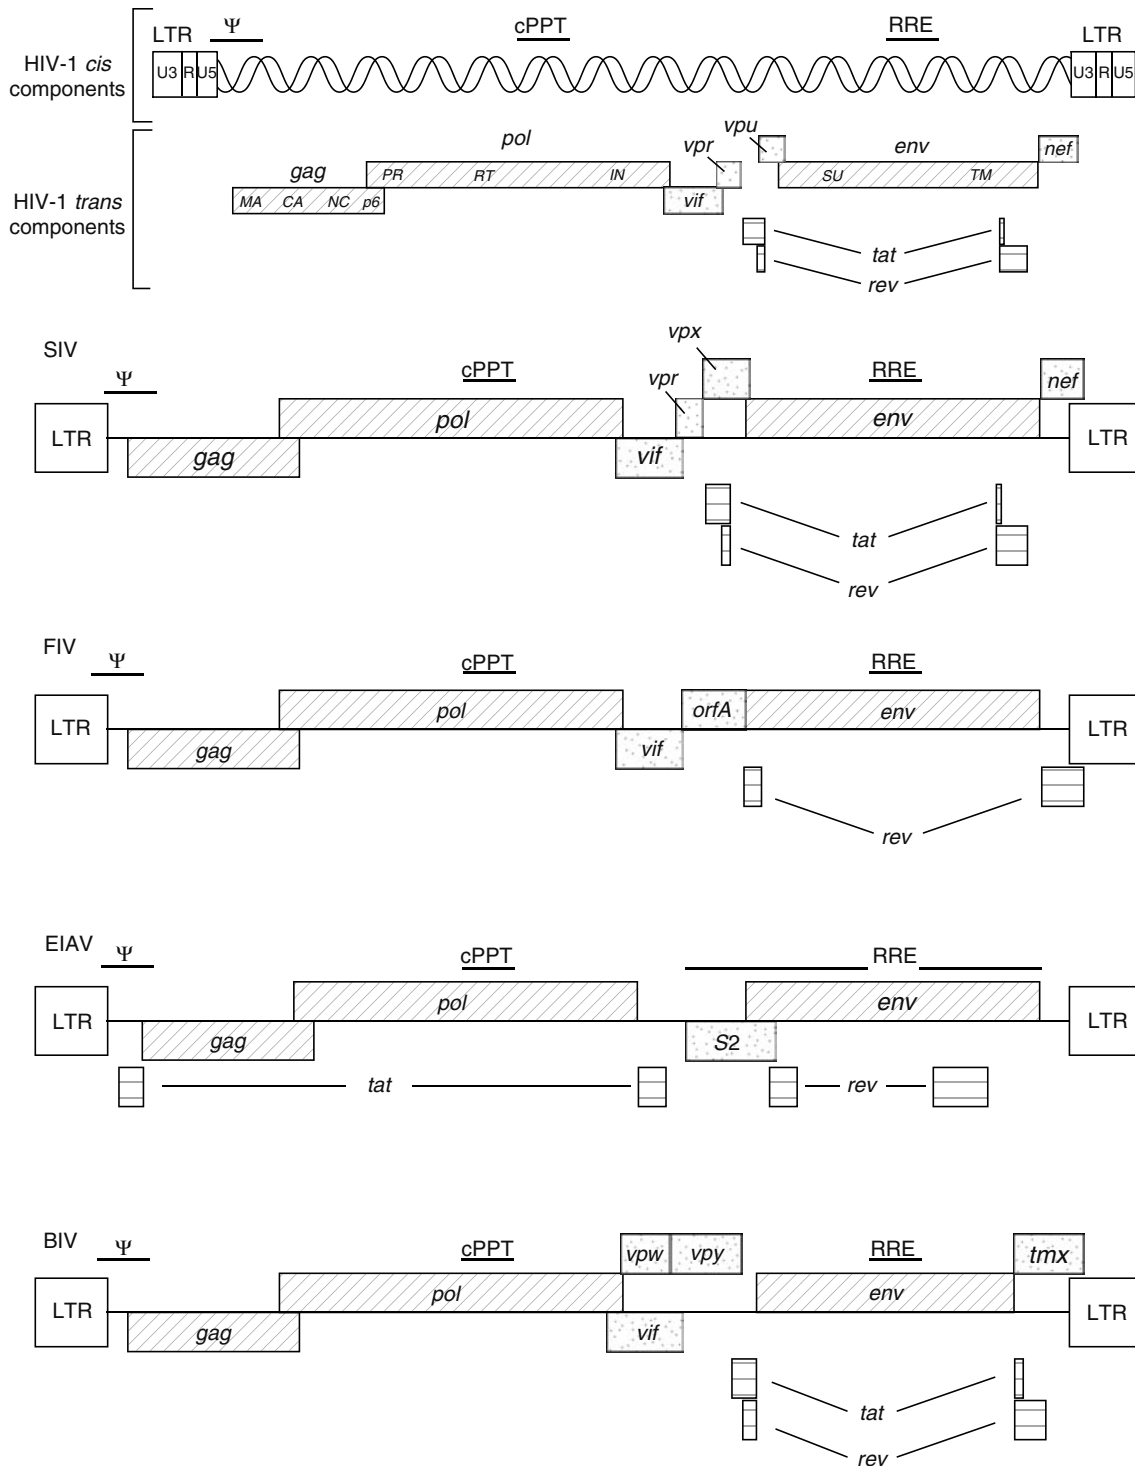

FIGURE 9.2 Genomes of lentiviruses that have been used as the bases for vector construction. Genes coding for structural proteins are shaded with diagonal lines, regulatory genes with horizontal lines, and accessory genes are speckled. Ψ , packaging signal; RRE, rev responsive element; cPPT, central polypurine tract; LTR, long terminal repeat.

of viral DNA synthesis following infection [17,18]. It is known to exert pleiotropic effects, including interference with cellular signal transduction pathways, alteration of normal cellular trafficking patterns, and downregulation of CD4 and class I major histocompatibility complexes (MHCs) [19,20] from the

cell surface. Vpu acts as an adapter protein to aid in the endocytosis and degradation of surface CD4 molecules, and is important for optimal virus release in certain cell types [21–25]. Finally, Vpr [26,27] is known to cause cell-cycle arrest in the G(2)/M phase [28–30] and to modulate gene transcription [31].

Vpr has also been implicated in the ability of HIV to infect nondividing cells. Vpr has a noncanonical nuclear localization signal and it has been demonstrated to directly interact with cellular nucleoporins and cause physical disruptions in the cell's nuclear envelope [32–35].

Several nonhuman lentiviruses [36], shown in Figure 9.2, have also been used to construct vectors. The standard *cis* and *trans* retroviral features are conserved among all of them, but accessory proteins vary somewhat in number and function. All of the viruses have a Rev/RRE system that allows export of unspliced or partially spliced viral RNA from the nucleus. The Tat and Vif proteins and functions also appear to be conserved with the exception that EIAV has no Vif protein and FIV has no recognizable Tat, although some Tat-like functions are performed by ORFA [37]. In addition, the non-primate lentiviruses encode other genes of unknown function, such as EIAV's S2 gene and dUTPase in the Pol polypeptide. The variety of accessory proteins among different lentiviruses and the uncertainty regarding the nature of some of their functions presents another level of complexity. However, while both human and nonhuman lentiviral accessory proteins all doubtlessly play important roles in viral pathogenesis *in vivo*, it is generally the case that they are not needed for replication *in vitro*. As we will discuss shortly, they are also not needed for effective *in vitro* gene delivery, and so for the purposes of gene therapy and vector construction, can largely be removed and ignored.

9.1.2 NUCLEAR IMPORT AND INTEGRATION IN NONDIVIDING CELLS

As mentioned in the introduction, the ability to infect nondividing cells has been a key issue driving the development of vectors based on lentiviruses. This is in part due to the fact that most oncoretroviruses (such as murine leukemia virus), whose use and prominence in gene therapy predates that of lentiviruses, do not share this property and must instead target actively dividing cells, whose nuclear membranes are periodically disassembled, in order to gain access to chromatin for integration [38,39]. The discovery that lentiviruses could infect nondividing cells [40–42] provided a vector whose shared heritage with oncoretroviruses meant that it maintained the desirable properties of such vectors but was able to transduce a range of target tissues (such as neurons) that were previously inaccessible via retroviral vector technology. This is an important ability for viruses such as HIV, whose initial targets are likely to be terminally differentiated tissue macrophages found near mucosal surfaces and whose later targets may include quiescent helper T cells, CNS microglia, and tissue macrophages.

After fusing with the cellular membrane and being deposited in a target cell, HIV-1 viral cores shed their CA protein and begin the process of reverse transcribing double-stranded cDNA, forming what is known as a reverse transcription complex (RTC). When reverse transcription is completed and viral cDNA is ready for import into the nucleus, the complex is termed a preintegration complex (PIC) and contains viral

and cellular proteins along with the cDNA [43]. The PIC traverses an intact nuclear membrane via an energy-dependent mechanism [44], likely utilizing nuclear pore complexes. Exactly how the PIC (whose diameter is more than twice that of the pores themselves) is able to cross the intact nuclear envelope remains controversial. Traditionally, nuclear import of HIV PICs has been attributed to three seemingly redundant nuclear localization signals (NLSs) [45]: a canonical NLS within the structural protein MA [46,47], a bipartite, canonical NLS within the enzyme IN [48], and a noncanonical sequence within Vpr [32–35]. However, no sole determinant of import has been reproducibly identified and instead the current picture suggests a multitude of contributing factors govern import [43]. Recent evidence points to several previously unconsidered factors that may underlie PIC import, including the viral central DNA “flap,” structure formed during reverse transcription [49], the viral CA protein [50,51], and the cellular proteins importin 7 and nucleoporin 98 [43].

Integration into host chromatin by IN is another important event in the viral life cycle to be considered, since it allows permanent, irreversible modification of the host cell genome. At this point, relatively little is known about the factors that determine the choice of HIV integration sites within the host cell chromatin. Several genomic analyses have observed that the pattern of integration occurs preferentially within genes [52], but importantly throughout the transcriptional unit of each gene [53]. This contrasts to the 5' bias of murine leukemia viral vector integration sites, and it may improve the safety profile of HIV-based vectors compared to those of MLV. Recently LEDGF/p75 [54] has been shown to modulate the interaction between HIV PICs and host cell chromatin via a tethering-like mechanism and may be an essential host factor for integration.

9.2 CREATION AND FEATURES OF INITIAL LENTIVIRAL VECTORS

The purpose, life cycle, and structure of lentiviral vectors differ considerably from that of their parent viruses. With the understanding of lentivirus biology gained in Section 9.1, we can now contrast these differences in detail as we explore the vectors themselves.

9.2.1 HOW ARE LENTIVIRAL VECTORS DIFFERENT THAN LENTIVIRUSES?

The “purpose” of the lentiviral life cycle is to deliver genes needed for viral replication to a cell and then replicate those genes for delivery to another cell. In contrast, the purpose of a lentiviral vector is to deliver a “particular” gene or set of genes, chosen by its designer, into a cell in order to effect a chosen function (beyond mere replication) within the cell. Unlike their parent viruses, a lentiviral vector typically does not replicate its components once it integrates into the target cell.

FIGURE 9.3 A typical lentiviral transfer vector (top), along with plasmids encoding requisite trans-acting genes. CMV, cytomegalovirus promoter; R, repeat region of LTR; U5, 5' untranslated region; ΔU3, deleted 3' untranslated region; polyA, polyadenylation sequence. Only the relevant portions of plasmids are shown.

The life cycles of lentiviruses and vector (see Figure 9.1) are also different, although they can both be conceptually divided into two stages: (1) viral entry, reverse transcription, transport into the nucleus, and integration correspond to the use of the vector to carry heterologous genes into target cells and (2) the subsequent provirus transcription, synthesis of viral proteins, packaging of the viral genome, maturation of the viral particle, and export from the cell correspond to the production of the vector particle [55]. Methods for producing vector particles are discussed in detail in later sections, but it is important to note now that vector production is markedly different than virus production. Whereas viruses autonomously reproduce and spread themselves within and among cells, vectors are nearly always initially generated in a laboratory using tissue culture cells to assemble specific viral and transgene components that are chosen in advance. Following generation, vector particles are then collected and used to transduce a target cell of choice.

Genomes are another point of difference between lentiviruses and vectors. While the genomes of lentiviruses such as HIV-1 are notoriously susceptible to small mutations, they are nonetheless relatively fixed structurally, and one genome can be put forth for each species of virus that accurately portrays the organization and gene products for that virus (Figure 9.2). Vector genomes, in contrast, may vary widely, depending upon the design of the vector (see Figures 9.3 through 9.7). It would be difficult to draw a prototypical vector, since there are so many markedly different permutations of this concept (nonetheless, see Figure 9.3 for the sake of comparison between viral and vector genomes). Vector genomes may

FIGURE 9.4 pHXB-CAT1. The shaded area was replaced with the chloramphenicol acetyltransferase gene; otherwise, this simple vector is very similar to wild-type HIV-1.

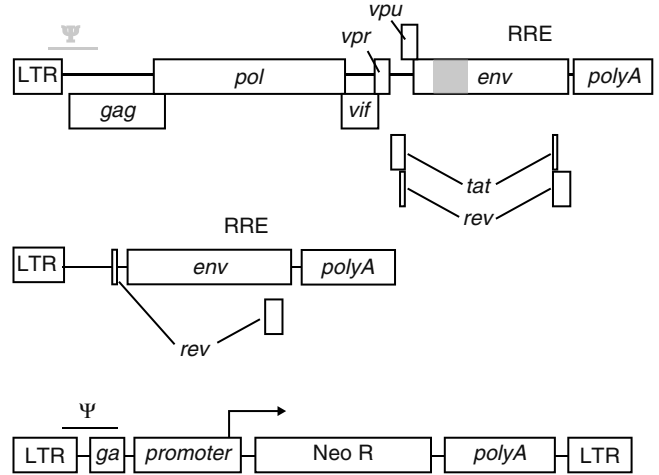

FIGURE 9.5 The three-component system introduced by Poznansky et al. Gray shaded regions indicate deletions. “ga” is a truncated gag ORF.

include some, all, or very few of the cis and trans elements that are found in their parent viruses, while they invariably contain some genes that are not. In addition, vector genomes are often divided into several pieces whereas lentiviral genomes are always entirely contained on a single, continuous strand of RNA or DNA. Certain factors, such as the intended application and included safety measures that determine the design and organization of a vector genome, will be discussed in detail below.

9.2.2 TURNING VIRUS INTO VECTOR

Given the essential difference in purpose between a virus and a vector defined above, the hypothetical design of the simplest

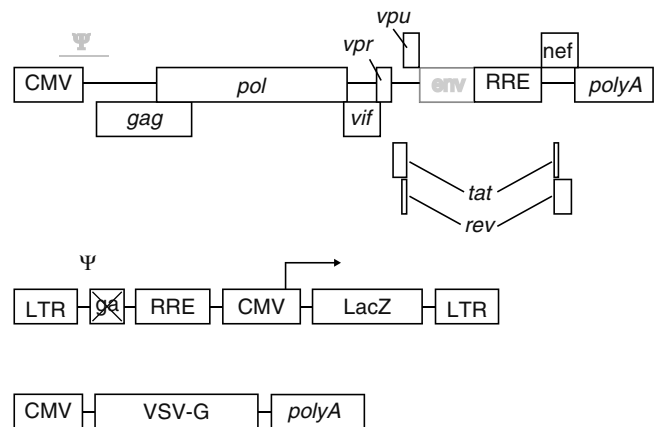

FIGURE 9.6 Vector system introduced by Naldini et al. At top is first-generation packaging vector, middle is transfer vector, and bottom is VSV-G expression construct. Gray shaded regions indicate deletions. “ga” is a truncated gag ORF that has been frame-shifted.

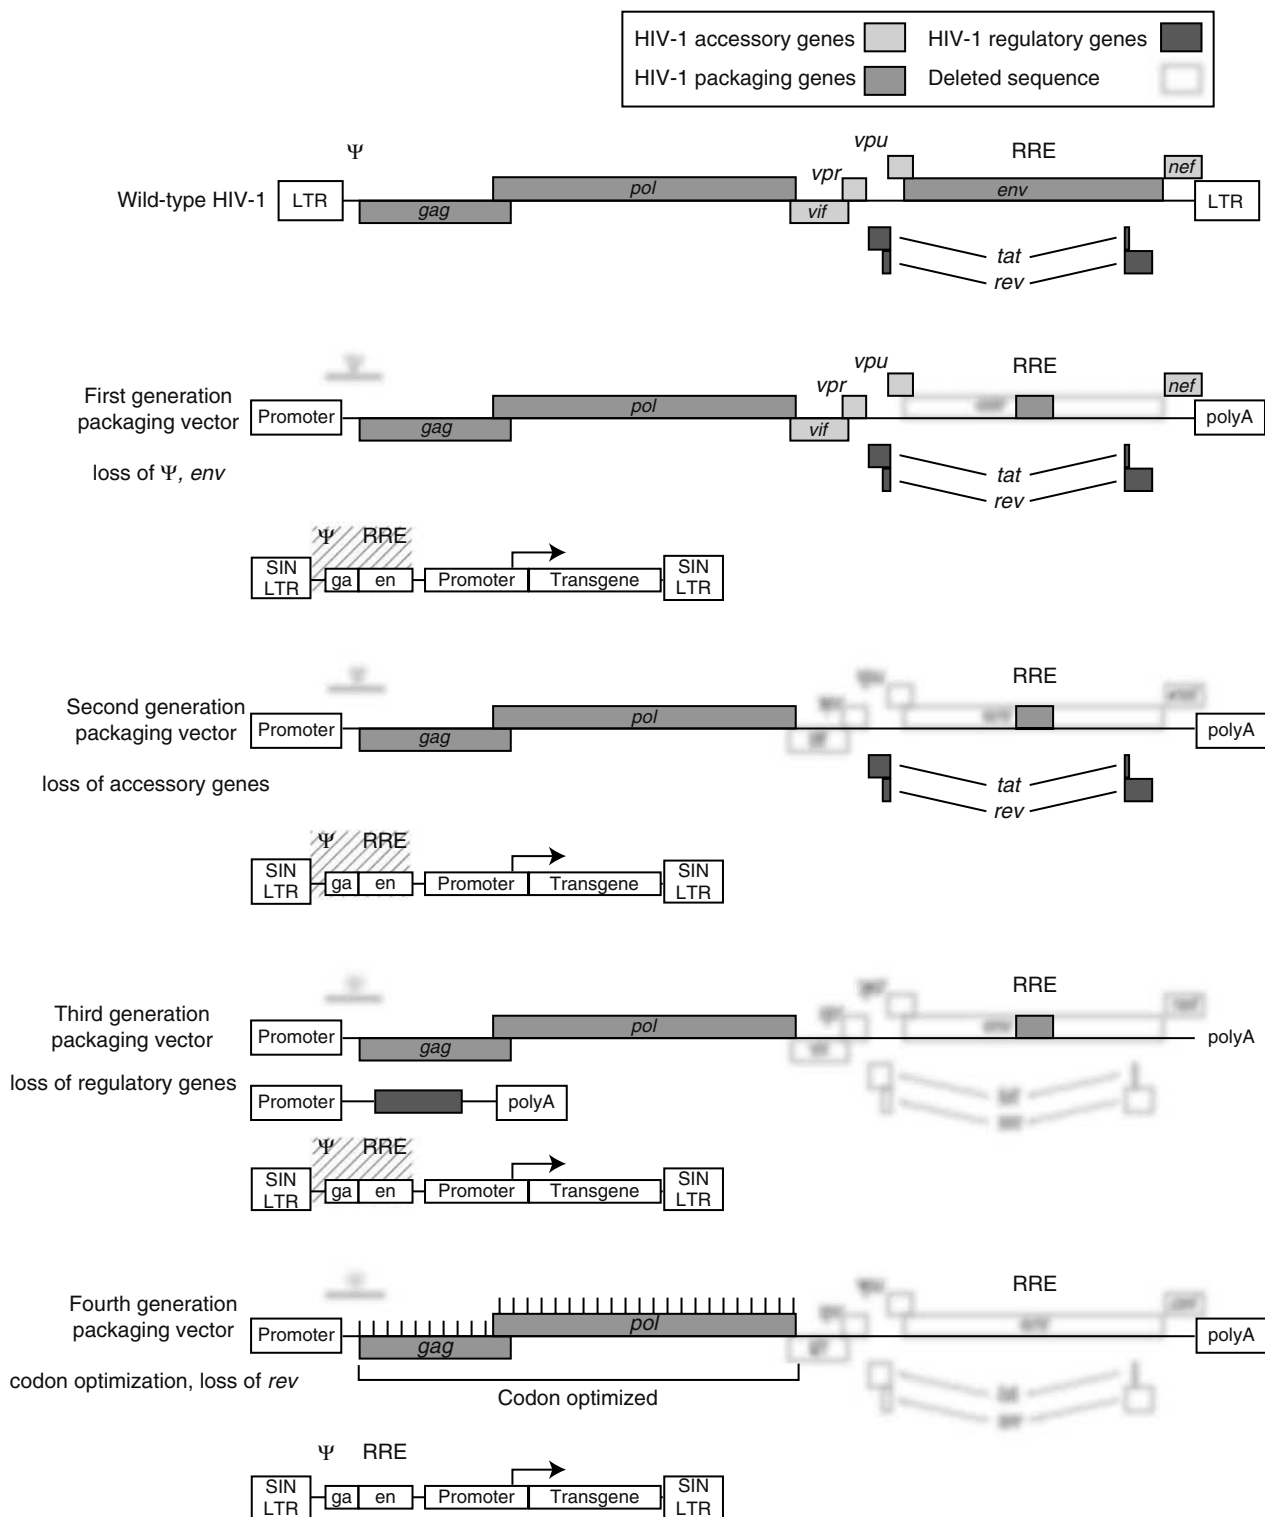

FIGURE 9.7 (See color insert following blank page 206.) Wild-type HIV-1 and the various generations of lentiviral packaging vectors for comparison. A minimal transfer vector is shown alongside each packaging vector and areas of sequence homology between the two are indicated by shading.

possible lentiviral vector would be nothing more than a parent virus that had been modified to include an exogenous gene chosen by the designer. In fact, the historical record of vector development matches these requirements: The first lentiviral

vectors were constructed by Sodroski and coworkers in 1989 and were nothing more than a T-tropic HIV-1 plasmid provirus (HXBc2) that had been altered to include a chloramphenicol acetyltransferase (CAT) reporter gene in place of

nonessential *nef*, near the 3' end of the virus (termed pHXB-CAT1) (Figure 9.4). When this plasmid was transfected* into Jurkat T cells, it was found to produce infectious virus that expressed CAT activity in proportion to the level of infection of a cell culture [56]. The replicating entity used in this experiment meets our criterion of “vector” since it transferred the CAT gene; however, this earliest vector was actually replication competent, used all of the viral gene products (except Nef) in their native forms†, and was produced in a manner similar to the “wild-type” virus that served as the experimental control.

Shortly thereafter the same group of investigators introduced the next level of complexity in vector architecture when they designed an HIV-based research tool to quickly assay the effects of different HIV envelope mutations on viral entry into cells. The assay relied upon pHXB-CAT1 as described above. The plasmid was further altered to include a 580bp deletion in the *env* gene (termed pHXBΔ*env*CAT) such that envelope was defective and the virus could not replicate. Full-length envelope was provided *in trans* by co-transfecting cells (COS-1 or Jurkat) with both pHXBΔ*env*CAT and a separate gp160 expression plasmid. Transfected cells proceeded to produce infectious but replication-defective virus. The presence of the packaging signal, Ψ, on transcripts of pHXBΔ*env*CAT allowed its RNA to be incorporated into nascent viral core particles, while the gp160 RNA was not. The harvested virions could then be used to transduce target cells with only a single cycle of replication [57].

This laboratory “tool” intended to test different gp160s was an important step in the evolution towards modern vectors. Instead of a self-replicating entity, the gene transfer agent now served to permanently modify target cells with a gene of interest and then remain in that cell, without the ability to spread from cell to cell. This method makes available the desirable ability of lentiviruses to infect and alter cells while separating it from replication. It also demonstrates that producer cells can be transfected with a variety of different plasmids, and RNAs are incorporated into infectious viral particles based on the presence of the packaging signal [5]. Already one can see how this sort of technology would be very applicable to gene therapy. Creation of replication-defective vectors in order to carry a gene of interest and provision of requisite *trans*-acting factors is a mainstay of lentiviral and retroviral vector technology.

Contemporaneous with the above innovations, Page et al. constructed an HIV vector that similarly included a deletion in *env*, making it replication defective, but also introduced several other important innovations. First, by replacing the region of deleted envelope with the drug resistance gene *hypoxanthine-guanine phosphoribosyl-transferase* (*gpt*), this vector allowed the first quantitative measurements of titer (number of infectious units or IU per mL) [58]. This type of

measurement cannot be obtained by similar vectors encoding CAT. Co-transfection of cells with the *gpt*-containing vector and a gp160 expression cassette resulted in a cell-free virus titer of 825–3000IU/mL. Ultrastructural features of these replication-defective viral particles were comparable to those of wild-type HIV.

The other important innovation in vector design that was introduced by this group was the demonstration that defective HIV viral cores could be packaged not only by HIV's native gp160, but also by the heterologous envelope proteins of other viruses. Moloney murine leukemia virus amphotrophic envelope 4070A (A-MoMLV) was used for this purpose [58], and later human T-cell leukemia virus type I (HTLV-I) envelope [59]. This process, known as pseudotyping, had been pioneered previously (like many of the “innovations” in lentiviral vector technology) with oncoretroviral vectors, but was an important step in the evolution of lentiviral vectors since it extended their host cell range, broadening the potential applications in which they might be useful. As will be discussed shortly, continued experimentation in the arena of pseudotyping would eventually yield an enormous boon to the utility of these vectors.

9.2.3 MAKING LENTIVIRAL VECTORS SAFER AND MORE USEFUL

Although the constructs described above had features that distinguished them as vectors rather than viruses, they were still considered to be molecular tools for the study of HIV and other viruses and not for gene transfer. Others first suggested using lentiviral vectors for gene therapy when they constructed a Tat-inducible vector and argued that such a vector could be used to transduce HIV-infected cells, where a therapeutic gene would preferentially be expressed in the presence of Tat [60]. A vector encoding a Tat-inducible trans-dominant interfering mutant version of *env* selectively inhibited viral replication in cells that had been infected by HIV and produced Tat [61].

As with all vectors, the issue of safety is paramount. Safety concerns regarding the use of lentiviral vectors are largely engendered both by the fact that HIV is a well-known and potentially lethal human pathogen, and by the possibility of regenerating some form of replicating virus (by DNA or even RNA recombination events in the producer cell). The fear of unwittingly generating replication-competent lentivirus (RCL) has its roots in a well-known precedent wherein replication-competent retrovirus was generated in MLV vector production systems and was linked to the development of lymphoma in monkeys [62,63]. Additionally, most lentiviruses slowly but eventually destroy the immune system and are transmissible.

As the design of lentiviral vectors has progressed, steps have been sequentially taken to minimize the possibility of producing RCL. The first of these measures appeared early in the historical development of these vectors when a three-component vector system was created in 1991 (Figure 9.5). Investigators, who had recently identified the packaging signal Ψ near the 5' LTR of HIV [5], realized that any RNA sequence containing it could be efficiently packaged into an HIV core if

* See Section 9.4 for a better description of the process of transfection.

† There was a small deletion in the 3' end of the *env* gene that was found not to affect the kinetics of replication.

the necessary trans-acting HIV elements (e.g., Gag, Pol, Env) were present. Likewise, any RNA lacking Ψ would not be packaged. Thus, the transfer vector did not need to contain any coding sequences but instead simply the requisite cis-acting elements. A transfer vector that consisted of only the necessary cis-acting sequences flanking a neomycin phosphotransferase gene (an antibiotic selection marker) driven by an internal promoter was constructed [64]. All of the proteins required to package the transfer vector were provided in *trans* by co-transfection with either a full-length provirus with a small deletion in the Ψ (so it would not be packaged) or with both an HIV envelope expression construct and a separate provirus that had a deletion in Ψ and envelope. When all *trans*-acting functions were provided by two separate expression plasmids (i.e., utilizing the full three-component system), the generation of replication-competent viruses was reduced to an undetectable level. This work of course paralleled that of retroviral vectors in terms of splitting components to improve safety. Later vectors also went on to incorporate additional, improved safety features that will be discussed shortly.

With evidence that the risk of generating RCL could be minimized, the final significant obstacle to the realistic use of lentiviral vectors in gene therapy was the efficient production of vector particles at high-enough titers to be useful. A major breakthrough occurred in the mid-1990s when, extending the technique of pseudotyping and borrowing a trick from the retroviral vector field, Naldini et al. demonstrated that high-titer, pseudotyped HIV particles could be generated using vesicular stomatitis virus (VSV)-G (glycoprotein) as an envelope [65]. Using a vector system with extensive deletions of viral genes from the packaging vector and employing the heterologous VSV-G envelope, titers of 1×10^5 IU/mL (as measured using a LacZ transgene) after transient transfection of 293T cells were achieved (Figure 9.6). Because of increased particle stability conferred by VSV-G pseudotyping, vector supernatants resulting from such transfections could be concentrated up to 1000-fold by ultracentrifugation without significant loss of IU, resulting in titers in the range of 1×10^8 IU/mL. Additional refinements and improvements led to titers of 10^9 IU/mL, which is quite useful for a number of *in vivo* applications [55,66]. Additionally, VSV-G is apparently “pan-tropic,” and thus confers a very wide range of potential cellular target types when used as the pseudotyping glycoprotein.

The discovery of high-titer VSV-G pseudotyping was enough to abolish the final obstacle to realistic consideration of the use of lentiviral vectors for gene therapy purposes. However, in the same landmark study, Naldini et al. also provided a remarkable incentive to do so when they demonstrated that HIV-based vectors (like the intact virus) could efficiently and persistently transduce rat neurons, human macrophages, and other nondividing cells. This cemented the importance of lentiviral vectors as a potential tool with true clinical utility and created a large amount of excitement in the field since, as mentioned previously, oncoretroviral vectors were the predominant tool being used for long-term gene transfer at the time but they lacked the ability to transduce nondividing cells. The adaptation of VSV-G pseudotyping to safer, multicomponent

HIV-based vectors and proof of their ability to transduce nondividing cells could be considered the start of the development of modern lentiviral vectors [67]. Thus, systems such as the one used by Naldini et al. are often referred to as first-generation lentiviral vectors.

9.3 DESIGNS AND PROPERTIES OF MODERN LENTIVIRAL VECTORS

9.3.1 FOUR GENERATIONS OF MODERN LENTIVIRAL VECTORS

The steps taken by Naldini et al. in 1996 ushered in an era of intense interest in the use of lentiviral vectors for gene therapy which drew many new researchers to the field. Many of those seeking to improve and expand upon the exciting new results began by using the vector system that was successfully employed by Naldini et al. This system, pictured in Figure 9.6, employed three separate plasmids for production to minimize the generation of RCL: (1) a transfer vector containing the transgene of interest along with the minimum viral cis-acting sequences necessary for packaging, reverse transcription, and integration, (2) a packaging vector encoding all necessary trans-acting genes minus envelope but also with its 5' and 3' LTRs replaced by an heterologous CMV promoter and an SV40 poly(A) site, respectively, and (3) an envelope construct expressing typically VSV-G (or amphotropic MLV envelope). As mentioned previously, the impressive success of this system in achieving high titer and transducing nondividing cells led to its widespread adoption and hence it became known as a first-generation lentiviral vector. However, even in a multicomponent system such as the first-generation vector, it is theoretically possible to generate RCL by homologous recombination of the viral sequences that are shared by the packaging construct, the transfer vector, and possibly by endogenous retroviral or other DNA sequences within the producer cell. Therefore, as research in the field continued, so did efforts to reduce sequence homology between components of the vector system by identifying the minimal *cis* and *trans*-acting sequences required for effective vector production.

The ideas behind this process are simple: (1) remove as many viral genes as possible and (2) minimize sequence overlap or identity between transfer and packaging vector. In practice, however, changes along these lines proceeded via a series of discrete modifications, with the advent of each giving rise to another distinct “generation” of vector. It is useful to trace the history of these developments since each one represents another important aspect of modern vector design (Figure 9.7).

First-generation vectors contained a number of undesirable sequence homologies (see Figure 9.7) that are seemingly unavoidable at first glance, since they contain genes essential for proper packaging of the transfer vector. Therefore, if the goal is to reduce sequence homology, a logical place to begin is by deleting those genes which are not known to be essential for packaging. This is in fact what took place in the creation of the second-generation HIV-based vectors when the remaining

viral accessory genes (*nef*, *vif*, *vpr*, and *vpu*) were deleted from the packaging construct and the resulting vector was still capable of transducing noncycling cells and sustaining transgene expression just as effectively as first-generation vectors [68,69]. By removing many of the genes thought necessary for HIV pathogenesis but not essential for HIV to function as a vector, the generation of RCL became less probable, and any RCL generated would be unlikely to be pathogenic [70].

Second-generation vectors lacking any HIV accessory genes made the recombinant generation of a pathogenic RCL very unlikely. However, since even the smallest safety risk might preclude the clinical use of such vectors, third-generation lentiviral vectors focused on improvements that would further increase their theoretical biosafety. Namely, they attempted to decrease any remaining sequence homology and cripple any potential RCL even further by reducing the reliance on HIV regulatory genes (*tat* and *rev*) in the vector system. As described earlier, Tat serves an indispensable role in the transcription of genes from viral LTRs. Thus, in order to achieve independence from Tat, all constructs within the vector system would have to rely on promoters other than HIV LTRs. The packaging and pseudotyping constructs had been using heterologous (usually CMV) promoters since the first generation of vectors, so it was only the transfer vector whose promoter required modification. Since some parts of the HIV LTRs are needed for reverse transcription and integration of the vector, the entire LTR could not be replaced by a heterologous promoter. Instead, a portion of it, the 5' "U3" sequence, was selectively replaced by a portion of the LTR from an avian retrovirus, resulting in a chimeric promoter that allowed Tat-independent transcription in producer cell lines [71].

rev has proven to be more difficult to eliminate than *tat*, since, as discussed in Section 9.1.1, it is needed for the nuclear export of unspliced RNAs, such as those of the packaging construct and transfer vector. In addition, it is well known that HIV coding sequences contain *cis*-repressive elements, also called inhibitory sequences (INS), that produce instability in transcripts and cause mRNAs to be targeted for destruction in the absence of Rev. For both of these reasons, the *rev* gene was still included in third-generation vector systems, but was moved to its own separate plasmid. Doing so would theoretically decrease the chances of RCL generation and thus improve the margin of safety. Separation of viral sequences usually means that a greater number of discrete recombination events need to take place in order to reconstruct an RCL, and of course the statistical probability of this happening decreases markedly as the number of events increases. So, because expression of viral genes of the packaging construct require Rev, relegating Rev to a separate plasmid makes the generation of RCL dependent upon one more recombination event than would have been necessary in second-generation vectors, thus decreasing its likelihood even further.

By the third generation of lentiviral vectors in 1998, the contribution of HIV to the vector had been reduced to a fraction of *cis*-acting sequences and to only three genes, *gag*, *pol*, and *rev*, in the separate packaging constructs, compared with

the nine genes necessary for the *in vivo* replication and pathogenesis of wild-type HIV [71]. Because of their excellent transduction efficiency and very good theoretical biosafety profile, derivatives of these vectors are still what is predominantly in use today. Nonetheless, efforts have continued at optimizing the vector genome, leading to a more loosely defined "fourth generation" of lentivectors that share several features aimed at the further reduction of sequence homology and a decreased reliance on viral genes. The primary trend shared among this latest showing of vector designs is expression independent of Rev. One method of achieving this has been to replace the RRE with heterologous viral sequences known to enhance the export and stability of unspliced RNAs by interacting with cellular factors [72]. The Mason-Pfizer monkey virus constitutive transport element (CTE) is the classical representative of this group but more recently, functional analogs of it such as the posttranscriptional control element (PCE) of the spleen necrosis virus and even the human nuclear protein Sam68 have been suggested as alternatives [73–77]. Although the inclusion of such *cis*-acting sequences has been shown to provide some success in replacing the functions of Rev, all such mechanisms share the same set of problems: All show a decrease in titer compared with systems that use Rev/RRE, and all have an arguably decreased theoretical biosafety profile compared with third-generation vectors because of the elimination of dependency on a separate Rev plasmid for expression of viral genes in the packaging construct. Finally, such systems do nothing to address the sequence homology remaining between Ψ in the transfer vector (which necessarily includes several hundred base pairs of *gag* for proper encapsidation—see Figure 9.7) and *gag* in the packaging vector.

In order to address these problems, another, very different, approach termed "codon optimization" was introduced in 2000. Codon optimization consists of introducing a mutation in the wobble codon position into the majority of codons in the *gag-pol* packaging construct, preserving the primary amino acid sequence but effectively eliminating any areas of homology with naturally occurring HIV-1 *gag-pol* sequences [78]. This heavily modified sequence eliminated the problem of DNA homology between portions of *gag* in the packaging construct and transfer vector.* It also had the added benefit of inactivating the INS within *gag-pol*, which made expression of the packaging construct completely independent of Rev. Kotsopoulou et al. were also able to show that deletion of several hundred nucleotides of the remaining *gag* sequence surrounding Ψ in the transfer vector removed enough INS to allow efficient export independent of the RRE while keeping enough of Ψ intact to allow efficient packaging. The end result was a true fourth-generation vector genome that eliminated all significant remaining areas of sequence homology and whose titers were only fivefold lower than third-generation systems based upon wild-type HIV sequence that utilizes Rev and the RRE. Most investigators, especially those that are

* The transfer vector retained w.t. *gag* coding sequence.

laboratory-based, are sufficiently comfortable with the safety and efficacy of third-generation vectors and thus do not use those of the fourth generation.

9.3.2 OPTIMIZATION OF THE TRANSFER VECTOR

Until the introduction of third-generation lentiviral vectors, most improvements in vector systems had focused on the packaging construct. From about 1998 onwards, optimization of the transfer vector itself also became an important priority beginning, as usual, with a focus on biosafety issues.

Unlike packaging constructs, alterations of the transfer vector always concern *cis*-acting elements, since the no *trans*-acting genes are present. Initial attempts to improve the safety of transfer vectors were carried out by deleting unnecessary viral sequences or replacing them with exogenous *cis*-acting genetic elements [72]. First-generation transfer vectors were already rather minimal, consisting of only the viral LTRs, tRNA primer binding site, packaging signal (including several hundred base pair of *gag*), donor and acceptor splice sites, polypurine tracts, and RRE (part of the *env* ORF). Attempts have been made since then to define exactly the extent to which each of these sequences is necessary. One of the best examples of this is the packaging signal, whose exact boundaries are important because they unavoidably overlap with the *gag* ORF (providing an unfortunate sequence homology with the packaging vector) [6]. When possible, remaining viral sequences were attenuated, a measure that is exemplified by the frameshifting of residual *gag* sequence in the first-generation transfer vectors used by Naldini et al. [79]. Elimination of viral sequences from the transgene served the important purpose of reducing sequence homology, but also created space that could be filled with larger transgene “payloads.” In a minimal transfer vector, the packaging capacity of lentiviral vectors is generally considered to be 5–8 kb; however, unlike AAV or adenovirus where the limit is strict, the packaging efficiency is inversely proportional to the insert size [80].

Drawing from the long experience of the retroviral vector field, it was obvious to those pondering the safety features of lentiviral transfer vectors that even after minimizing viral *cis* sequences, those viral sequences that did remain would have some sort of biological activity after integration into target cells and could still be conceivably mobilized, especially by a virus that provided the requisite *trans*-acting sequences. The most ideal situation would of course be to selectively introduce the gene of interest into a target cell (along with an active promoter to ensure that it is transcribed) without any other sequences. The prospect of how to do this posed yet another engineering question whose answer would have a significant impact on vector design. Luckily, vectors created in response to this problem had already existed for many years in the closely related retroviral vector field [81,82]: The so-called self-inactivating vectors (SIN) cleverly take advantage of the viral replicative cycle (Figure 9.8). The U3 region is known to contain the TATA box, transcription factor binding sites, and other sequences important for the promotion of transcription. This is why the U3 region of the 5' LTR was replaced by

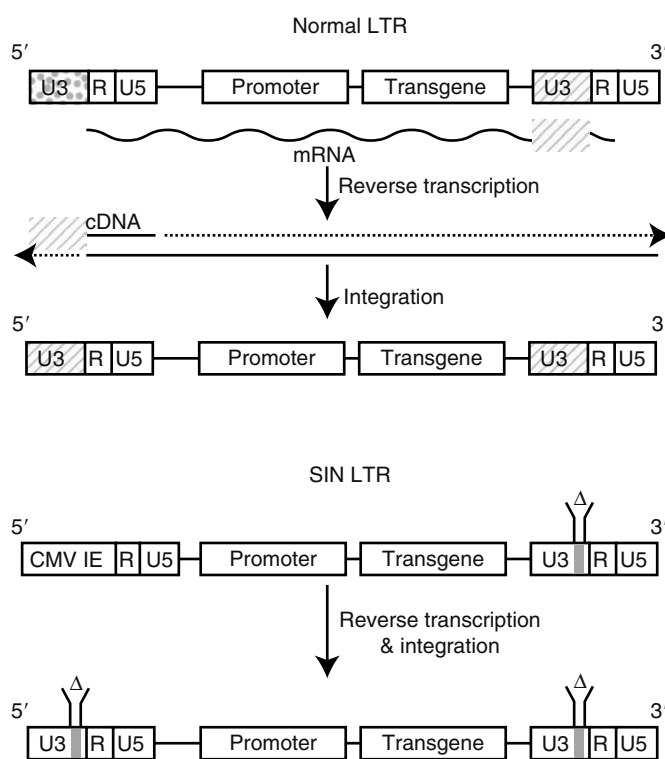

FIGURE 9.8 Safety modifications of the transfer vector. Because the 5' U3 region acts as a promoter, it is not part of the mRNA transcript. Therefore, during normal reverse transcription a 5' U3 must be regenerated from the 3' U3. Thus, both U3 regions of the integrated vector will reflect the 3' U3 of the original transfer vector. A SIN vector is created by introducing a deletion in the promoter/enhancer region of U3 (Δ) which is duplicated during reverse transcription to the 5' LTR, thereby inactivating it.

heterologous promoters beginning with third-generation vectors, as discussed above. SIN vectors are created by deleting the 3' U3 region of the viral LTR (except for a small region termed ATT needed for integration [83]). During the normal process of reverse transcription, this deletion is duplicated and transferred to the 5' LTR so that upon integration of the viral cDNA, both LTRs are inactivated. This also means that the integrated form of the transfer vector lacks the heterologous promoter that is found in the 5' LTR of its plasmid and RNA precursors.

In the retroviral vector field, SIN vectors had been plagued by poor titers compared to conventional vectors. When adopted by the lentiviral vector field in 1998 [71,84–86], SIN vectors seemed to be of equivalent if not greater utility compared to conventional vectors. One of the initial constructs had no significant decrease in titer and was able to transduce more cell types in greater numbers than a comparable non-SIN vector when injected into the subretinal space of rats [85]. This observation has led to the recognition that in addition to providing increased biosafety, SIN vectors have the added benefit of reducing promoter interference by inactivating the LTR. Less promoter interference meant that transgene expression could be driven more efficiently by the heterologous

promoter included in the transfer vector, thus reducing the variability of expression between tissues caused by the activity of the LTR in some cell types but not others.

The adaptation and successful use of basic SIN constructs have been by far the most important improvement to the biosafety of transfer vectors. However, some of their putative ability to improve biosafety has recently come under question. Whereas it was once thought that these vectors are virtually impossible to mobilize once introduced into a target cell, even if the target is infected with wild-typed, replication-competent HIV [87], more recent work suggests that full-length transcripts competent for encapsidation, transduction, and integration are made at low levels even from an SIN LTR [88]. This may be due to the presence of transcription factor binding sites within the 5' untranslated "leader" region between the LTR and the truncated *gag* ORF of the transfer vector. Additionally, although it was initially thought that the risk of triggering cellular oncogenes by the enhancer activity of the LTR is diminished in SIN vectors [85], more recent studies have found that by interfering with normal polyA signals, SIN LTRs allow considerably greater 3' transcriptional read-through than wild-type LTRs. In fact, the level of read-through is similar to that of MLV-based vectors [89,90]. Whether that would promote expression of oncogenes found near the vector integration site is not known.

Of course, there are likely to be solutions for all of these problems. It has already been shown that the inclusion of a heterologous poly(A) signal in the 3' U5 region of SIN LTRs can terminate transcription efficiently and prevent 3' read-through [86,89] and that selective mutation of certain sites in

the 5' leader region significantly reduces the production of full-length transcripts from the SIN LTR [88]. Further modifications of the transfer vector, particularly to reduce the likelihood of vector mobilization, are also foreseeable. For example, it has been shown that MLV has a propensity to delete large direct sequence repeats during the process of reverse transcription, and that if a transfer vector is constructed with direct repeats flanking its packaging signal, the packaging signal is efficiently deleted following transduction. This property has been exploited in MLV to create the so-called Ψ^- vectors wherein nearly 90% of proviruses show a deleted packaging signal and mobilization of the vector in the presence of a helper virus is subsequently reduced 28,000-fold [91]. It has also been shown that the frequency of direct repeat deletions in HIV is very similar to that of MLV [92], so it seems likely that such strategies will eventually be employed in the creation of even safer lentiviral transfer vectors. In the meantime, however, the theoretical biosafety of this platform has progressed to such an apparently high degree that newer developments in the evolution of transfer vectors have focused less on safety concerns and more on improving performance, flexibility, and vector capabilities.

As with biosafety modifications, optimizations of the performance and capabilities of transfer vectors have proceeded through the modification of *cis*-acting sequences (Figure 9.9). Generally, *cis*-acting sequences have been added to the transfer vector in response to challenges posed by specific gene therapy-related issues. A good early example of one of these problems is the difficulty that was experienced in achieving high levels of transgene expression even from tissues that had

Modifications to improve transduction

Modifications to increase expression

Modifications to prevent silencing

A transfer vector can use all of the above synergistically

FIGURE 9.9 Modifications that enhance transfer vector performance. cPPT, central polypurine tract; WPRE, woodchuck hepatitis virus posttranscriptional regulatory element; LCR, locus-control region; "insulator," an example would be the HS4 core from the β -globin LCR.

been successfully transduced. Since it was well known that many steps, both transcriptional and posttranscriptional, are involved in the regulation of gene expression, investigators reasoned that the simplest point at which to intercede may therefore be at the posttranscriptional step. This line of reasoning led to the introduction and subsequent widespread inclusion into vector design of the woodchuck hepatitis virus posttranscriptional regulatory element (WPRE), a *cis*-acting RNA element shown to increase the level of transgene expression by two- to fivefold over non-WPRE-containing vectors [93]. It has been postulated to accomplish this by several mechanisms including mRNA stabilization, an interaction with the nuclear export machinery, and enhanced efficiency of transcriptional termination or polyA [94]. In the past several years, concerns about possible tumorigenic effects of this hepadnavirus-derived element [95] have led to the development of an optimized version with truncated viral ORFs and deleted promoter regions [94]. Moreover, experimentation with *cis*-acting elements such as the spleen necrosis virus PCE, cytomegalovirus immediate-early enhancer (CMV IE), murine stem cell leukemia virus LTR, and others continues to yield novel combinations that, when incorporated into the transfer vector, produce even greater yields of transgene expression [77,96].

In the field of retroviral vectors, it is well-known that even achieving efficient transduction and high levels of transgene expression are not always enough—often transgenes are eventually subject to the phenomenon of transcriptional silencing. This problem also exists in the lentiviral field, although to a lesser degree because, perhaps, of a lower CpG dinucleotide content in the HIV genome [97]. The widespread use of SIN vectors has largely abrogated the issue of silencing by deleting those elements within the LTR thought to be involved in mediating these effects. Nonetheless, when silencing remains a particular problem it can often be modulated by the addition of certain positive regulatory elements to the transfer vector [72]. Among these are the so-called DNase hypersensitive regions which act in *cis* to prevent nucleosome formation around themselves. Thus, inclusion of such a region in the transfer vector can cause chromatin surrounding the transgene to be more “open” and accessible to transcription factors, and less prone to histone-dependent silencing. The classic example of this is incorporation of portions of the β -globin locus control region (LCR) to prevent silencing of the β -globin transgene gene in cells of the hematopoietic lineage [98]. Conceptually similar to but mechanistically different from the LCR are “chromatin insulators,” which protect gene expression from neighboring enhancers or silencers [99]. The best characterized of these is the HS4 core from the β -globin LCR, which has been shown to facilitate persistent transgene expression in human hematopoietic cells [100]. S/MARs (scaffold/MA attachment regions) are DNA sequences that mediate attachment of chromatin loops to proteinacious MA or scaffold proteins of the nuclear envelope. It is thought that by doing so, they may make nearby chromatin more accessible and therefore act as insulator elements if present in the vicinity of transgenes. Adding S/MARs to lentivectors has so

far resulted in increased liver and hepatocyte transduction efficiency [101,102] and an increase in the duration time of transgene expression in human HSCs [100].

Other approaches to improving the effectiveness of transfer vectors, instead of attempting to improve transgene expression, focus on the earlier step of transduction. After it was realized that a DNA flap structure formed during reverse transcription was important for nuclear translocation [49], some investigators reasoned that this could be a rate-limiting step in lentiviral transduction. They therefore attempted to rescue the efficiency of this process by the inclusion of a *cis*-acting element, termed the central polypurine tract (cPPT). The cPPT is a portion of the HIV-1 *pol* ORF that coordinates in *cis* a central strand displacement event that occurs during reverse transcription and results in a 99-nucleotide plus-strand overlap known as the central DNA flap (for a detailed review of this process, see [103]). This central, three-strand flap mediates a late step involved in the nuclear import of HIV's genome (although it is not essential). During the early development of HIV-based vectors, this homologous sequence was not included in the transfer vector because its importance was not appreciated. Recent reports, however, have found that if incorporated in any of a variety of positions in the transfer vector [104], it can confer markedly improved transduction efficiency in certain cell types, notably HSCs [105–107]. Both the WPRE and cPPT have been shown to be quite potent in enhancing titer or transduction efficiency in some situations, but are ineffective in others [45,55,108]. Regardless, the combination of these two elements is often present in modern transfer vectors (especially since their inclusion is not detrimental) and, when used in conjunction with a third- or fourth-generation packaging construct, has been referred to as an “advanced generation” vector [109].

9.3.2.1 Multicistronic Expression

The features discussed above and others have created such a multiplicity of design options that engineering a lentiviral transfer vector with efficient transduction and transgene expression is now quite common and feasible in most situations. Thus, attention has been turned towards other practical aspects of transfer vector design, including the ability to express more than one transgene. Vectors designed for this purpose are deemed “multicistronic,” and such designs have improved the flexibility and capabilities of the vectors considerably. For instance, a bicistronic vector may be used to selectively enrich for a population of transduced cells *in vitro* by encoding both a transgene of interest and a selectable resistance marker, such as *hygro*. When a population of cells is then exposed to hygromycin, only transduced cells actively producing the transgene will survive, allowing them to be studied in isolation. The most common method of achieving this type of bicistronic expression is by inserting an internal ribosome entry site (IRES) between transgenes. Transcription of both genes will be initiated by the heterologous promoter included in the expression cassette. At the stage of protein synthesis, however, the 5' mRNA cap will drive translation of the upstream transgene, while translation of the downstream

ORF will begin after ribosome entry at the IRES. More than two transgenes may be expressed by using multiple, distinct IRESs [110]. In a striking example of this principle, three distinct catecholaminergic enzymes from one expression cassette were encoded on a single vector to successfully intervene in a rat model of Parkinson's disease [111].

Designs utilizing an IRES between transgenes are by far the most commonly used for multicistronic expression. However, it is an unfortunate truth that transgenes downstream from the IRES may suffer from decreased expression relative to upstream transgenes [112]. In response to this, a recent approach to multicistronic expression vectors has been engineered that involves the use of a synthetic, bidirectional promoter situated between two transgenes in opposite orientations to drive the transcription of both. In this design, an efficient promoter such as that of the phosphoglycerate kinase gene (PGK) initially recruits RNAP to the transcription site, and then flanking minimal core promoters, such as minCMV, direct RNAP either upstream or downstream to achieve expression of both genes [113,114] (Figure 9.10).

Following nature's cues, splice sites have also been used to express more than one transgene. In one construct two transgenes are separated by the RRE; the upstream transgene is expressed in unspliced mRNAs and the downstream transgene is expressed when mRNAs are spliced. Variable deletions of the RRE can alter the balance between expression of the two genes by fostering either more (longer RRE) or less (shorter RRE) nuclear export of unspliced mRNA [115].

Finally, "pseudo-multicistronic" expression can be realized by expressing a hybrid fusion protein to carry out more than one function [116–118]. Many of these multi-transgene

expression constructs have also been employed in retroviral vector design.

9.3.3 SPECIALIZED ASPECTS OF VECTOR DESIGN

9.3.3.1 Pseudotyping

As previously discussed, a major step towards clinical use of lentiviral vectors came when they were first pseudotyped with VSV-G [41]. VSV-G imparted vector particles with increased stability (allowing concentration by centrifugation and some freeze-thawing), and a very wide target cell tropism (possibly pan-tropism). Because of these properties, VSV-G has been used in making the vast majority of vector particles to date. However, VSV-G is not the "perfect" pseudotype for every application. To begin with, the VSV-G protein is toxic to producer cells (by causing membrane fusion) and therefore sustained production of VSV-G-pseudotyped particles poses a challenge (discussed later). Moreover, the broad tropism of VSV-G, though valuable, can be an impediment to progress when targeted transduction of specific tissues is required.

In response to these obstacles, a number of other pseudotyping options have been explored, and HIV-based vectors have proven amenable to pseudotyping with a remarkably wide variety of heterologous viral glycoproteins and envelopes while still retaining their basic functionality. In general, new pseudotypes are created either to provide a specific tissue tropism or delivery method, look for a nontoxic alternative to VSV-G, provide higher titers, or simply explore what novel properties such pseudotypes might possess. Some of the more intriguing examples include Ebola-glycoprotein pseudotyped

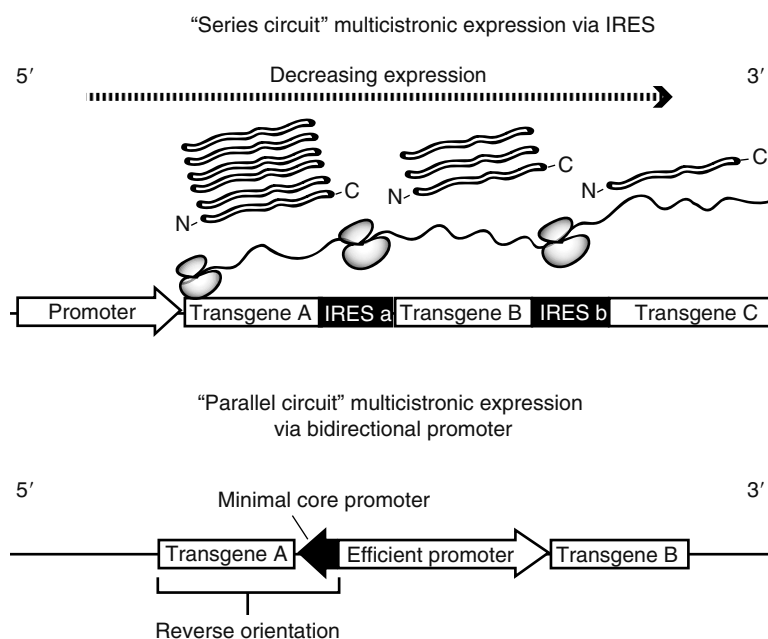

FIGURE 9.10 Methods for achieving multiple transgene expression from a single transfer vector. mRNA levels (and consequently amount of protein) of a transgene may decrease after each IRES. A bidirectional promoter may provide more equal levels of protein expression for two transgenes.

vectors for delivery to airway epithelium, and rabies glycoprotein-pseudotyped vectors for retrograde transport of the vector genome from the axons of neurons to the nucleus [119]. This latter example raises the possibility of introducing genes into the easily accessible muscle of a clinical subject and transducing the nuclei of neurons in the not-easily-accessible spinal cord, with prospects for treating motor neuron diseases [55,120].

Every glycoprotein confers a slightly different set of qualities or properties on the vector system and so each pseudotype may have its own potential niche, either in research or therapeutics. Table 9.1 below summarizes some of the glycoproteins that have been employed to date, along with their titers, tropisms, and potential uses.

9.3.3.2 Vector Targeting

There are a variety of circumstances in which it is easy to appreciate the value of a vector that is targeted to certain cell types. The most prominent of these is, of course, *in vivo* gene therapy, where a simplified, idealized scenario would involve a single, parenteral administration of a dose of therapeutic vector to permanently modify a disease state involving a specific tissue, organ, or structure. In such an ideal scenario, vector targeting would be necessary both to avoid depletion of limited numbers of viral particles and to specifically transduce certain cell types. But how to best accomplish this valuable goal?

One obvious approach to this problem is to directly inject the vector into the tissue of interest. This primitive strategy has been demonstrated to be effective in certain animal models, notably by stereotactic injection of vectors into the substantia nigra [111] and subretinal space [149] of rats, and may prove to be useful for certain localized *in vivo* gene therapy applications in man. However, true vector containment using this approach is uncertain and this tactic also falls short of the idealized scenario described above, wherein any condition ought to be treatable by a limited number of injections using a nonspecific site, such as an easily accessible vein. More elegant methods of vector targeting involve modification of the vector itself rather than modification of the delivery method, and are generally aimed at creating vectors that show gene expression limited to specific, selectable tissues under the conditions described above.

There are two general paradigms for achieving this type of vector targeting, and the first of these to be attempted is also the most intuitive: altering the surface of virion particles so that they specifically interact with certain cell types but not others. The goal of this type of modification is best exemplified by certain naturally occurring virus–host interactions, with HIV-1 itself being a prime example. The envelope glycoprotein of HIV-1, gp160, is known to initially and specifically interact with the cellular surface protein CD4, such that only cells bearing surface CD4 molecules (and co-receptor) can be infected by the virus. This type of specificity is exactly what is desired for gene therapy applications and so from very early on, vector makers have turned to the use of pseudotyping as a mechanism to confer particular tropisms on vector particles that would be suitable for *in vivo* targeting.

Pseudotyping confers tissue tropism via interactions between components of the chosen viral envelope and their counterpart elements on cell surfaces. The recognition of this feature in HIV-1, as mentioned above, prompted several studies to suggest the potential use of gp160 “pseudotyped” particles as CD4⁺ cell-targeted vectors for anti-HIV therapy [150,151]. Since lentiviral vectors have shown themselves to be permissive to pseudotyping with a wide range of viral glycoproteins, it was naturally hoped that different, heterologous pseudotypes would provide the same kind of specificity for other desirable tissues that gp160 was known to provide for CD4 positive cells. Unfortunately, the type of specificity seen with HIV gp160 seems generally to be the exception rather than the rule. Pseudotyping lentiviral vector particles with heterologous envelopes nearly always produces an altered range of particle tropism, with range being the operative word. It is true that some pseudotypes are vastly superior for transducing certain cell types: The Ebola Zaire (EboZ) glycoprotein has shown clear superiority to other glycoproteins in transducing apical airway epithelia, for instance [138]. However, it is almost always the case that those heterologous envelopes that afford high titers and stable vector particles (necessary features for therapeutic utility) do not confer any meaningful level of specific tissue tropism in the context of our idealized conditions. This holds true for EboZ, which has been shown to also transduce liver, heart, and muscle tissues [152]. The ultimate example is VSV-G, whose consistently high titer and particle stability have helped to make it the standard bearer against which most other pseudotypes are compared but whose extraordinarily wide tropism has made it very non-useful in targeted transductions *in vivo*.

For all of these reasons, straightforward heterologous pseudotyping has failed to provide a uniform targeting solution that would work within the context of our ideal scenario. This is not to say that pseudotyping as a targeting mechanism will not be useful in the future of gene therapy; however, it may be that the ideal use for many pseudotypes will be in conjunction with specialized delivery methods to a localized space where selection among only a few cell types is necessary. An example of this would be a localized injection into the subretinal space for the treatment of retinitis pigmentosa: If VSV-G is used as the pseudotype, both photoreceptors and cells of the retinal pigment epithelium (RPE) are transduced, whereas if Mokola virus glycoprotein is used, transduction is limited to the RPE [153]. Clearly, neither pseudotype would offer an effective targeting solution if administered via peripheral vein. However, if injected in the subretinal space where only two cell types are directly available, Mokola pseudotypes can be used to selectively treat retinitis pigmentosa due to defects in the RPE, whereas VSV-G might be better for retinitis pigmentosa due to defects in the photoreceptors themselves.

More recently, some investigators are continuing to work within the same paradigm, but have shifted their efforts away from simple pseudotyping and towards engineering viral envelope glycoproteins with modifications designed to enhance their targeting abilities. Initial efforts towards this

TABLE 9.1
Properties of Lentiviral Vectors Pseudotyped with Various Heterologous Viral Glycoproteins

Family	Genus	Species/Envelope	Vector	Comments/Titer (IU/mL)	References
<i>Rhabdoviridae</i>	Vesiculovirus	VSV-G	HIV-1	Very wide tropism. Particles durable against high-speed centrifugation. Causes syncytium/cytotoxicity to producer cells. Susceptible to complement-mediated degradation which can be minimized by PEGylation Titer: 10^5 – 10^7	[41,125–132]
			HIV-2		
			FIV		
			EIAV		
			SIV		
			BIV		
			JDV		
	Lyssavirus	Rabies	HIV-1	Rabies confers retrograde transport in neuronal axons	[122,123,133,134]
		Mokola	EIAV	Mokola selectively transduces RPE upon subretinal injection Titer: 2×10^6	
<i>Arenaviridae</i>	Arenavirus	Lymphocytic choriomeningitis virus (LCMV)	HIV-1 FIV SIV	Low toxicity, may be best for pancreatic islet cells	[134–136]
<i>Togaviridae</i>	Alphavirus	Ross River virus	HIV-1 FIV	Transduces hepatocytes upon systemic administration, transduces glia > neurons on administration to brain. Titers [after concentration]: 1.5×10^8 (FIV), 6×10^7 (HIV-1)	[137,138,139]
		Sindbis virus	HIV-1	pH-dependent endosomal entry. Useful for vector targeting	[140]
		Venezuelan equine encephalitis virus	HIV-1	Broad tropism, pH-dependent endosomal entry, immunity distinct from other alphaviruses Titer: 10^6	[141]
<i>Filoviridae</i>	Filovirus	Ebola Reston (EboR) EboZ Marburg	HIV-1 HIV-1 FIV	Efficiently transduces airway epithelium (EboZ > EboR)	[142,143]
<i>Retroviridae</i>	Betaretrovirus	Jaagsiekte sheep virus (JSRV)	FIV	May be more specific to type II cells than other airway epithelial cell types Titer: $>10^8$ (after concentration)	[144,145]
	Gammaretrovirus	Moloney murine leukemia virus 4070 envelope Feline endogenous retrovirus (RD114)	HIV-1 HIV-1 SIV SIV	Able to transduce most cells Titer: 1×10^5 More efficient and less toxic than VSV-G in cells of the hematopoietic system	[41,59,134,146] [134,147]
<i>Coronaviridae</i>	Coronavirus	SARS-CoV	HIV-1	Transduces airway epithelium	[148]
<i>Orthomyxoviridae</i>	Influenzavirus D	Influenza virus hemagglutinin	HIV-1	Transduces airway epithelium Titer: 10^6	[149]
<i>Baculoviridae</i>	Nucleopolyhedrovirus	Autographa californica multiple nucleopolyhedro virus (AcMNPV)–GP64	HIV-1 FIV	Poor transducer of hematopoietic cells. Efficiently transduces airway epithelium Titers 10^7 – 10^9 (FIV)	[149–151]
<i>Bunyaviridae</i>	Hantavirus	Hantavirus (HTNV)	HIV-1	Enhanced transduction of vascular cells	[152]

end involved the modification of glycoproteins to include a heterologous polypeptide or ligand, which could then bind to an appropriate target on cell surfaces, even if that cell did not express the original receptor for the particular glycoprotein used. One obvious possibility for targeting with this type of system is to alter a surface glycoprotein, for example that of amphotropic MLV, to include a single-chain antibody against a specified target such as a tumor cell antigen. All vector particles bearing the altered surface glycoprotein would then have a targeting specificity for tumor cells, because of the antibody now displayed on the virion surface.

This intuitive concept was initially tested on retroviral and lentiviral vectors using retroviral glycoproteins. However, efforts to this end met with little success in part because the fusogenic activity of retroviral envelope glycoproteins, which is crucial for cellular entry of the virion after it has bound its target, appears to be largely dependent upon intrinsic properties of the specific retroviral receptor, which is bypassed by using a heterologous peptide or ligand for targeting instead of the unmodified retroviral glycoprotein (for an in-depth review of these topics, see Ref. [154]). Thus, more recently attention has shifted away from using retroviral envelope glycoproteins and towards other heterologous glycoproteins that are known to initiate virion-cellular fusion through a mechanism independent of interaction with the virion receptor. The two best characterized such glycoproteins are the HA (hemagglutinin) glycoprotein of influenza virus and the E1/E2 glycoproteins of Sindbis virus (E2 is responsible for receptor binding and E1 mediates cell fusion). Both of these glycoproteins have a binding domain that binds to a non cell-type specific receptor, such as sialic acid, which is not involved in cell fusion. Instead, after binding to the cell surface the virion is taken up by the cell in an endocytic vesicle. Once activated by acidic pH inside the endosome, a second component of the viral glycoprotein, termed the *fusogen*, acts to mediate virion-vesicular fusion and entry of the viral contents into the cytoplasm [154].

This separation of the functions of binding and fusion (in contrast to retroviral glycoproteins where both cell binding and fusion depend upon specific interactions between the envelope glycoprotein and the cellular receptor) has recently

allowed the creation of a number of vector designs that have shown successful targeting *in vivo*. Examples of this include the use of Sindbis-pseudotyped lentiviral vectors whose E2 glycoproteins have been modified to encode single-chain monoclonal antibodies. When delivered via the tail vein of a mouse, the vectors have been shown to specifically target and transduce melanoma xenograft cells that display the antigen [155] or to cells expressing the chemokine receptor CCR5 [156]. At the time of this writing, the most recent group to take advantage of this sort of design has opted to include a monoclonal antibody (in this case, α CD20) in the producer cell transfection mix, not within the fusogenic glycoproteins themselves. This is possible since many cell surface proteins are incorporated into viral particles. By completely separating the binding and fusogenic proteins, the activity of the fusogen was not disturbed, resulting in a greater titer. Using lentiviral vectors based on this system and administered again through the mouse tail vein, Yang and coworkers were able to show specific transduction of xenografted human B cells bearing CD20 [136]. Systems based on such pH-dependent fusogenic pseudotypes combined with a heterologous targeting moiety seem to show great promise for *in vivo* gene transfer, with the only provision being that the targeted cellular receptor must be efficiently endocytosed after virion binding.

In addition to modifying the surface of virion particles, other important advances that have been made in vector targeting may be largely described under a second, distinct paradigm: These efforts are aimed not at controlling which cells are transduced by vector, but instead controlling which transduced cells express the vector's transgene (Figure 9.11).

The classic method for exerting this type of control has been to include tissue specific promoters and enhancers in the transfer vector to drive expression of the transgene. Thus, whereas a standard transfer vector might use the constitutively active CMV promoter to drive transgene expression, a vector optimized to target only liver cells would use a promoter such as the albumin gene promoter (ALB), which is normally only transcriptionally active in hepatocytes that produce albumin. Using this approach, many groups have shown tissue-specific expression even when many different

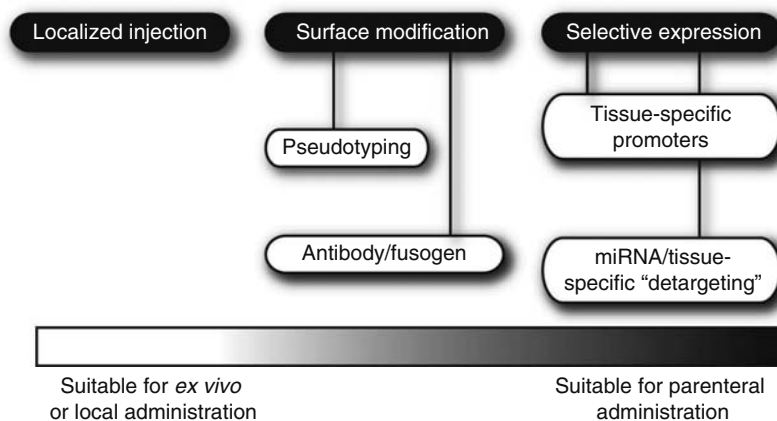

FIGURE 9.11 Vector targeting.

tissue types are known to have been transduced. In fact, the ALB promoter driving a GFP or human factor IX transgene was used to show that transgene expression was essentially limited to hepatocytes after systemic administration via mouse tail vein [157]. One obvious benefit of this type of targeting is high-level, tissue-specific expression of the transgene. However, another important benefit of limiting expression to the target tissue using tissue-specific promoters is that cells of the immune system, even if transduced, will not express the transgene. This is important because direct transgene expression within antigen presenting cells (such as dendritic cells or macrophages) may result in more efficient antigen processing and presentation to the immune system than selective expression in parenchymal cells [158,159]. The consequences of this type of efficient immune recognition of the transgene are often a swift immune response aimed at eliminating transgene expression, thus negating any potential therapeutic effect achieved by gene transfer in the first place. After systemic administration into the tail vein of immunocompetent mice of a vector with a liver-specific promoter, expression of Factor IX was limited to hepatocytes and continued for a prolonged period without a significant immune response. When the same experiment was performed using a vector with a CMV promoter, expression occurred in many tissue types including those of the immune system, and a transgene-specific immune response quickly reduced expression of the foreign antigen [160].

Unfortunately, even when tissue-specific promoters are used, neutralizing antibodies against the transgene and immune-mediated vector clearance may still be observed, albeit at a reduced incidence and extent [160,161]. To further counteract this detrimental immune response, Brown and colleagues have capitalized on the recent proliferation of research in the area of miRNAs to create a completely novel lentiviral vector system capable of further downregulating the immune response by specifically “de-targeting” cells of hematopoietic lineage for transgene expression [161]. The mechanism is based on the recognition that miRNAs of the family miR-142 are expressed only in hematopoietic lineages [162] and exploits this fact by incorporating four tandem copies of short (23 bp) sequences (termed miR-T) complementary to members of the miR-142 family into the 3' UTR of the GFP transgene. Thus, whenever a mRNA transcript of the transgene is made in a hematopoietic cell, miR-142 miRNAs (which are constitutively present in these cells) will bind to the tandem complementary miR-T sequences in the nascent transcript, forming a short segment of double-stranded RNA, which then reduces translation of the mRNA in those cells. In nonhematopoietic cells, by contrast, miR-142 miRNAs are not expressed so that binding to the miR-T sequences never occurs, double-stranded RNA is not formed and transcripts are translated at normal levels. miRNA-mediated restriction of transgene expression in this manner is very robust, vastly reducing transgene expression compared to controls even when greater than 100 copies of the vector genome were present within a target cell. Following intravenous

administration of the vector, many different organs and cell types were transduced but it was always the case that within these organs, no immune cells or other cells of hematopoietic lineage expressed the transgene. This hematopoietic de-targeting prevented immune-mediated vector clearance better than tissue-specific promoters, resulting in more stable, long-term gene expression [161].

Clearly, this new approach offers a powerful mechanism to regulate a transgene and it is not difficult to envision vector systems that utilize both miRNA-mediated immune cell de-targeting along with tissue-specific promoter-based targeting to maximize transgene expression in the tissue of interest and minimize it in immune cells. Indeed, it is conceivable that future vector systems will utilize these elements along with features of the previously discussed envelope modification targeting paradigm to produce vectors that restrict transgene distribution both by selective transduction and selective expression.

9.3.3.3 Regulatable Vectors

Vector targeting systems as described above provide a means of control over which cells express a transgene. However, it is obvious that a prerequisite for almost any case of intervention into the genetic homeostasis of a human being will be control over not only where a transgene is expressed, but also if, when, and to what degree it is expressed [163]. This need to create gene therapy vectors whose products behave more like traditional pharmaceuticals has not gone unnoticed by investigators in the lentiviral vector field, and to date several systems, deemed regulatable or inducible vectors, have been designed and tested that allow conditional expression of a transgene (Figure 9.12).

Although HIV-1 is known to form pools of latently infected cells *in vivo*, it nonetheless is lacking any easily manipulable or well-understood intrinsic mechanism for regulating its gene expression. Therefore, most regulatory systems employed to date in lentiviral vector design have their origins in other organisms, and have been refined through experimentation down to a series of cis-acting DNA elements which have been adapted to function in eukaryotic cells and can be easily transplanted by cloning into any vector. The prototypical example of these regulatory systems is derived from the tetracycline-resistance operon of *Escherichia coli*, in which gene transcription is negatively regulated by the tetracycline repressor (*tetR*) protein. In the presence of tetracycline, *tetR* does not bind to its operators located within the promoter

FIGURE 9.12 Regulatable vectors.

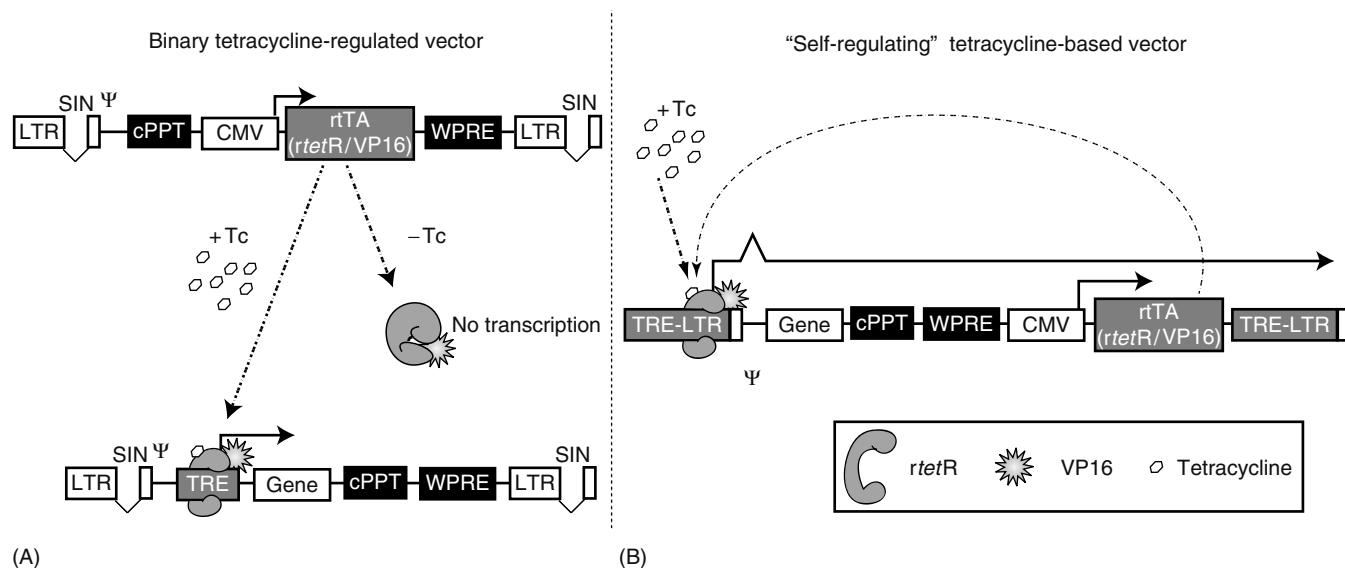

FIGURE 9.13 Binary versus self-regulating vectors using tetracycline-mediated transactivation. Shown is the “tet on” system, but the “tet off” system would look similar. rTA, reverse tetracycline-controlled transactivator of transcription; *rtetR*, reverse tetracycline repressor; VP16, transcription activation domain from HSV; TRE, tetracycline-responsive element (a series of repeated tetracycline operator [*tetO*] sequences). Part A shows a binary system that requires two transfer vectors; B shows a self-regulating, single transfer vector.

region of the operon and thus allows transcription [164]. This operon was first modified to control gene activity in eukaryotic systems by engineering the “Tet-off” system by fusing *tetR* to the herpes simplex virus (HSV)-VP16 transcription activation domain to create tTA, a tetracycline-controlled transactivator that strongly promotes transcription at modified tetracycline operator (*tetO*) sequences in the absence of tetracycline (Tc) [164]. These *tetO* sequences could be placed upstream of genes of interest, acting as a promoter for their transcription in the presence of tTA. The same group later created a “Tet-on” version of the system by mutagenizing *tetR* to make it dependent upon Tc for DNA binding (a reversal of its wild-type binding properties), and then fusing this mutant protein to VP16 once again to generate a reverse Tc-controlled transactivator, dubbed “rtTA” [165] (see Figure 9.13 for a schematic representation of this mechanism).

Tetracycline-regulatable promoters rapidly became a well-characterized and widespread tool in molecular biology and, following its successful use in adenoviral and AAV vectors, were incorporated into the lentiviral vector platform by several groups in 2000 [166,167]. By using a single vector that encoded tTA and a tet-responsive element (TRE)* just upstream of the GFP transgene, Kafri et al. were able to show a more than 500-fold increase in transgene expression upon Tc withdrawal *in vitro* and a similarly dramatic difference in rat brains *in vivo*. Importantly, the vectors were produced at titers equivalent to conventional vectors ($>10^9$ IU/mL after concentration) [166].

The vector introduced by Kafri et al. was the entry point of small-molecule regulation into the lentiviral vector field and, although it was sound as a proof-of-concept, nonetheless

contained undesirable limitations. Notably, although Tc withdrawal increased transgene expression >500 -fold, background expression of transgene was observed even in the presence of Tc. This was thought to be due to the activity of enhancer elements in the U3 region of the HIV LTR. Other investigators have employed a variety of strategies to reduce this activity, including replacing U3 with an alternative promoter [168], inserting an insulator element [169], or using SIN vectors [170], all with some success. Unwanted interactions between the Tc-responsive fusion protein and Tc-responsive promoter element were also found to play a role in driving background transgene expression. These concerns have been largely addressed by the engineering of alternative, synthetic versions of both tTA and rtTA that display improved *in vivo* stability, greater Tc sensitivity, and practically nonexistent background expression of transgene [171]. Concurrently, “second generation” synthetic TREs have been engineered to have optimal promoter activity and better fidelity with tetracycline-responsive fusion proteins. When tested in the setting of a lentiviral vector, these optimized chimeric transactivators and TREs have been shown to provide lower background expression while maintaining reasonable levels of induction [169].

With the inclusion of all of the above refinements, the most modern tetracycline-regulatable vectors based on a Tc-responsive fusion protein can achieve inducible transgene expression repeatedly and reproducibly, with low background, over a range spanning 2 orders of magnitude. Binary vector systems, in which one transfer vector encodes a version of tTA or rtTA and the other encodes a TRE and transgene, appear to achieve the tightest control, lowest background, and greatest inducible range. However, for gene therapy purposes, it is thought that a single vector approach would be advantageous,

* Seven copies of the Tet operon binding site flanked downstream by a minimal CMV promoter.

since proper regulation in the two vector system mandates that every target cell be transduced by at least one copy of each vector. Transfer vectors that incorporate both the transgene and all of the elements needed for Tc regulation (e.g., the TRE and a chimeric transactivator) have been called “self-regulating” and, while they are more convenient therapeutically, generally suffer from internal promoter interference and have a lower maximum level of transgene induction (Figure 9.13). Further challenges thus lie ahead in the design of a self-regulating vector that has both undetectable background and acceptable induction levels, although recent work has shown that optimal arrangement of the internal elements of a self-regulating transfer vector can achieve expression levels equivalent to those of a traditional CMV-driven noninducible vector [168].

The use of tTA or rtTA along with a TRE is the prototypical and most common method of exercising Tc regulation over vector transgene expression. However, it is not the only scheme for doing so. Effective regulation in a lentiviral vector has been achieved using tetR (not fused to a transactivator) and tetracycline operator sites placed between the TATA box and the transcription start site of the hCMV major immediate-early promoter [172]. This construct more closely resembles the structure of the original prokaryotic *tet* operon in that transcription is blocked by bound tetR until Tc is added, whereupon the promoter becomes open to the activity of the cell’s normal transcriptional machinery.

More recently, Szulc et al. have described a novel twist on the idea of a Tc-regulated fusion protein for transcriptional control of the transfer vector [173]. Instead of using a protein that transactivates transcription from the TRE (a frequent source of “leaky” background expression), a fusion protein was constructed that consisted of the tetracycline repressor (tetR) and KRAB, a protein domain known to mediate epigenetic silencing and heterochromatin formation. The resultant protein, dubbed tTRKRAB, epigenetically silences 2–3 kb of surrounding sequence when recruited to a tetracycline operator site, thus drastically reducing the possibility of transcription in the off state. Importantly, transgene expression was under tight control in multiple target tissues *in vitro* and *in vivo* (in rat brain), even after several on/off cycles. This system was also shown to accommodate both RNA polymerase (Pol) II promoter-driven transgenes and Pol III-controlled sequences encoding small inhibitory hairpin RNAs (shRNAs). Using such a vector, the expression of an endogenous gene was reduced using an appropriate shRNA, while simultaneously producing a transgene in transduced cells—a scenario with important implications in gene therapy, where it may be necessary to knockdown a mutant endogenous gene product while replacing it with a functional wild-type version.

To date, the majority of regulatable lentiviral vectors have used elements of the *E. coli tet* resistance operon and are structured to respond to the administration of tetracycline or one of its derivatives (commonly doxycycline). Tetracycline-based regulation has probably become predominant because of its extensive characterization and track record of successful use, acceptable range of inducible expression, the relatively

small sequence size of its regulatory elements, and the availability, safety, and favorable tissue penetration properties of the tetracycline class of drugs. It is not, however, the only inducible system that has been applied to gene regulation in lentiviral vectors. Others include regulatory systems responsive to the *Drosophila* hormone ecdysone [174], the human hormone progesterone (or its analog mifepristone) [175], and gaseous acetaldehyde [176]. An elegantly designed regulatable vector based on Cre–LoxP recombination has also been demonstrated to be effective [177], but lacks the reversibility of other systems. Each of these alternatives have proven their feasibility, but some are hindered by certain unalterable aspects of their nature. For instance, the genes required for a single self-regulating vector that responds to ecdysone are large enough (around 9 kb simply to express GFP) to raise concern over the packaging efficiency of the vector [174]. Equally, Cre–LoxP-based inducible vectors, while very effective, are not reversible and require a second transduction step by a vector expressing Cre in order to achieve recombination [177]. Finally, none of these alternative systems has yet matched the extensive use that has been enjoyed by Tc-based designs on account of their relative simplicity, ease of construction, and inducibility characteristics.

9.3.3.4 Control over Integration

Retroviruses and lentiviruses have gained popularity as agents of gene transfer largely because features of their natural life cycle correspond very favorably to the aims of gene therapy. These viruses are able to enter cells and permanently modify the target genome via the integration of new genetic material. However, therapeutic use of these viruses has required a series of modifications intended to retain their desirable properties while nullifying their pathogenicity. So far, this has been achieved by providing essentially wild-type proteins (from the packaging vector) to carry out the desirable infection and integration functions of the viral life cycle, while modifying the contents of the viral genome (in the transfer vector) to control expression from the integrated vector. Custom tailoring of the *cis* and *trans* elements of the transfer vector has allowed exclusion of most viral sequence as well as some control over not only what is expressed from the provirus, but also when and where it is expressed, thus markedly increasing biosafety. Host genome integration, however, is an unavoidable step that can reduce biosafety.

Many mechanisms exist to provide control over safety issues stemming from what is inserted, but virtually none over dangers that stem from where it is inserted. The most pressing of these dangers is posed by the very process of integration that is such an attractive feature of the lentiviral technology. Retroviruses, of which the lentiviruses are a subgroup, were first identified by their ability to cause tumours in animals [2]. For those animal retroviruses that do not carry an oncogene, the cause of the cancer is the same in each case: proviral integration that has transcriptionally activated a cellular proto-oncogene. After proto-oncogene activation, uncontrolled cellular proliferation may result. This type of insertional

oncogenesis was always recognized as a potential threat of retrovirally mediated gene therapy, but has been the focus of especially intense interest since 2003, when leukemia developed in several of the children with X-linked SCID following *ex vivo* gene transfer of the common γ -chain cDNA to CD34⁺ hematopoietic stem cells using an MuLV vector [178]. Although insertional oncogenesis has been demonstrated to be much less likely with lentiviral than retroviral vectors [179] (and in the natural setting no lentivirus has been shown to cause malignancy directly), this is a risk that is understandably still taken very seriously in the context of human gene therapy trials. It is also theoretically possible that vector integration will disrupt a tumor suppressor gene, which may lead to cancer in the setting of haploinsufficiency.

To improve control over the process of vector integration and reduce the chances of such a catastrophe occurring, investigators have pursued two general lines of research. The first and most investigated of these consists of various attempts to direct the HIV PIC towards a single or limited number of sites in the host genome that is favorable or non-detrimental to the host (i.e., unlikely to cause insertional oncogenesis or tumor suppressor inactivation). In the absence of any modification, HIV appears to integrate in a quasi-random manner along the entire transcriptional unit, with the only discernable preference being for active genes [53,180]. In order to direct integration to distinct sites, fusions of IN with proteins that have strong, site-specific DNA recognition domains have been used, with limited success. The earliest effort to this end was utilizing a fusion of HIV-1 IN and the λ repressor protein. When the purified λ R-IN fusion protein was incubated *in vitro* along with substrate lentiviral DNA and phage λ target DNA, integration was found to occur preferentially in the regions surrounding λ operator sites, suggesting that tethering IN to a target could control site selection [181]. Subsequent studies obtained similar *in vitro* results with fusions of IN and the *E. coli* protein LexA [182], or the DNA binding domain of the zinc-finger protein zif268 [183]. These early fusion protein experiments were as much an effort to understand the biology of lentiviral integration as they were an attempt to control it. Because of this, they were generally performed as *in vitro* chemical reactions between purified proteins and nucleic acids. Additionally, all of these experiments relied upon proteins whose DNA-binding domains recognized fixed sequences that were not necessarily unique or even present within the human genome, potentially limiting their utility. Many of these efforts were doomed because IN has nonspecific DNA-binding activity coupled with the fact that the human genome is a vast target.

The results of the XL-SCID trial, however, have prompted extensions of this work. Specifically, Tan et al. have recently developed fusions of IN and a polydactyl protein (E2C) which contains six zinc-finger domains and recognizes an 18 bp stretch that is unique within the human genome. In addition, each of the six zinc-finger domains can potentially be developed as a modular building block for specific recognition of each of the 64 possible 5'-NNN-3' sequences, thus making any prespecified 18 bp sequence of DNA a potential target for

directed integration [184]. More recently, the same group has incorporated several variants of the IN/E2C fusion into vector particles and used them to infect HeLa cells. They were able to show directed integration near DNA flanking the E2C recognition sequence at a relative specificity that was perhaps 10-fold greater than wild-type IN. Demonstrating some efficacy in living cells was an encouraging step for this technology, however, the vast majority of integration events still took place in a seemingly undirected fashion and packaging of the fusion protein relied upon using a Vpr fusion that resulted in very low titers compared to controls [185].

Another strategy to achieve directed integration takes advantage of growing knowledge regarding the interaction between lentiviral PICs and eukaryotic nuclear proteins. Recent investigations have shown that a number of endogenous nuclear proteins contribute to or are essential for proper HIV integration. One of these proteins, LEDGF/p75, has been shown to interact with both IN and with chromosomal DNA and may play a part in directing HIV integration preferentially towards transcriptional units [54,186]. By fusing LEDGF/p75 to the λ repressor protein, Ciuffi et al. have shown that an unmodified IN can be recruited to integrate in positions closely flanking the λ operator site via what seems to be a protein-protein "tethering" mechanism [187]. This method has yet to be tested in cells, and it achieved directed integration at only very low levels. By relying on the alteration of cofactor nuclear proteins rather than IN itself, it offers a different potential approach for exerting control over integration site selection.

While the ultimate goal of safe and site-specific integration will undoubtedly continue to draw further attention, methods for directing integration to a particular site with high efficiency and specificity are currently in their infancy. It will require a tremendous technical leap forward to fully direct integration in cells. As an alternative to such endeavors, another means to control integration has been explored: foregoing it altogether (Figure 9.14).

By introducing a variety of mutations into the coding sequence of HIV IN, several vectors have been constructed that can still transduce nondividing cells, but are unable to integrate their cDNA into host cell chromatin [188–191]. Typically, IN catalytic activity is reduced by four orders-of-magnitude by these mutants. A certain percentage of transfer vector cDNA becomes circularized and persists as a nuclear episome, termed "extrachromosomal DNA" (E-DNA), which is transcriptionally active, albeit at lower levels than integrated proviral DNA [188]. The E-DNA is stable within a cell's nucleus but since it lacks an origin of replication, will quickly be "diluted" in a population of dividing cells. It is also subject to endonuclease degradation. Hence, nonintegrating vectors seem very well suited to provide either transient expression in a dividing cell population, or relatively long-term expression in quiescent, terminally differentiated cells. As an encouraging proof-of-concept, Yanez-Munoz et al. have used a nonintegrating lentiviral vector to show substantial long-term rescue of several clinically relevant rodent models of retinal degeneration [190]. When equipped with an SV40 origin of replication,

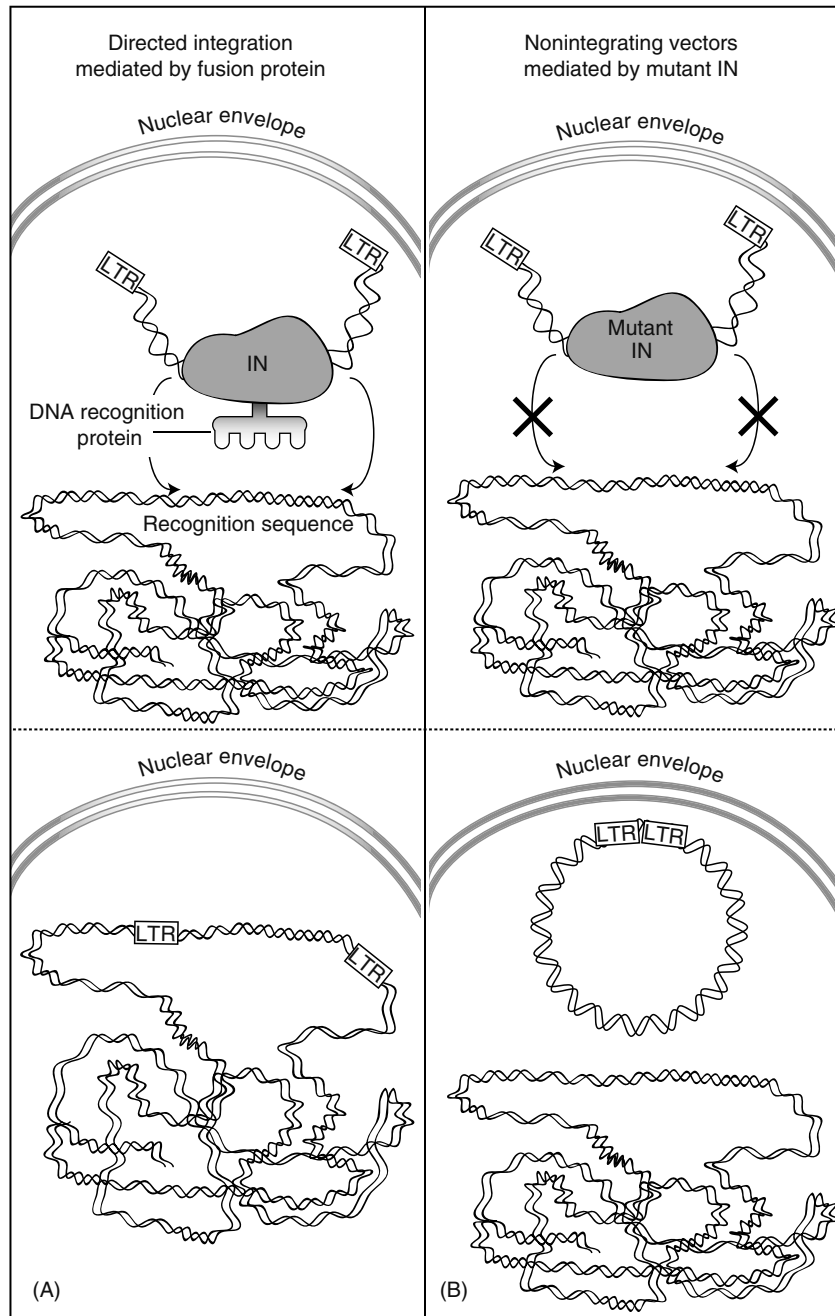

FIGURE 9.14 (A) Site-specific integration mediated by IN fused to a protein with DNA recognition domains. (B) Lentiviral vectors can generate persistent, nonintegrating episomal DNA if packaged with a defective IN.

circular E-DNA persisted and provided long-term expression in dividing cell lines (such as 293T) that also expressed the SV40 large T antigen. Such a vector could be useful in an approach that allows conditional replication of the E-DNA only in cells that provide a required viral or cellular *trans*-acting factor, such as in virally infected cells, or cancer cells expressing transforming proteins [188].

Nonintegrating lentiviral vectors retain most of the promising features of their traditional, integrating counterparts: a large transgene capacity, transduction of nondividing cells, flexibility in pseudotyping, and a paucity of immune response.

By preserving these features but removing the major safety drawback of insertional oncogenesis, they signify a major step forward. The advantages of nonintegrating vectors extend beyond the obvious, such as diminishing the magnitude of negative positional effects, silencing or extinction of expression, and making it unlikely that any RCL generated would be replication competent [189]. Even a more modest viewpoint would have to concede that while IN-defective vectors may not become standard for every application, they markedly increase the versatility of the lentiviral vector platform while quelling fears related to insertional oncogenesis. And, unlike

with schemes for directing integration, excitement surrounding the potential of nonintegrating lentiviral vectors seems all the more well founded by recent demonstrations of their effectiveness *in vivo* [189,190]. It should be emphasized, however, that for uncertain reasons levels of transgene expression are reduced compared to that of integrating vectors.

9.4 PRODUCTION, PURIFICATION, AND TESTING

Section 9.3 was devoted to an in-depth exploration of the various components and design features of modern lentiviral vectors. Section 9.4 discusses the very practical aspects of

how these intangible designs are translated into actual, physical vector particles and how these particles are then purified and prepared for use in either the laboratory or clinical settings.

9.4.1 PRODUCTION OF LENTIVIRAL VECTORS

Vectors based on lentiviruses, like most other viral vectors, are generally produced in one of two ways: (1) by transient transfection of highly transfectable cells (generally HEK 293T) or (2) from stable vector-producing cell lines (VCLs) (Figure 9.15).

Transient transfection is the most commonly used method of lentiviral vector production because it can be performed

FIGURE 9.15 Two common methods for producing lentiviral vectors. (A) In transient transfection, plasmids coding for each element (transfer vector, packaging construct, envelope) of the vector particle are introduced into naive 293T cells in the presence of a transfection reagent such as calcium phosphate. The cells produce vector for a few days before succumbing to the cytotoxicity of vector components such as PR and VSV-G. (B) In a VCL, cells already contain stable copies of the various vector genes. Production is initiated according to the administration or withdrawal of tetracycline. Although producer cells will die, uninduced cells can be maintained/expanded in tissue culture for future inductions. Only the relevant portions of plasmids are shown. Elements of the tetracycline-based regulation system are shaded in gray. Cell shown in B is larger only for the sake of convenience.

rapidly, inexpensively, and it provides suitable titers for most laboratory applications. In this process, separate plasmids encoding the transfer vector (with its transgene), the packaging construct (containing viral structural proteins and enzymes), an envelope protein (most commonly VSV-G), and any necessary regulatory proteins (usually just Rev) are mixed together and introduced to naive 293T cells in the presence of a reagent capable of mediating transfection. Once inside the cells, vector RNA and protein products are produced and assembled by the producer cells, as directed by the genetic information contained in the DNA plasmids. The process is termed “transient,” since it is only expected to produce vector for 2–3 days before the cells begin to suffer from the toxicity of viral proteins.

VCLs, in contrast, are engineered to already contain some or all of the components necessary to produce vector and cells of this lineage will produce vector particles throughout their lifetimes (Figure 9.15). They can be created either via stable transfection or transduction with the necessary packaging, transfer, and envelope sequences. The creation of stable VCLs is an important step in bringing a viral vector-based gene therapy into clinical trials because they offer a nonvariable, scalable source of vector production that can be characterized in detail and scrutinized for safety concerns before their products are used in human trials. In addition, the use of stable producer cell lines eliminates the problem of carrying over plasmid DNA into vector batches as well as the risk of homologous recombination between transfected plasmids (although recombination at other levels to generate RCL is still possible), both of which are concerns with transient transfection.

When lentiviral vectors arrived as a feasible alternative for gene therapy, long experience garnered previously in the retroviral vector field allowed work on development of a lentiviral VCL to begin immediately, and several groups have since reported the creation of stable, well-characterized packaging cell lines for the production of lentiviral vectors [192,193–197]. However, despite the existence of these systems, there has been a significant barrier to their widespread adoption, and transient transfection currently remains the predominant method by which these vectors are produced. This is probably the case for a number of reasons, but the foremost of these are related to the cytotoxicity caused by various viral proteins (notably PR [198]) and the fusogenic VSV-G, which is very commonly used as an envelope protein. To get around this problem, most lentiviral VCLs employ inducible expression cassettes to limit expression of VSV-G and viral proteins to periodic intervals [194,196,199], however, these are generally accompanied by titer loss and unregulated basal activity. Even so, toxicity to producer cells has reduced the life span of most producer cell lines to 4–7 days at maximum, which is hardly longer than the 3 or so days of production obtained with transient transfection and contrasts unfavorably with MLV-based packaging cells that use nontoxic envelopes and can produce vector for 2 weeks or more with one run. Some of the difficulties of sustained lentiviral production appear to be offset if the vector is introduced into the packaging cell line by transduction rather than transfection and one group has

used this technique to create a cell line, “STAR,” capable of generating high titer HIV-based lentiviral vectors ($>10^7$ TU/mL) for at least 3 months [193,200]. However, this cell line uses a gammaretroviral pseudotype, and so does not solve the significant issue of VSV-G toxicity to VCLs.

The relative importance of each of these production methods to the future of the field remains unclear: Traditionally, VCLs have been seen as a prerequisite for the production of clinical-grade vectors, however, the first clinical trial using lentiviral vectors has proceeded using transient transfection as its production method [201,202]. Both methods continue to be refined, with new VCLs frequently being introduced [192,197,203] and transient transfection being honed through various optimizations in reagents and reaction protocols [204–206].

9.4.2 PROCESSING AND PURIFICATION

After production, a variety of protocols can be implemented to purify the resultant vector in a concentrated form. The most common method by far is ultracentrifugation and resuspension [66,206]. This process generally consists of collecting supernatant from producer cells, clarifying it by an initial filtration step to remove cellular debris, ultracentrifugation to produce a viral pellet, resuspension in an isotonic buffer over several hours, and occasionally further purification (such as by centrifugation through a sucrose cushion) [206]. These maneuvers typically concentrate supernatant 100–1000-fold, taking an unpurified preparation of producer cell supernatant at a titer of 10^6 TU/mL to a final titer of 10^8 – 10^9 TU/mL in the purified preparation [55,206]. Such a preparation is generally of sufficient titer and purity for most laboratory purposes, including cell culture work and administration to animals. In fact, this ease of preparation has been one of the driving factors behind the widespread adoption of these vectors in laboratory science.

Ultracentrifugation and resuspension, however, is not an ideal technique for every application. To begin with, although VSV-G pseudotyped vector particles are stable under these conditions, most other viral glycoproteins cannot tolerate such high *g* forces. Additionally, since preparative ultracentrifuge rotors such as Beckman’s SW28 only accommodate up to 240 mL, production scale-up to 100 L for clinical use is problematic. Third, ultracentrifugation also leads to pelleting of cellular membranes, aggregated proteins, and other debris, which may be problematic in terms of immune response. For example, expression of VSV-G leads to the formation of tubovesicular structures (TVS) carrying VSV-G along with a variety of plasmid and cellular DNAs. If these TVS are not removed, the DNA may be recognized by toll-like receptors to initiate an innate immune response [207].

For all of these reasons, alternative protocols are very desirable and a multitude of different options are available. Some of these focus intensely on specific areas of processing, such as concentration. To this end, a method has been developed to rapidly concentrate vector particles from large volumes of supernatant by coprecipitation with poly-L-lysine [208], and others have described similar methods [209].

Similar to ultracentrifugation, however, these methods tend to cause precipitation of cellular debris or other impurities that can lead to undesirable or unpredictable immune responses [210]. Therefore, while convenient for concentration, such methods may mandate additional steps for purification [211].

A very different approach to vector concentration and manipulation rests on modification of the vector particles themselves. Copackaging of vector particles with biotinylated proteins from producer cell membranes has been described, allowing vectors to be subsequently manipulated via streptavidin-equipped paramagnetic particles [212,213]. Similarly, using a novel peptide insertion library, Yu and Schaffer have created a variant of the VSV-G protein that retains its functionality yet includes a His₆ tag, allowing facile purification with a Ni-nitrilotriacetic acid affinity chromatography column [214]. Though exciting, such methods are relatively new and have yet to be extensively adopted, thus their current impact is unclear.

Concerns over purity have led to other innovative methods intended to simplify or improve purification and reduce the likelihood of unwanted antigens in the vector preparation. Among these are sucrose-gradient fractionation of concentrated vector, and the use of serum-free media in producer cells [210], along with the technique of tangential flow ultrafiltration [215]. Because of a need to produce large amounts of highly purified vector, protocols intended for clinical use often employ different methods. The first approved clinical trial with a lentiviral vector used a combination of ultrafiltration, benzonase digestion (to remove contaminant DNA) [216], and size-exclusion chromatography [217]. Anion exchange and other column chromatography methods, in which vector is initially adsorbed and then eluted, have also been described [217–219]. These offer hope for further improving scalability by allowing more rapid throughput of unpurified supernatant than can be achieved compared to other methods.

9.4.3 TITER DETERMINATION

As lentiviral vectors are relied upon more and more heavily as laboratory tools and as they begin to make their way into clinical use, it is becoming absolutely essential to have a reliable means of determining the titer or potency of a given preparation of vector. A multitude of different methods to evaluate vector titers have been described and are commonly used [220]; however none of these has the universality required to become the much-needed standard measure of vector potency.

Methods for titering lentiviral vectors can be roughly divided into functional and nonfunctional assays [221]. Nonfunctional assays are generally aimed at characterizing and somehow quantifying the contents of a vector preparation by measuring either (1) p24 (Capsid) antigen ELISA, (2) vector genomic RNA content (typically by quantitative RT-PCR), or (3) endogenous RT activity. While all of these methods provide quantitative information, the values often only poorly correlate with vector transduction efficiency or gene expression. This is probably due to multiple reasons,

but some obvious examples for each case include the facts that (1) Capsid ELISA results will include quantitation of free and aggregated p24 that is not associated with transducing vector particles, (2) vector genomic RNA titers will include partial RNA transcripts or full-length RNA incorporated into defective particles, and (3) RT may be associated with bald or noninfectious particles [221]. In general, these nonfunctional assays tend to overestimate the functional vector titer. As an example, based upon CA amounts, it has been estimated that only about 1% of viral particles present in vector preparations are infectious [222] and that genomic RNA values overestimate functional eGFP titers (TU/mL) by anywhere from 200- to 10,000-fold [222,223]. In addition, nonfunctional assays do not take into account the nature of the vector construct (such as the inclusion of additional cis-acting sequences or cell-specific promoter) or cell type to be transduced, both of which can have a substantial impact on functional titer.

Although poor at predicting gene transfer efficiency, measurements of CA and genomic RNA content may be useful for experimentally normalizing vector preparations [221] such that two batches of vector produced under the same conditions and with a very similar Capsid ELISA value are likely to provide similar functional titers if used under identical transduction conditions. A Capsid ELISA, however, cannot substitute for a functional assay.

By focusing evaluation on steps that follow successful transduction, the so-called functional titering assays may give a more meaningful interpretation of the number of infectious vector particles within a preparation and, in some cases, the capability of said particles to express transgene at a particular level in a particular cell type. Of these, the most commonly used by far is the addition of vector to target cells in serial dilutions, followed by assessment of transgene or marker expression either by quantifying colony formation (in the case of antibiotic resistance reporter genes), staining (for LacZ and other enzymatic reporters), or fluorescence-activated cell sorting (for autofluorescence or cell surface proteins). Titer is measured in the linear dilution range. End-point dilution is not suitable for every vector since it relies upon the presence of a reporter gene (which may not be present). Additionally, target cell type and precise transduction conditions may complicate functional titering [224].

Functional titer posttransduction may also be measured by determining the total number of integrated vector DNA copies by quantitative PCR (qPCR), normalizing to the number of target cells by qPCR of an endogenous cellular gene such as β -actin. However, because of positional variation in transgene expression, vector DNA qPCR assays tend to overestimate functional eGFP titers anywhere from 6- to 60-fold [220,223,225–227].

In efforts to make a quantitative assessment of functional titer in situations where a reporter gene is not included in the transfer vector, several groups have found that transgene mRNA expression correlates very closely to reporter gene expression [221,225]. Thus, posttransduction quantitative RT-PCR (qRT-PCR) of transgene mRNA (often with a primer

directed against the WPRE or other nucleotide sequence included in the transcript) seems well suited to measuring the functional titer of transgenes whose protein products are not readily quantifiable, as may often be the case. Such a method does require a normalization control for interpretative purposes.

9.4.4 RCL AND OTHER SAFETY ISSUES IN MANUFACTURING

The primary safety concern in the production of lentiviral vectors is the possibility of reconstitution of an RCL either by homologous or nonhomologous recombination between the distributed transfer, packaging, and envelope vector components introduced into producer cells (either at the level of DNA plasmids or RNA), or possibly by nonhomologous recombination of vector components with human endogenous retroviral elements in the producer cell genome. The separation of cis and trans elements of the vector into separate transfer and packaging vector plasmids, the reliance on a separate pseudotyping plasmid for the provision of a functional envelope, the removal of all nonnecessary viral genes, and various other measures such as codon-optimization and truncation of remaining viral ORFs that were discussed in earlier sections make it exceedingly unlikely that a recombination event between plasmids could regenerate a replication-competent entity. Generation of RCL has not yet been reported in the published literature. Nonetheless, careful scrutiny for the presence of any potential RCL is warranted by both the precedent of replication-competent retroviruses being generated in MLV-based production systems and the link to lymphoma in monkeys [63], and the fact that HIV is a well-known and potentially lethal human pathogen. An RCL could have highly unpredictable properties and, depending upon its structure, could be transmitted both horizontally and vertically.

For these reasons, screens for RCL are a mandatory step in the testing of vector preparations to be used in clinical trials. It is generally agreed that any such assay should begin by amplification of potential RCL in a permissive cell line in tissue culture. The main difficulty thus far in settling upon an acceptable test for the presence of RCL has been that since an unintentionally generated RCL is still only a theoretical possibility, its properties are unknown and hence it is difficult to design a detection assay with a suitable positive control. To get around this, a variety of different test methods have been proposed, with most of these focusing on generic aspects of lentiviral biology that would presumably have to be included in any possible variant of an RCL. Among these, perhaps the most likely to emerge as universally acceptable indicators of RCL activity are PCR-based protocols such as the very sensitive product-enhanced reverse transcription assay (PERT) and its derivations [228–230]. The PERT assay uses a defined RNA template (usually phage RNA) as a substrate for RT activity. If RT is present, the predefined RNA template will be reverse-transcribed into cDNA which can then be amplified by quantitative PCR, giving a measure of the amount of RT present in the sample.

Thus, PERT and the similar fluorescence PERT (F-PERT) are only successful in the presence of exogenously provided RT such as would be present in a preparation contaminated with RCL and ought to be capable of detecting any imaginable configuration of RCL since all of these, by definition, would have to contain functional RT. Furthermore, PERT and its derivations have been evaluated by several groups in the context of an assay for RCL [231–233] and shown by some to be at least as sensitive as other available methods for the detection of RCL after amplification in a permissive cell line, even in the presence of competing vector. PERT can be carried out as a single-tube, one-step assay and various improvements to the technique have been described that facilitate ease of handling and reproducibility while reducing background and maintaining sensitivity (<10 virions) [234,235].

Several other assays for RCL exist and are used in conjunction with or in place of the PERT assay. Standard or quantitative PCR or RT-PCR assays to detect VSV-G nucleic acid sequences and recombination between *gag* and the transfer vector (in the region of Ψ) have been described [236,237], as have ELISAs that measure CA amounts during blind serial passaging of tissue culture supernatant, with the expectation being that an RCL will have the structural HIV genes intact [238]. These assays share the common problem that they depend upon the presence of a predicted element within the postulated RCL and may thus lack the requisite broad sensitivity to detect unusual forms that may be produced by recombination of vector elements with genomic retroviral elements endogenous in the producer cells. However, conventional assays can discern recombinants arising solely from components of the vector system, as demonstrated by the detection of as little as one man-made RCL in a background of 2.5×10^8 IU of vector using Capsid ELISA, after a period of biological amplification [238]. With regards to lentiviral vector clinical trials, none of these methods are CLIA-certified or approved by the FDA, and at the moment the FDA is examining the assay methodologies of the involved investigators on a case-by-case basis.

For a summary of the various steps in vector production, processing, and safety testing, see Figure 9.16.

9.5 NON-HIV-BASED LENTIVIRAL VECTORS

HIV-based vectors offer great promise as a platform for gene therapy, but it was recognized very early on that safety concerns would be the primary factor hampering or inhibiting their eventual entry into the clinical arena. Many investigators have therefore sought to retain the desirable traits of HIV-1-based vectors while diminishing their perceived safety risks (namely the generation of an RCL) by turning to other members of the lentivirus family that are closely related but have decreased or absent pathogenicity in man. A number of less-familiar lentiviruses have been engineered into vectors for the transduction of nondividing cells. Most nonhuman lentiviral vectors have been found to behave very similarly to HIV: Generally all of them are capable of VSV-G-pseudotyping and transduction of nondividing cells; however, they differ somewhat in titer and the types of cells they can transduce efficiently.

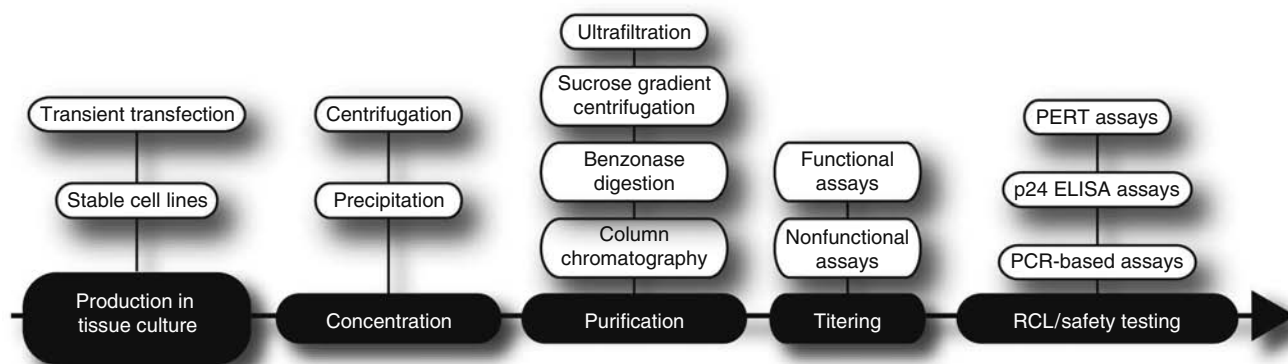

FIGURE 9.16 Generic sequence of processing events that take place after vector production. Some of the more common protocols are shown as variations.

HIV-2, a relative of HIV-1 that induces a milder course of disease and a slower progression to AIDS [239], was among the first of the lentiviruses to be modified as a vector, following in the footsteps of HIV [121,240,241]. At roughly the same time, a proliferation of animal lentiviruses that are not considered to be pathogenic to man were all introduced as vectors within a few years of each other. Vectors based upon FIV [122], EIAV [123], SIV [115,124,242,243], BIV [125], jembrana disease virus (JDV—another bovine lentivirus) [126], and caprine arthritis encephalitis virus (CAEV) [244] all serve as potential alternatives to HIV for gene delivery. All of them have been demonstrated to transduce mitotically inactive cells, and most of them have advanced from a first generation (helper genome with an envelope deletion) through a second generation (elimination of unnecessary accessory proteins with an attempt to precisely define the packaging signal), to a third generation in which all of the accessory and regulatory proteins except for Rev have been eliminated [55,73,127,245–247]. In the case of EIAV and BIV, even codon-optimized vectors have been generated [233,248], and beneficial cis-acting sequences, such as the cPPT/CTS and WPRE, have been included.

Because they were among the first to be introduced and have reasonable VSV-G-pseudotype titers (unlike CAEV [244]), FIV, EIAV, and SIV have become the most frequently employed animal lentiviral vectors. This extensive use has led to the availability of relatively fine-tuned vector designs and their properties, including integration site preferences [249–251], have been increasingly characterized. Each of them has played relatively prominent roles: FIV vectors were one of the first to be used in demonstrating that RNAi-induced transcriptional gene silencing is operational in human cells [252], and an EIAV vector may be the initial one to be used clinically to treat Parkinson's disease (see <http://www.oxfordbiomedica.co.uk/news/2006-ob-24.htm>). As the best characterized of the animal lentiviral vectors, FIV, EIAV, and SIV all appear to have applications similar to those of HIV-based vectors, with notable caveats. Some reports suggest EIAV vectors may be more subject to silencing

in human cells than are HIV vectors or have lower transgene expression levels, despite equivalent transduction efficiencies [253–255], and FIV vectors may be inferior for transducing human hematopoietic cells [256]. Comparative performance interpretations are complicated by the fact that the best of each system are usually not used, although it makes sense that a well-adapted human pathogen (such as HIV) is likely to be superior in terms of infectability, transgene levels, and persistence in human cells.

Many arguments have been put forth for the further development of vectors based on non-primate lentiviruses, with most of these based on the purported safety advantages of these vectors over those based upon HIV. While it is true that animal lentiviruses such as FIV and EIAV lack the capability to replicate efficiently in human cells, it is not clear whether or not their corresponding vectors are truly advantageous over those based upon HIV. Some argue instead in the favor of HIV vectors, citing the very low probability of generating an RCL with modern vector systems, and the preferability of generating an RCL based on a known pathogen with effective treatments, versus an RCL based on an animal virus whose properties could be very unpredictable if given the ability to spread in human tissues [257]. It remains to be seen which lentivirus, if any, will be the superior template for human gene therapy, but in the meantime animal lentiviral vectors have established themselves as flexible and useful tools for many *in vitro* applications and are not likely to disappear in the near future.

9.6 LENTIVIRAL VECTOR UTILITY

The intrinsic capability to transduce and permanently modify targets at any stage of the cell cycle as well as the wide tropism afforded them by pseudotyping has rapidly made lentiviral vectors a tool of leading importance in an astounding number of different applications, both at the bench and bedside. The list of possible uses of these vectors seems likely to grow as novel technologies like RNAi are discovered and increase in importance. That being said, an exhaustive description of every potential use for these vectors is beyond the scope of this chapter and so preference will be given to

those with likely applications in gene therapy, although a few illustrative examples of their importance in basic research will be discussed first.

9.6.1 LENTIVIRAL VECTORS IN BASIC RESEARCH

As mentioned earlier, lentiviral vectors were originally conceived of in the late 1980s by Sodroski and collaborators for the purpose of studying viral biology, with a focus on cell binding and entry. Although they have since become widely regarded as promising therapeutic tools, these vectors continue to make important contributions to an increased understanding of lentiviral replication.

It has long been known that the innate tropisms of lentiviruses and their derivative vectors prevents them from efficiently infecting or transducing cells of certain species, with the one of the best known examples being the failure of HIV-based vectors to transduce some species of monkey cells. Recently, Stremlau et al. uncovered one mechanism behind this “restriction” by introducing a cDNA library derived from rhesus macaques into a human cell line [258]. The human cells were then screened for clones that were resistant to transduction with HIV-based vectors encoding eGFP but still permissive to transduction of a similar SIV vector. When such a clone was isolated, it was found to contain a cDNA encoding TRIM5 α , and this gene was later confirmed to be a key host cell factor mediating the type of species–species restriction that explains not only the curious inability of HIV vectors to transduce certain monkey cells, but also the broader biological phenomenon as to why some retroviruses are restricted to specific species.

The discovery of TRIM5 α demonstrated that lentiviral vectors may have much to contribute towards uncovering host cell factors involved in viral replication. More recently, however, these vectors have begun to be applied widely to the study of mammalian biology, with powerful implications. While these vectors have long been used to permanently modify cells (either to produce a desired alteration or explore novel properties), they are now being combined with the power of genomics and RNAi to do so on a previously unattainable scale. cDNA and shRNA libraries cloned into lentiviral vectors are making it possible to perform genome-wide gain-of-function or loss-of-function screens in essentially any cell type *in vitro* or perhaps even *in vivo*. Furthermore, this technology can be combined with regulatable vector technology to allow for the development of conditional phenotypic screens, especially if the gain or loss-of-function is cytotoxic or lethal [259–262].

Finally, because HIV vectors are resistant to transcriptional silencing, transduction of either oocytes or early embryos offers a truly efficient and relatively simple method for producing transgenic animals, not necessarily limited to rodent species. The applications for this technology range from generation of disease models to the use of animals for production of human therapeutic proteins. Specialized vectors used in transgenesis can produce either permanent loss-of-function models (via mating with Cre-expressing animals) or tunable RNAi knockdown or transgene expression (using

regulatable vectors). This should allow a high degree of temporal manipulation over the transgenic phenotype, which should be useful not only in the study of disease progression but also in aspects of animal physiology [173,263].

9.6.2 TARGET TISSUES AND THERAPEUTIC MODELS (PRECLINICAL MODELS AND CLINICAL APPLICATIONS OF LENTIVIRAL VECTORS)

As with any gene delivery approach, lentiviral vectors are not ideal for all gene transfer applications. However, one of the exciting aspects about them has been the identification of tissues and diseases where the technology seems to have great potential and there are no other current significant alternative approaches. Table 9.2 shows several candidate diseases in which success has been achieved in preclinical animal models; note that it is focused on illnesses that affect the central nervous system (CNS) and the hematopoietic system. The low immunogenicity and persistent expression of lentiviral vectors make them well suited for neuronal cell transduction in the context of chronic diseases, and their ability to transduce quiescent hematopoietic stem cells opens the door to effective, lasting treatment for a variety of genetic and infectious diseases (e.g., sickle cell anemia and AIDS, respectively) that involve multiple lineages of the hematopoietic system. Predictably, future gene therapeutics will likely focus on these promising areas (e.g., www.oxfordbiomedica.co.uk/ and <http://www.genethon.com/index.php?id=1&L=1>). Because of the characteristics of the vector, there has been comparatively little work in targeting cancerous tumors [155,264–266]. However, there is a significant interest in using lentiviral vectors to “vaccinate” dendritic cells or T cells with tumor antigens, invoking a potentially effective immune response against various cancers [211,267–269]. At this point, a large number and variety of primary cells and tissues have been efficiently transduced by lentiviral vectors, and it would be no more than educated supposition to say which disease and transgene will be targeted next for phase I clinical trials. Below, however, we briefly discuss clinical trials involving these vectors.

9.6.3 LENTIVIRAL VECTORS IN CLINICAL TRIALS

The latest generation of lentiviral vectors contains no open reading frames from the parental viruses and, when integrated into the host genome, should only express the transgene of interest. These advanced vectors take advantage of a number of features such as split-coding and codon optimization to improve safety and increase structural/enzymatic gene expression. Given that HIV is a known human pathogen, there will likely always be safety concerns regarding vectors derived from it. Patient well-being and assessment of risk to benefit is paramount in clinical trials. Recruiting patients already infected with wild-type HIV to evaluate potential gene therapeutic strategies offers a favorable risk-to-benefit ratio for the first clinical trials with these vectors [282], with the caveat that there could be recombination between wild-type virus

TABLE 9.2

Animal Models Showing Disease Improvement after Therapeutic Transduction with Lentiviral Vectors

Disease	Gene	Animal	Method	Correction	Comments	References
Parkinson's disease	GDNF	Rhesus monkey, Rx MPTP	Direct CNS injection	Reversed functional defects, prevented NS degeneration	8 month F/U	[270]
Parkinson's disease	Tyrosine hydroxylase (TH), aromatic amino acid dopa decarboxylase (AADC), GTP cyclohydrolase 1 (CH1)	Rat, Rx 6-OH DA Rhesus monkey PD model	Stereotactic injection to striatum	Consistent, complete reversal of phenotype in chronic macaque model	Three genes for DA synthesis delivered by a single vector. 5 month F/U	[111,271]
Retinitis pigmentosa	cGMP PDE β	Mouse rd	Subretinal injection	Expression confirmed in photoreceptors	6 month F/U	[272]
Metachromatic leukodystrophy	Arylsulfatase A	Mouse KO	Direct CNS injection	Decreased neuropathology and hippocampal learning impairments	Hippocampal neuronal degeneration central to disease	[273]
Mucopolysaccharidosis type VII	β -glucuronidase	Mouse KO	Direct CNS injection	Reversal of histopathology	Regression in entire brain	[274]
Sickle cell disease	Anti-sickling β -globin	Mouse with sickle globin	Transduction of progenitors	Improved anemia and pathology	Vector included LCR	[275]
Thalassemia	β -globin	Mouse KO	Transduction of progenitors	Improved anemia and RBC morphology	Vector included LCR	[3]
ALS	VEGF	Superoxide dismutase (SOD1) (G93A) mouse	Injection into muscle with retrograde transport to spinal cord	Delayed onset, slowed progression of dz. Increased life expectancy ~30%	Effective use of Rabies G pseudotyped retrograde transport	[120]
ALS	RNAi against SOD1	SOD1(G93A) mouse	Injection into muscle with retrograde transport to spinal cord	100% delay in onset of symptoms, 80% extension in survival	Effective use of Rabies G pseudotyped retrograde transport, RNAi	[276]
Alzheimer's disease	siRNA targeting β -secretase (BACE1)	Amyloid precursor protein (APP) transgenic mouse	Direct CNS injection	Reduced amyloid production and behavioral deficits		[277]
Leber congenital amaurosis	RPE65	<i>Rpe65</i> ^{rd12/rd12} mouse	Subretinal injection	Significant functional improvement on ERG	Nonintegrating vector used	[190]
Cyclic neutropenia	G-CSF	Gray collie	Intramuscular injection	Substantially increased neutrophil count, correction of immunodeficiency		[278]
SCID	ADA	ADA (-/-) mouse	<i>Ex vivo</i> transduction of bone marrow, irradiation, reimplantation	Restored normal immune function, including antibody production	F/U 6 months	[279]
Wiskott-Aldrich syndrome (WAS)	WAS protein (WASP)	WAS (-/-) mouse	<i>Ex vivo</i> transduction of HSCs, irradiation, reimplantation	Significant engraftment of WASP expressing hematopoietic cells		[280]
Exudative age-related macular degeneration (ARMD)	Endostatin or angiostatin	Mouse with laser-induced choroidal neovascularization (CNV)	Subretinal injection	>50% reduction in CNV area. Also reduction in vascular hyperpermeability	12 month F/U	[281]

and vector components. If VSV-G is encoded within such a recombinant expanded host range and germline transmission is possible.

A variety of strategies have been proposed to utilize HIV-based vectors to combat HIV. These are aimed primarily at HSC and their resultant progeny or at T cells directly and are intended to protect them from HIV using approaches such as inducible suicide genes [283], antisense RNA [284], siRNA/shRNA [285], and a multitude of others [286]. In January 2003, the first clinical trial using lentiviral vectors was initiated in the United States with VRX496, an HIV-based vector engineered to conditionally express an antisense RNA against envelope glycoprotein in the presence of regulatory proteins provided by wild-type virus. After establishing clinical-grade production and quality assurance methods [217,237], autologous peripheral CD4⁺ T cells were bead-activated, transduced *ex vivo* with high-titer vector stocks, and then reinfused into HIV+ patients failing conventional anti-retroviral therapy. The results of the recently published phase I safety and tolerability data indicate that the procedure was well tolerated and follow-up studies over 2 years have not detected any adverse clinical events [202]. Although vector-virus recombinants have not yet been excluded and the vector appears to be safe thus far, it is difficult to draw meaningful conclusions regarding efficacy from such a limited phase I trial.

Importantly, analysis of the patient blood samples after the T cell reinfusion revealed wild-type viral particles housing RNA transcripts of the vector. This process, known as vector “mobilization,” may be beneficial here since it presumably allows spread of the vector to other CD4⁺ T cells, where it may have a protective effect. However, in many other circumstances, vector mobilization would be undesirable and for reasons outlined above vector mobilization or recombination after superinfection with HIV is considered one of the greatest safety concerns surrounding the use of these vectors. For example, the generation in man of an RCL with unpredictable or unwanted properties would pose complex biosafety and ethical issues that may be difficult to address [282].

Other safety issues regarding these vectors trace their origins to the development of leukemia resulting from insertional oncogenesis in four patients treated with γ -retroviral vectors in a gene therapy trial for X-linked SCID (see Refs. [90,178] and [http://www.esgct.org/upload/4th_CaseofLeukemial.pdf]). Vectors based upon lentiviruses are thought to be less likely to pose this sort of threat because (1) they exhibit less of a propensity than retroviruses to integrate near the 5' end of genes, where promoters are usually located, (2) lentiviral LTRs exhibit less read-through of the 3' LTR than MLV-based vectors (although SIN lentiviral vectors do exhibit MLV-like read-through unless a heterologous polyA addition signal is included at their 3' end) [89], and (3) initial studies comparing the potential for oncogenesis among retro- and lentiviral vectors suggest that lentiviruses do not have the same oncogenic potential as their retroviral cousins [179], although further study is needed.

Overall, the clinical safety issues surrounding lentiviral vectors are real, but very manageable. The excellent safety

and tolerability results of the first lentiviral gene therapy trial will likely open the door for these vectors to be used in applications outside of HIV infection. Indeed, as this chapter goes to press, seven new human gene therapy trials utilizing lentiviral vectors are ongoing or just beginning. The majority of these are for the treatment of late-stage HIV+ patients, but one is for the totally unrelated condition of mucopolysaccharidosis type VII and the other two are aimed towards treating melanoma and lymphoma (<http://www.gemcris.od.nih.gov/>). Several commercial entities may enter the fray soon with lentiviral vector treatments for Parkinson's disease, WAS, various retinopathies, and perhaps other conditions.

9.7 SUMMARY

Lentiviral vectors are at an exciting stage of development. The realization of their unique properties as a gene transfer agent has led to an explosion in investigation and innovation in this field, with thousands of published reports being generated in the span of roughly a decade. All of this interest has resulted in a large number of increasingly tailored and sophisticated vector designs being available and an ever-increasing knowledge of how effectively these vectors might one day be put to use for very well-defined therapeutic applications. Additionally, the general pervasiveness of these vectors in the last few years has led to their adoption for powerful new basic science techniques with the potential to accelerate biological research in other fields. Although these vectors may be years away from FDA-licensure, encouraging preliminary results coupled with the growing number of clinical entrants suggests that true clinical applicability may be less than a decade away.

10.1 INTRODUCTION

Vaccinia virus has been used clinically as a vaccine for smallpox for over 150 years, and thus is associated with a rich history and extensive clinical experience [1,2]. In 1798 Edward Jenner demonstrated protection from smallpox by vaccination with the cowpox virus obtained from infected milkmaids. In the early nineteenth century this evolved into the use of vaccinia virus [3]. The precise origin of vaccinia virus is difficult to identify, as the virus has no known natural host, leading some to suggest that it may have arisen from mutations in the cowpox or smallpox viruses [4]. However, it is more likely that vaccinia represents a distinct strain that is extinct in its natural host or so rare that it is difficult to identify naturally [5].

Vaccinia virus was widely used as a vaccine for the eradication of smallpox until 1978. Since that time it has been used experimentally as an *in vitro* gene expression vector and to express foreign genes as a vaccine for infectious agents and cancer [6]. Vaccinia has many advantages over other viruses as a vector for gene delivery. Vaccinia has a wide host range. Its genome has been completely sequenced facilitating the creation of recombinant vectors. It can hold up to 25 kb of foreign DNA without a need for viral deletions [7]. Recombinant vectors are easily produced in high titers for use *in vivo* [8].

Vaccinia virus has previously been modified to carry various antigens, cytokines, and immunostimulatory molecules [9]. It has also become evident that several properties make it useful as an oncolytic virus for cancer therapy [10]. Any cell infected with the virus is rapidly killed, and cell-to-cell spread

is efficient. Also, a natural tumor tropism exists in animal models. Applications requiring long-term gene expression, however, are not feasible with vaccinia. This chapter will review the relevant aspects of vaccinia biology necessary for its use as a gene transfer vector, and review the preclinical and clinical development of vaccinia virus for gene therapy and oncolytic virotherapy.

10.2 BIOLOGY OF VACCINIA

Poxviruses are classified into two subfamilies, chordopoxvirinae (vertebrate poxviruses) and entomopoxvirinae (insect poxviruses), and at least 46 species [11]. The classification scheme is based on host range, sequence homology, and antigenicity. Vaccinia virus is a member of the orthopoxvirus genus. It is genetically distinct from both cowpox virus and variola virus (smallpox). All members of the orthopoxvirus genus have immune cross reactivity and are genetically stable. This allowed for the complete eradication of variola virus in 1977 (last case of endemic smallpox).

Multiple strains of vaccinia viruses exist (Table 10.1). As vaccination became widespread throughout the world, numerous centers produced and maintained the vaccine in different ways, resulting in numerous strains, which differ in characteristics, pathogenicity, and host range. The New York City Board of Health (NYCBH) strain was obtained from England in 1856 and was originally used for small pox vaccination in the United States [5]. The western reserve (WR) strain is a laboratory derivative of this strain and appears to be one of the more virulent

TABLE 10.1
Vaccinia Strains Reported in the Literature

NYCBH	Tashkent	Ikeda

WR	Evans	DIs
Copenhagen	Praha	LC16
Lister	LIVP	EM63
MVA	Tian Tan	IC
		AS

strains in laboratory animals and nonhuman primates. It has not been utilized in patients to date. A recent comparison of vaccinia strains has suggested that WR has superior tumor lytic effects [12]. Another derivative, the Wyeth strain, was produced by Wyeth as a smallpox vaccine and is the backbone commonly used for experimental vaccines in clinical trials. The modified vaccinia Ankara (MVA) strain was developed through multiple rounds of infection in avian cells. This strain is highly attenuated and does not replicate in human cells [13].

As with all poxviruses, the vaccinia virus is a double-stranded DNA virus whose entire life cycle exists within the cytoplasm of eukaryotic cells. The virus contains an outer envelope as well as an internal membrane and it carries the enzymes required for initiation of transcription. The genome of the Copenhagen strain of vaccinia virus was completely sequenced and reported in 1990 [14] (other strains have been sequenced subsequently [15]). The genome consists of double-stranded DNA with inverted terminal repeats and a terminal hairpin loop, which mimics a large, circular, single-stranded DNA. The genome consists of 191,636 base pairs encoding approximately 2063 proteins of 65 or more amino acids in length. It is among the largest viruses in size, averaging 270 × 350 nm in the shape of a brick [16].

Vaccinia has two infectious forms, the mature virus (MV) and the enveloped virus (EV) [17]. MV is the form recovered during viral purification *in vitro*, as it is released on cellular disruption. Purification of EV is quite difficult as the envelope is too fragile to withstand the purification process. While attachment to the cell surface is different for MV and EV [18], recent studies have shown that cell entry by vaccinia occurs by fusion with the host cell membrane [19]. This is mediated by an entry-fusion complex consisting of eight viral proteins: A16, A21, A28, G3, G9, H2, J5, and L5 [20]. This complex is also required for cell-to-cell spread of EV suggesting that the outer envelope is lost prior to fusion. Recently a low pH, endosomal entry pathway was identified [21]. The MV contains several other proteins on its outer envelope including A17L, A27L, and D8L [22–28] which likely play a role in viral attachment. D8L was one of the first membrane proteins identified in the MV. It is nonessential in the viral life cycle but may mediate MV binding to cell surface chondroitin sulfate [26,27]. A27L mediates vaccinia interaction with cell surface heparan sulphate [25,29]. Virus infection was inhibited by up to 60% in the presence of soluble heparin [25] depending on the cell line used. EV is believed to be responsible for cell-to-cell spread and long-range transmission

of vaccinia virus *in vivo* [30]. Six proteins (encoded by A33R, A34R, A36R, A56R, B5R, and F13L) are EV-specific [11]. A56R has no effect on infectivity or spread if mutated [31].

It may be possible to circumvent normal receptor requirements by engineering vaccinia virus to bind to alternative cell surface molecules. Consistent with this, expression of an ScFv to erbB2 on the surface of the EV (created as a fusion with A56R) was shown to bind erbB2 by ELISA [31]. Creation of a fusion protein between an ScFv and A56R is technically feasible and may direct binding of the EV to a specific antigen or cell type. Fusions of other surface proteins, including B5R have been reported [32].

The life cycle of vaccinia is illustrated in Figure 10.1. Vaccinia virus (as with all poxviruses) spends its entire life cycle in the cytoplasm of the host cell and has never been shown to integrate into the host genome. Although originally it was thought that vaccinia virus has very few interactions with host-cellular proteins, host proteins are important. The CCR5 chemokine receptor has been shown to mediate a cascade of downstream signaling events required for late gene transcription in some cell lines [33]. The transcription factor YY1 is utilized for initiation and termination of intermediate and late gene transcription [34–36]. The virus induces a profound cytopathic effect very soon after viral entry, as early viral enzymes completely shut down host cell functions. By 4–6 h after infection there is almost complete inhibition of host protein synthesis. This allows for very efficient expression of viral genes and viral replication. In fact, approximately 10,000 copies of the viral genome are made within 12 h of infection [37]. Half of these are incorporated into mature virions and released.

After vaccinia enters the cell transcription begins. Three stages of transcription—early, intermediate, and late—have been described, each with its own specific promoters and transcription factors [38]. The enzymes and other proteins required for transcription are contained within the viral core along with the viral genomic DNA [36]. Proteins needed for viral replication are synthesized at the early (pre-replicative) stage of infection. A DNA-dependent RNA polymerase is contained within the viral core leading to the synthesis of early messenger RNA (mRNA). Early mRNAs appear within minutes of viral infection [36]. Translation of this RNA forms early proteins, which are involved in uncoating of the viral DNA, DNA replication, and intermediate transactivation for transcription of intermediate mRNA. Intermediate mRNA is then expressed which encodes for late transactivators leading to late mRNA synthesis. Late proteins include structural proteins for membrane formation and early transcription factors to be incorporated into the new virus particle. Only a relatively small number of proteins are required for DNA synthesis, making the system simple and largely autonomous.

The vaccinia double-stranded DNA genome replicates in the cytoplasm forming multiple concatamers of the genome. These concatamers are then resolved into individual genomes which are encapsulated along with the early transcription factors into Golgi-derived membranes. The first stage in the formation of infectious particles is the development of viral crescents composed of lipid and viral protein. To date, the

FIGURE 10.1 Vaccinia virus replication cycle. A diagram of the infected cell is shown with an exaggerated view of the endoplasmic reticulum (ER), *cis*-, *medial*-, *trans*-Golgi and the *trans*-Golgi network (C, M, T, and TGN, respectively). The major stages of the virus life cycle are listed. Following late gene expression, previrion forms assemble to form intracellular mature virus (MV). The MV is targeted to the TGN and following envelopment, intracellular enveloped virus (IEV) is formed. IEV are propelled to the cell surface by the polymerization of actin filaments. Once released the virus may remain attached to the membrane as cell-associated enveloped virus (CEV) or be released into the medium as extracellular enveloped virus (EV). (From Grosenbach, D.W. and Hruby, D.E., *Front. Biosci.*, 3, 354, 1998. With permission.)

origin of these crescents is disputed. Currently, the crescent is thought to be composed of a single-lipid bilayer without continuity to cellular membranes [39]. These crescents then coalesce into immature virus that lack infectivity. Immature virus becomes MV by condensation of the core and processing of core proteins (Figure 10.2). MV is transported to sites at which it becomes wrapped with two additional membranes. These membranes are derived from trans-Golgi network membranes that have been modified by the inclusion of virus-encoded proteins and ultimately become part of the EV outer envelope. These wrapped, intracellular enveloped viruses move along microtubules to the cell surface where the outer membrane fuses with the plasma membrane, exposing the viruses on the cell surface. If the virus is retained or reattached it is called the cell-associated EV (CEV), but if released becomes EV. Upon reaching the plasma membrane vaccinia switches from microtubule-dependent transport to the formation of actin tails needed for cell-to-cell spread of virus [40]. This is dependent on phosphorylation of an EV protein A36R which recently has been shown to be mediated by multiple families of tyrosine kinases [40–42] and likely contributes to wide host range and rapid spread of vaccinia virus. The A34R gene product plays a role in holding the virus to the cell surface. The WR strain exists almost exclusively as a cell-associated virus [43]; however, mutations in A34R can lead to increased EV release and decreased CEV [44].

This entire life cycle occurs very rapidly. Initial RNA transcripts are detectable within 20 min of infection and DNA

replication begins 1–2 h after infection. Within several hours after infection the majority of mRNA within the cytoplasm is from vaccinia-encoded genes. The entire replication cycle occurs in approximately 12 h [6].

10.3 CONSTRUCTION OF RECOMBINANT VECTORS

Homologous recombination occurs naturally during the replication of vaccinia virus, thus lending itself towards efficient insertion of foreign DNA. The creation of recombinant vaccinia vectors is relatively simple. The issues to be considered when creating a recombinant vaccinia vector include choosing a site for proposed recombination, choosing a selection method(s), and choosing a promoter for the foreign gene.

A shuttle plasmid is first created where a foreign gene expressed off a vaccinia promoter is flanked by vaccinia DNA sequences. Care must be taken that the foreign gene does not contain vaccinia transcription termination signals for early promoters (TTTTTNT) [45]. The most common site of recombination has been the vaccinia thymidine kinase (TK) gene. Insertion of genes into the TK locus eliminates functional viral TK, leading to attenuation of the virus *in vivo* [46]. Recombinations into numerous other loci have been performed, including intergenic segments such that no functional deletion occurs [47,48]. The functional analysis of many vaccinia genes has been defined through insertional deletion.

FIGURE 10.2 Electron micrograph of intracytoplasmic MV form of vaccinia. The virions have a characteristic brick shape with a biconcave central core. (Courtesy of Maria Tsokos, and Mones Abu-Asab, Laboratory of Pathology, NCI. With permission.)

A wide range of vaccinia promoters are available for expression of transgenes. It is necessary to use vaccinia promoters for creation of the recombinant vectors, as these are specific for vaccinia polymerase. Eukaryotic promoters will not function in vaccinia infection as the host cell polymerase is not present in the cytoplasm where vaccinia transcription occurs. Several natural and synthetic early and late promoters have been described with various levels of activity [49,50]. The native vaccinia promoters are generally very strong and compare favorably to other viral promoters used in other viral vectors. The synthetic early/late promoter described by Chakrabarti et al. [50] has led to consistent, reliable high levels of gene expression in numerous systems tested.

Several methods for selection of recombinant viruses are available. Growth in the presence of the thymidine analogue BdU_r can be used to select for a TK negative phenotype in select cells after recombination into the TK locus [51]. Others have commonly used the selection gene xanthine-guanine phosphoribosyltransferase (XGRPT) which allows for selective growth in media containing mycophenolic acid [52]. Positive selection through replacement of an essential gene previously deleted from a backbone virus grown on permissive cell lines is also available [53]. β -Galactosidase and green fluorescent protein can aid in selection of recombinants. Once the shuttle plasmid is constructed, it can be transfected into a cell that has been infected with vaccinia. Homologous recombination leads to the insertion of the foreign gene into 0.1% of progeny virus

genomes [6]. The use of at least 3–5 rounds of selection ensures that there is no contaminating parental virus.

In order to improve the efficiency of creating recombinant vaccinia viruses, Domi et al. [54,55] have developed vaccinia-bacterial artificial chromosome (VAC-BAC) technology to allow one-step insertion of a gene of interest into the VAC-BAC plasmid, selection in *Escherichia coli*, and then transfection of the DNA into fowlpox-infected helper cells to generate infectious vaccinia virions. This avoids the need for multiple time-consuming plaque purifications.

10.4 *IN VITRO* GENE TRANSFER VECTOR

It has long been recognized that vaccinia is a valuable tool for expression of foreign genes *in vitro* [56,57]. It is relatively easy to make recombinant viruses and to grow and purify the virus. Large inserts can be accepted in the genome, and strong synthetic promoters lead to high levels of protein expression from infected cells. The virus has a broad tropism and will infect and replicate in most mammalian cells. The high efficiency of expression with vaccinia obviated the need for other vectors which permanently integrated into the genome and the cloning of high-expressing cells. Infection with recombinant vaccinia leads to high levels of expression of foreign genes that are processed in the appropriate way such that their function can be studied. Vaccinia infection of cells at an multiplicity of infection (MOI) of 1.0 leads to greater than 99% of cells expressing the gene of interest in most cell lines. Rather than make recombinants, simple

plasmid transfection in a virally infected cell leads to efficient expression of foreign genes. The gene must be placed under control of a vaccinia promoter. The backdrop of vaccinia infection allows for cytoplasmic transcription avoiding the inefficient process of trafficking into the nucleus. This leads to greater than 90% of cells expressing foreign genes after simple plasmid transfection [58]. This efficient transient expression system has been utilized for the functional analysis of innumerable foreign proteins over the years. Inactivation of the virus with psoralen and UV light can result in an efficient expression vector that does not cause a cytopathic effect [59]. This may be important for the functional analysis of some proteins.

10.5 HOST IMMUNE RESPONSE TO VACCINIA

The immune response to vaccinia viral vectors serves as our paradoxical friend and foe in the attempt to develop vaccinia as an effective vector for gene therapy. On the one hand, the vigorous immune response is desirable because we believe that it enhances its potential as a vaccine. On the other hand, the vigorous immune response leads to premature clearance of the virus before adequate levels of replication have occurred, thus decreasing the level of transgene expression and possibly the overall efficacy.

Most viruses which infect human cells are also endemic in the population, and therefore many patients will have circulating antibodies against the viruses and preformed cellular precursors. Vaccinia is unique in that it is not endemic to humans, and since wide scale smallpox immunizations terminated in the 1970s, young patients will not have been exposed to the virus. Most cancer patients, however, are older and have been

exposed to vaccinia. As with other viral vectors, reinfection is possible after prior exposure. Laboratory workers and military personnel who undergo revaccination for smallpox usually form pox vesicles in the skin, despite prior vaccination. This has also been demonstrated in tumor vaccine trials in patients previously immunized [60]. Workers at vaccine production plants in the past suffered from repeated skin infections with vaccinia and pox lesions in the skin. Some viruses can avoid circulating antibodies by mutating their coat proteins and changing serotype. This is not seen with vaccinia virus. However, vaccinia has evolved expression of immunosuppressive proteins [61–63]. Viral surface proteins act to inhibit complement, and the extracellular envelope is known to be almost completely resistant to antibody neutralization [64].

Both cellular immunity and neutralizing antibodies play a role in protection from vaccinia infection. The T-cell response to vaccinia seems to be quite potent and is probably more important than antibodies in the primary host resistance to the virus. Progressive vaccinia infection correlates with a defect in cell-mediated immunity [65]. In murine models, lacking a functional T-cell population, vaccinia is able to replicate and express genes within tumor cells at high levels for greater than 30 days [66]. On the other hand, in an immunocompetent host the window of gene expression only lasts for about 8 days with high levels of gene activity lasting approximately 4 days [67].

The success of vaccinia as a gene therapy vector relies on its efficiency *in vivo*, thus vaccinia virus possesses a wide range of immune evasion strategies in order to survive (Table 10.2). Understanding and manipulating these factors may optimize the vector for clinical use. If one examines

K3L	Prevents phosphorylation of e1F2 α	[61,62,167]
N1L	Inhibits NF- κ B	[170,171]

these factors closely, it is clear that the majority of them encode for proteins that are able to actively suppress both innate immunity and the development of a T helper 1 (Th1) immune response. For example, vaccinia virus has adopted at least three different genes whose product can block the function of the type 1 interferon family members IFN- α and β [68–70]. These factors are secreted by a variety of cells in response to innate danger signals. They can induce an antiviral state and upregulate adaptive immune functions. Vaccinia also carries genes for multiple inhibitors of chemokines, some of the earliest substances produced during the initiation of an immune response [71–73].

Vaccinia encodes for at least three factors that can directly block the function of IFN- γ , one of the most potent Th1 cytokines [70,74–76]. In addition, vaccinia encodes for the recently described IL-18 binding protein (IL-18BP) [77–81]. IL-18BP is a naturally produced soluble factor that blocks the binding of IL-18 to its cognate receptor. IL-18BP has been shown to be one of the most potent inhibitors to the development of a Th1-biased immune response [79]. Vaccinia virus also encodes for several other immunosuppressive factors including factors to block complement activation, IL-1 β soluble receptor, and soluble TNF-receptor antagonist [72,82–90]. These observations suggest that subverting the early innate immune response and slowing development of Th1 responses is important for the efficacy of vaccinia therapy.

Other studies have confirmed the critical role of the Th1 response to clearance of vaccinia viral infection. Van den Broek et al. examined the effect of Th1 (IFN- γ , IL-12) and Th2 (IL-4, IL-10) balance in the clearance of vaccinia virus in mice using cytokine knockouts [91]. Vaccinia viral replication was enhanced in IL-12 and IFN- γ knockout mice, with IL-12 $-/-$ demonstrating greater susceptibility to infection than IFN- γ deficient mice. Interestingly, development of anti-vaccinia CTL was completely abrogated in IL-12 $-/-$ mice but remained normal in IFN- γ $-/-$. In contrast, IL-4 and IL-10 deficient mice showed marked enhancement of vaccinia viral clearance, suggesting that these cytokines naturally suppress the host response to vaccinia. IL-10 $-/-$ mice exhibited greater inhibition of viral replication than IL-4 deficient mice. When the effects of each of these cytokines on vaccinia infection was examined in recombinant viral constructs, local expression of IL-4 showed a much greater inhibition of host responses. In fact, while the absence of IL-10 resulted in improved clearance of vaccinia virus which was mediated by increased levels of IL-6 and IL-1, the local expression of IL-10 had little to no effect on viral clearance. Similarly, Deonarain et al. have shown that IFN- α/β knockout mice demonstrate markedly enhanced susceptibility to vaccinia-viral infection [92].

There are several strategies that have been investigated to circumvent this problem of premature immune clearance. First, one could create a virus that is less recognizable by the immune system. This could be accomplished by mutating the viral coat of the vaccinia virus to make it less cross-reactive with antibodies. However, the Poxviridae and in particular vaccinia virus are antigenically very complex and it is unlikely that one or two mutations in viral envelope genes could significantly alter

antibody recognition. Further any mutations in the viral envelope may decrease the infectivity of the virus. Another strategy would be to develop other poxviruses that are able to selectively infect and lyse human tumor cells but do not cross-react immunologically with vaccinia virus. Viruses from the Yatapox genus infect monkeys and secondarily have infected monkey caretakers [93]. These viruses do not cross-react with vaccinia, yet they cause human disease and replicate in human cells. The yaba-like disease (YLD) virus is under investigation as another replicating poxvirus for tumor-directed gene therapy [18]. Avian poxviruses also do not cross-react with vaccinia virus and have become popular expression vectors [94]. They do not replicate in human cells and are less efficient vectors overall.

Another approach to circumventing premature clearance of a vaccinia vector is to create a viral recombinant that actively suppresses host cellular immune responses. Several groups have reported that insertion of Th2 like cytokines such as IL-4 or IL-10 into vaccinia virus increases *in vivo* viral replication and slows host clearance of infection [91,95]. However, creation of a virus that is not recognized by the immune system obviously creates serious safety concerns for the population as a whole as unforeseen events could lead to a pathogenic virus which is not immunologically cleared.

A third approach to improving *in vivo* viral replication involves reversible, transient host immunosuppression. Because of the growth of knowledge in solid organ transplantation we now have available multiple immunosuppressive agents that can very precisely target specific pathways of the host immune response. This knowledge combined with our growing understanding of the immune response to vaccinia virus should allow us to reversibly slow the immune response theoretically allowing for more efficient *in vivo* viral replication in the tumor, higher transgene expression and greater oncolysis. This will be a feasible approach with vaccinia mutants exhibiting tumor selectivity.

10.6 *IN VIVO* PATHOGENICITY AND BIODISTRIBUTION

Vaccinia virus has been used as a live vaccine in the smallpox eradication program, and more recently as a vaccine against cancer [96]. It has not been widely accepted as a potential tumor-directed gene therapy vector, however, due to concerns regarding the safety of a systemically administered, replicating virus. With the recent heightened interest in the smallpox vaccine due to threats of bioterrorism more information has emerged regarding the safety of the smallpox (vaccinia) directly and secondary spread to healthcare workers, immunocompromised patients, and family members [97]. Although it is generally considered to be a relatively safe vector for vaccinations, a defined risk exists for generalized vaccinia, vaccinia-associated encephalitis, vaccinia necrosum, and eczema vaccinatum in infants and the immunosuppressed population, specifically those with deficits in cellular immunity [98–103]. Vaccinia-associated encephalitis is a recognized complication of smallpox vaccination that can lead to death, and vaccinia can be recovered from the central nervous

FIGURE 10.3 Example of vaccinia necrosum in a 66-year-old male 50 days after vaccination with a vaccinia melanoma cell lysate. The man had chronic lymphocytic leukemia. (From Wills V.L., et al., *Aust. N. Z. J. Surg.*, 70, 149, 2000. With permission.)

system [102]. Classically, vaccinia infection in immunosuppressed patients leads to a progressive necrotic ulcer known as vaccinia necrosum. This ulcer can progress to destroy significant amounts of tissue, leaving exposed bone, requiring tissue grafts or amputation [104] (Figure 10.3). Often this dramatic local infection does not lead to systemic viral spread. Patients with eczema, however, can get vaccinia infection of eczematous skin throughout the body (eczema vaccinatum). A large viral load such as this leads to fever and malaise and can lead to death from a “septic syndrome.” The risk of secondary spread of vaccinia has been estimated to be in the range of 10% and of secondary cases the mortality rate was 11% [97]. As with the vaccine, risks of secondary infection are most common in children, patients with dermatological conditions such as eczema, and immunocompromised individuals [97].

The exact cause of vaccinia pathogenicity and lethality in animal models is difficult to determine. Mice moribund from wild-type vaccinia infection have demonstrated high levels of circulating inflammatory cytokines, and it is suspected that the systemic inflammatory response syndrome (SIRS) plays a significant role in viral pathogenicity as opposed to specific organ dysfunction (Naiak, A. et al., unpublished data).

The biodistribution of systemic injection of wild-type and TK-deleted vaccinia virus has been studied extensively in many animal models, including mice, rats, rabbits, and primates [10,67,105]. The highest titers of recoverable virus are always from the ovary. Many-fold less virus is recoverable from the liver, spleen, lung, and brain. Cutaneous pox lesions can form which have high titers of vaccinia. Mutations (such as TK-deletion) which attenuate the virus by making it less efficient for replication in nondividing cells are less recoverable from normal organs after systemic injection [106].

10.7 SAFETY CONSIDERATIONS AS A GENE THERAPY VECTOR

Safety considerations for cancer gene therapy vectors include direct pathogenicity of the virus, toxicity of the therapeutic gene product, genome insertion with risk for malignant transformation and germ line mutations, teratogenesis, and the ability to recombine with endemic virus or spontaneously mutate to form a more virulent pathogen. Because vaccinia is a cytoplasmic virus, the viral DNA does not transport to the nucleus and therefore integration into the genome is very unlikely. In addition, there is no known latent infection with vaccinia virus and all cells infected by the virus will be killed by the virus. In addition, since poxviruses are not endemic in the population, it is extremely unlikely for recombinations to occur in patients between attenuated strains and wild-type strains which would result in a more virulent virus with world health implications [107]. The stability of the virus has already been proven during vaccination as part of the small pox eradication program, so it is unlikely for spontaneous mutations to occur which would change the pathogenicity.

On the other hand, the properties that make it a useful virus for tumor-directed gene therapy also make it potentially dangerous. It replicates efficiently in human cells, and its pathogenicity as a systemically delivered virus in humans is unknown. The scarification of the skin during vaccination for small pox results in viral replication in the dermis, pox formation over 5–7 days, followed by an aggressive immune response against the virus which eliminates the virus and prevents systemic spread. A permanent scar in the skin results from the infection. It is not difficult to imagine that if such an infection occurred in an organ such as the brain that this could result in a poor outcome. During vaccination for smallpox, some patients with T-cell deficient immune systems suffered progressive systemic infection and death from vaccinia [65]. In vaccine trials for HIV patients, deaths have been attributed to systemic viremia in the setting of an immunocompromised host [108]. While intradermal delivery is quite safe for the vaccine strains, more virulent strains such as WR delivered systemically may be more pathogenic. These viruses need to be carefully examined in preclinical toxicology studies prior to human trials.

Vaccinia and other poxviruses have been identified, designed, or treated such that they no longer replicate in human cells, but still efficiently express genes. These include the MVA strain (attenuated by serial passage in chick embryo fibroblasts, until it no longer replicated in human cells), NYVAC (life cycle blocked prior to DNA replication in non-avian cells), fowl poxvirus, and entomopox viruses [109–111]. Vaccinia can also be reliably inactivated using UV light and psoralen such that early genes are still expressed, but no cytopathic effect or replication occurs [59]. Also, viral mutants can be constructed with deletions in essential genes preventing replication except in cell lines where the gene is compensated for by stable integration into the genome. While nonreplicating viruses improve the safety profile, they would not be expected to be efficient for the purpose of tumor-directed

gene therapy. Any mutations which result in improved tumor specificity and decreased systemic virulence should be considered. An efficient strain of vaccinia virus such as WR may be mutated to inhibit replication in nondividing cells, but maintain efficient replication in tumor cells. This would significantly decrease viral pathogenicity but maintain the efficiency of vaccinia as a vector. An enzyme/prodrug approach may inhibit viral replication and provide a switch for turning off infection prior to host toxicity. Treatment with 5-fluorocytosine (5-FC) prolonged survival in a model where mice were administered a lethal dose of vaccinia expressing the cytosine deaminase gene [66]. This was the original intention of "suicide genes" and needs to be explored further in vaccinia [112].

Other strategies towards improving the safety of this vector have been described [46,47,96,113,114]. One strategy to attenuate the virus has been the deletion of genes required to evade the host immune response [61]. As discussed above, vaccinia expresses several proteins that interfere with the host response to viral infection. These include inhibitors of apoptosis such as the serpins SPI-1(B22R) and SPI-2(B13R), inhibitors of cytokines such as interferon, interleukins, tumour necrosis factor, and mechanisms to evade complement (vaccinia complement control protein). Deletions of many of these proteins have led to attenuation of the virus. Safety can also be improved by actively improving the host immune response against the vector. Vaccinia engineered to express inflammatory cytokines is rapidly cleared by the host, leading to decreased pathogenicity. IL-2 expressing vaccinia is rapidly cleared by NK cells, leading to marked attenuation. IFN- γ expressing vaccinia was also less virulent [115]. Another strategy to attenuate the virus has been the deletion of genes required for viral DNA synthesis. Deletion of the vaccinia TK gene or vaccinia growth factor (VGF) genes renders the virus dependent on the nucleotide pool of the host cell [46,47]. A mutant vaccinia virus with both the TK and VGF genes deleted was highly attenuated in nude mice [116].

10.8 CLINICAL EXPERIENCE

10.8.1 SMALLPOX VACCINATION

Extensive clinical experience exists with vaccinia virus as a vaccine for the eradication of smallpox. The most common commercial preparation used in the United States was the Wyeth Dryvax [117]. It is the only vaccine available today. The virus was produced by infection of live calves by dermal scarification, followed by physical scraping of the skin. Future vaccines will be produced on cell lines, and ongoing trials are comparing strains for safety and efficacy [104]. The vaccine is delivered by scarification of the skin. The lyophilized virus is reconstituted and spread on the skin. A scarification needle is then used to penetrate the dermis through the vaccinia coat in multiple places. Effective vaccination is indicated by the development of pustules 6–10 days after vaccination. The pustules represent replicating vaccinia within the dermis. Live virus can be recovered from the pustules from days

3 through 14 after vaccination. There is a direct relationship between the intensity and extent of virus multiplication in the skin and the magnitude and duration of antibody response. The immune protection seems to last a lifetime, including both circulating antibodies and memory T cells [118]. The current recommendation, however, is to be boosted with vaccinia every 10 years.

Adverse events occurred in about 1250 per million vaccinations, as described above, including vaccinia necrosum, vaccinia-associated encephalitis, and eczema vaccinatum [118]. Aggressive dermal replication occurred almost exclusively in patients who were T-cell immunodeficient. The majority of deaths occurred in infants who suffered postvaccinal encephalitis. The risk of complications increased with the more virulent strains of virus used in Austria and Denmark. Despite worldwide use of this live virus vaccine, no reported adverse events related to mutation of the virus to a more aggressive phenotype was ever reported. No viral-induced tumor formation has been reported. Overall the virus is remarkably safe for use in humans, despite controlled viral replication in the skin of a potentially destructive virus.

10.8.2 OTHER VACCINES

After proven success as a vaccine responsible for the elimination of endemic smallpox in the world, the obvious leap towards using vaccinia as a vaccine for other indications was made, and vaccinia was engineered to express antigens from other infectious agents. Likewise as tumor antigens were recognized and defined, vaccinia was used as a cancer vaccine. The size of the vector allows for flexibility in engineering, such that immune enhancing genes and antigen genes can be recombined together into the genome. In general, these approaches do not rely on targeting of any specific tissues and may not require viral replication. Rather they are designed to take advantage of the immune stimulatory effects of the complex viral particle and the efficient transcriptional machinery of the virus. For safety considerations, nonreplicating vaccinia mutants were developed. The known inflammatory response to the vector combined with expression of tumor antigens and immunostimulatory molecules holds promise for cancer therapy. The potential seems great, but controversy exists as to whether complex immunogenic viruses like vaccinia may be less effective as vaccine vectors against proteins foreign to the virus. It is possible that weaker epitopes from tumor-associated antigens are effectively hidden by the strongly immunogenetic vaccinia proteins [119].

Vaccinia virus has been utilized in multiple clinical trials as vaccines for treatment of a variety of tumors as well as treatment of infectious diseases such as rabies, malaria, papilloma virus, mycobacterium, and HIV (Table 10.3). Vaccinia virus has been delivered as subcutaneous, intramuscular, intratumoral, and intravesical (bladder) injections in clinical immunotherapy trials without significant vector related toxicity [60,120,121]. Doses of up to 10^9 plaque forming units (pfu) have been delivered safely. Intravenous injection of fowlpox virus has been performed with no significant toxicity; however,

this species does not replicate in human cells [122]. No systemic injection of a replicating vaccinia virus has been performed in human trials.

Approximately 69 clinical trials have been reported in the English literature using poxviruses (PubMed search); 39 of these are tumor vaccines and 30 are for infectious diseases. Over half use replicating vaccinia virus and about 20% use MVA. Allogeneic cell lysate vaccines incorporating vaccinia virus have been explored the most in clinical trials. In these studies vaccinia was not used as a vector, but as an immunogen, and the virus was not replication competent. A phase III randomized, double blind, multi-institutional trial of an allogeneic vaccinia virus-augmented melanoma cell lysate (VMO) vaccine was performed with 250 patients from 11 centers [123]. A 10% survival advantage to VMO-treated patients was detected; however, this was not statistically significant. Hersey et al. in Australia also reported an improved survival in patients treated with an allogeneic vaccinia melanoma cell lysate (VMCL) vaccine [124,125]. In many of these trials, DTH response and development of antibodies to tumor antigens correlates with disease free survival. No vaccinia pathogenicity was observed.

Eder et al. reported a phase I trial of vaccinia expressing prostate specific antigen (PSA) in prostate cancer patients [126]. The virus was delivered intradermally every 4 weeks for three doses. No significant toxicities were related to the virus, which was a Wyeth strain. A cutaneous reaction consistent with viral replication was seen in all patients treated with 2.65×10^7 pfu vaccinia or greater. After the third dose, 14 of 19 patients continued to demonstrate cutaneous replication. Several patients developed T-cell immune responses associated with prolonged stabilization of their cancer.

Preclinical and clinical data suggest an advantage to a prime-and-boost strategy using two different vectors [127]. This has become popular with poxviruses, given the immunologically diverse poxviruses available as expression vectors. Vaccinia virus has been combined with fowlpox virus, Sindbis virus, peptides, and plasmid DNA. A recent clinical study examined recombinant vaccinia expressing NY-ESO-1 followed by recombinant fowlpox-NY-ESO-1 in a prime boost setting for cancer patients. One of eight patients with melanoma had a complete response [128]. Vaccinia expressing CEA has been studied clinically as a priming vaccine followed by a boost with avipox expressing CEA [129]. This regimen consisted of 1×10^7 pfu Wyeth strain vaccinia injected intradermally, and it was well tolerated. Specific T-cell immune responses were generated without clinical responses.

A good example of the utility of vaccinia as an immune vector is the development of rV-CEA TRICOM by Greiner et al. [130]. This vaccinia expresses a triad of costimulatory molecules: B7.1, ICAM-1, and LFA-3 along with CEA for a vaccine against CEA expressing cancers. A phase I study of Fowlpox-CEA(6D)-TRICOM sequentially with Vaccinia-CEA(6D)-TRICOM with GM-CSF was reported demonstrating 40% stable disease for at least 4 months, and 1 of 58 patients had a complete pathologic response [131]. Poxviruses have also been used to infect dendritic cells and express antigens and costimulatory molecules for vaccination. A phase I trial was reported of dendritic cells infected with fowlpox encoding CEA and costimulatory molecules, demonstrating safety but minimal clinical efficacy [132].

10.8.3 REPLICATION-SELECTIVE VACCINIA: ONCOLYTIC THERAPY

The extent of experience with vaccinia over the years and its proven safety record has led to acceptance of exploration of this vector in more novel delivery systems for terminal cancer patients. As the field of tumor-directed cancer gene therapy has developed, the study of tumor-selective replicating viruses has become an important endeavor. Because of the known ability of vaccinia to destroy tissue (a complication of smallpox vaccination known as vaccinia necrosum) [133] vaccinia has also been developed as a direct oncolytic virus for cancer therapy. The concept of utilizing replication-competent viruses to selectively destroy tumors is quite appealing. Numerous viruses have been explored as tumor-selective replicating vectors, including adenovirus, herpes simplex virus, reovirus, newcastle disease virus, autonomous parvovirus, measles virus, vesicular stomatitis virus, coxsackievirus A21, and vaccinia virus [134–136]. Advantages and disadvantages exist for each of these vectors, and some limitations are common to all vectors.

Vectors are most limited by inefficient replication *in vivo*, inefficient tumor targeting, and safety concerns. Vaccinia has many characteristics that overcome these limitations: (1) It has a quick, efficient life cycle, forming mature virions in just 6 h after infection. (2) It spreads efficiently cell to cell thus increasing the efficacy of an *in vivo* infection. (3) It has a large genome that can accept over 25 kb of inserted DNA without deletions. (4) Vaccinia virus carries its own strong promoters capable of achieving very high levels of transgene expression. (5) It can infect a wide range of human tissues but does not cause any known human disease. (6) Lastly, there is a large body of knowledge about its biology and extensive experience with it clinically as part of the smallpox vaccination program.

Preclinical development has focused on mutating the WR strain of vaccinia virus to make it replication selective for tumor cells [66,116,137–139]. As well as being more tumor lytic *in vitro* [12], the WR strain of vaccinia virus appears to be more efficient *in vivo* than other strains used in vaccination trials. An intradermal injection of 10^6 pfu of a wild-type WR strain of vaccinia in rhesus macaques led to a necrotic ulcer of 108 cm² in diameter in only 8 days, without systemic spread of the virus (Figure 10.4). This compared to <1 cm for NYCBOH and Wyeth strains [140]. This ability to quickly spread, express genes, and destroy tissue to this extent is unique among current vectors in clinical and preclinical development.

Other nontumor sites of dividing cells need to be considered when developing tumor-selective viruses. These sites, known to suffer toxicity from chemotherapy agents, such as bone marrow-derived cells and gastrointestinal mucosa are not affected by systemic vaccinia in murine, rat, rabbit, or primate studies [10]. We and others have studied the wild-type virus and found that after intravenous injection, the highest amounts of virus can be recovered from the tumor and ovary, with minimal to no virus being recovered from other organs [12,67,105,116,141]. The natural tropism of this virus to tumor is surprising and the mechanism of this is not

FIGURE 10.4 (See color insert following blank page 206.) Cutaneous lesions 8 days after intradermal injection of 10^6 pfu of the various vaccinia viruses: vF13 (wild-type WR strain), vJS6 (TK- WR strain), vvDD (TK-/VGF- WR strain), WyTK+ (wild-type Wyeth strain), WyTK- (TK- Wyeth strain), NYCBOH (wild-type New York City Board of Health strain). (From Naik, A.M., et al., *Hum. Gene Ther.*, 17, 31, 2006. With permission.)

established. This tumor tropism was demonstrated in numerous tumor models, including murine colon cancer and melanoma, rat sarcoma, human colon cancer in nude mice, and rabbit kidney cancer. Historically, smallpox virus was noted to have tropism for injured and irritated skin. This is thought to be secondary to histamine release leading to leaky vasculature allowing for transfer of the virus out of the circulation. Vaccinia is a large virus particle (350 nm in diameter) and requires leaky vasculature for extravasation into tissues. This leaky vasculature is lacking in tissues such as the GI mucosa. Despite bone marrow-derived cells having ready access to circulating vaccinia, no bone marrow toxicity is encountered, even in animals succumbing to viral pathogenicity (unpublished observations). Bone marrow-derived cells are known not to infect well by vaccinia for unknown reasons. The one place that replicating virus is recovered is ovarian follicles. Notably tumors and ovarian follicles are both known to be sites of vascular endothelial growth factor (VEGF) production and leaky vasculature [142]. As demonstrated by immunohistochemistry, vaccinia tropism to the ovary is specific for ovarian follicles without infection or spread through normal ovarian parenchyma [116]. In addition, local hyperthermia, which increases the “leakiness” of tumor vessels, was shown to enhance viral delivery [143].

In order to develop more tumor-selective vaccinia viruses, a number of mutations have been introduced. The WR strain of vaccinia was mutated such that the VGF gene and the TK genes were deleted [12,116]. The TK gene is important for nucleotide synthesis and DNA replication, and is near essential for replication in nondividing cells where the host nucleotide pool is low. VGF is a protein that is

expressed early by vaccinia virus and is secreted by infected cells. It binds growth factor receptors on surrounding resting cells and stimulates them to proliferate. This increases the available nucleotides in these resting cells, priming them for vaccinia infection. Deleting both the TK and VGF genes leads to near complete abrogation of replication in resting cells, without decreasing the ability of the virus to replicate in the tumor environment as many tumors are known to have upregulated expression of EGF [12]. This mutant virus was found to have markedly enhanced tumor specificity (Figure 10.5). When tested in rhesus macaques it was found to be completely nonpathogenic when delivered intravenously at doses of up to 10^9 pfu [140]. Intradermal inoculation at 10^6 pfu demonstrated no viral replication. Nevertheless, 4 days after intravenous virus delivery, equal titers of wild-type and double-deleted virus could be recovered from subcutaneous tumors in mice [116]. This virus can be given systemically at doses of 10^9 pfu to a nude mouse without pathogenicity, and leads to marked responses in established subcutaneous tumors (Figure 10.6) [116]. The double-deleted WR strain virus has shown remarkable efficacy against the National Cancer Institute (NCI) panel of tumor cell lines (Figure 10.7) [12], and is significantly more tumor lytic than an oncolytic adenovirus Onxy-015 already in clinical trials.

A subsequent mutated WR vaccinia virus was made with deletions in SPI-1 and SPI-2 [139,144]. Viral serpin genes are required to help combat the host response to virus infection and SPI-1 and SPI-2 have been shown to inhibit apoptosis (Table 10.2) [145]. Normal cells and tissues would be expected to undergo apoptosis after infection with this mutant virus limiting infection and spread, yet viral replication should proceed normally in tumors which are known to harbor mutations in the apoptotic pathways [146]. This virus was able to replicate in tumors as well as the wild-type virus but was much less toxic. Systemic delivery led to

FIGURE 10.5 Differential viral recovery (median viral titers) from brain and tumor after systemic injection of 10^7 pfu wild-type, VGF-deleted, TK-deleted, and TK/VGF-deleted vaccinia virus in MC-38 tumor-bearing mice.

FIGURE 10.6 Antitumor response after systemic injection of 10^9 pfu of the TK/VGF-deleted virus in nude mice bearing 5 mm MC-38 tumors. (From McCart J.A., et al., *Cancer Res.*, 61, 8751, 2001.)

subcutaneous tumor regressions in both immunosuppressed and immunocompetent mice [139].

Other viral strains such as Wyeth, Lister, and LIVP have been similarly mutated to improve the tumor tropism of these viruses [147–149]. Wyeth and Lister are already attenuated vaccine strains of vaccinia virus and have been both further attenuated and rendered selective for dividing cells by insertional mutagenesis of the TK gene [147,148]. The LIVP strain was attenuated by three deletions: A56R encoding hemagglutinin, J2R encoding TK, and F14.5R an uncharacterized but highly conserved ORF. This led to improved survival of nude mice compared to wild-type virus. In contrast to the WR strain where tropism to the ovary is quite marked [116], LIVP is naturally not tropic to ovaries thus no viral recovery from the ovary was noted [149]. High-tumor replication and regression of established tumors in immunosuppressed mice was demonstrated.

In addition to the above mutations, which contribute to the tumor-selectivity of vaccinia virus, the antitumor efficacy has been enhanced by engineering transgenes into the deleted loci. The Wyeth and WR strain viruses were engineered to express GM-CSF in order to enhance the antitumor immune response [12,147]. Tumor-bearing, immunocompetent rats and rabbits showed significantly reduced tumor burdens after vaccinia-GM-CSF therapy [147]. Suicide genes such as cytosine deaminase and purine nucleotide phosphorylase [66,150,151] have also been used to improve the tumor responses. Interestingly, some prodrugs were also able to inhibit vaccinia replication [66] and may be able to be used as a safety switch if the viral infection becomes uncontrollable. The ability to noninvasively track vaccinia virus biodistribution and activity has been made possible by incorporating imaging transgenes such as the human somatostatin receptor

FIGURE 10.7 Cytopathic effect of JX-963 (vvDD expressing GM-CSF) versus Onyx-015 on a panel of human tumor cell lines. EC_{50} values were determined 3 days following infection of tumor cell lines with JX-963 and 6 days after Onyx-015 infection. The ratio of Onyx-015 EC_{50} to the JX-963 EC_{50} was plotted (a value greater than 1.0 indicates that JX-963 was more potent). (From Thorne S.H., et al., *J. Clin. Invest.*, 117, 3350, 2007. With permission.)

(SSTR2) for nuclear imaging (Figure 10.8) [152], green fluorescent protein for fluorescent imaging [116,149,153], and luciferase for bioluminescent imaging [148].

Clinical trials, focused directly on the oncolytic activity of vaccinia virus after intratumoral injections, have recently begun to recruit patients with metastatic melanoma (www.clinicaltrials.gov). Roenigk et al. described in 1974 direct injection of melanoma with vaccinia from standard vial smallpox vaccine (Wyeth strain) at unknown concentrations in 20 patients at 2 week intervals [154]. Numerous interesting antitumor responses of injected lesions were described. Even older studies from the 1960s describe the

treatment of warts with direct intralesional vaccinia injection with success [155].

Mastrangelo et al. reported their results of intratumoral injection of a NYCBH vaccinia strain expressing GM-CSF into cutaneous melanoma [60,156]. This was a phase I trial of escalating doses up to 2×10^7 pfu per lesion and 8×10^7 pfu per session (multiple lesions injected). Patients were administered twice weekly intratumoral injections over 6 weeks. Systemic toxicity was limited to mild flu-like symptoms that resolved within 24h and local inflammation at the injection site with doses of greater than or equal to 10^7 pfu per lesion. All patients were vaccinated against vaccinia within weeks

FIGURE 10.8 Posterior whole body images of tumor-bearing athymic mice 1 week after i.p. injection with vaccinia virus and 24 h after i.v. (tail vein) injection with ^{111}In -pentetreotide. Tumor (T) is visible on the right flank of vvDD-SSTR2-injected mouse (right) but not in the control vvDD-GFP-injected mouse (left). Prominent visualization of both kidneys (K) is noted in all animals as well as the tail (site of injection). The right (R) and left (L) sides of the mouse as well as the head (H) are indicated. (From McCart J.A., et al., *Mol. Ther.*, 10, 553, 2004. With permission.)

prior to receiving the vaccinia-GM-CSF. Interesting responses were seen in five of the seven patients treated. Three patients had mixed responses with complete regression of treated and untreated dermal metastases, one patient had a partial response with regression of injected and uninjected regional dermal metastases, and one patient with multiple dermal metastases confined to the scalp achieved a complete remission. This group plans to extend their observations with continued clinical trials using this vector.

10.8.4 TREATMENT OF POXVIRUS INFECTION

The treatment of orthopoxvirus infections has become of widespread interest recently due to the terroristic threat of biologic warfare with smallpox virus. As well, clinical trials utilizing vaccinia as a gene delivery vector would benefit greatly from a drug or compound which could turn off viral

replication. Vaccinia immunoglobulin (VIG) is the only approved product available for treating complications of vaccinia infection. VIG has been owned by the Department of Defense, with a small amount available through the Centers for Disease Control [103]. No randomized controlled clinical trials have been performed to evaluate therapeutic efficacy, and therefore there is doubt as to its effectiveness in established complications from vaccinia. A randomized trial examining concomitant treatment with vaccinia and VIG demonstrated a significantly lower rate of postvaccinial encephalitis. Recommendations from the Bioterrorism Preparedness and Response Program suggest VIG as first line therapy and cidofovir as second line therapy for severe adverse reactions to vaccinia vaccines [157].

Numerous antiviral drugs have been tested in animal models of orthopoxvirus infections [158] (Table 10.4). Of the licensed antiviral compounds, cidofovir has the greatest potential for protection against and treatment of vaccinia infections [159,160]. Numerous other agents have also been identified that demonstrate efficacy against different poxviruses. The pharmacokinetics and safety profile for most of these agents have not been defined in humans, so their true utility will have to be determined in the future.

Suicide genes engineered into the virus may function to decrease viral replication upon addition of the prodrug. This has been demonstrated experimentally both *in vitro* and *in vivo* using a vaccinia expressing cytosine deaminase followed by the addition of 5-FC [66]. Prolonged survival after inoculation with a lethal dose of vaccinia in a murine model was achieved with addition of prodrug compared to controls. Future studies with more potent enzyme/prodrug systems may enhance this effect. Combinations of antiviral drugs and prodrugs may improve outcome.

The recent finding that the cell-to-cell spread of vaccinia is dependent upon the phosphorylation of src- and abl-family tyrosine kinases has enabled the development of a new family of drugs. Drugs such as ST-571 (Gleevec), an Abl-family kinase inhibitor, improve survival from a lethal vaccinia challenge in mice by inhibiting viral dissemination [41].

The development of tightly regulated inducible gene expression systems would allow for *in vivo* induction of genes, which would be toxic to the virus itself and inhibit viral replication. This has been difficult in vaccinia virus, because of its unique transcription system. Nevertheless, Traktman et al. have reported on a tetracycline-inducible expression system in vaccinia [161]. This system should be explored further to demonstrate the potential for *in vivo* induction of genes that are self-toxic.

10.9 SUMMARY

Vaccinia virus is an interesting gene expression vector, which is worthy of continued exploration as a gene therapy vector. It is an efficient, destructive virus with some element of baseline tumor specificity. Powerful transcription machinery can lead to very high levels of therapeutic gene expression within tumor cells, and its immunogenicity may lead to an improved immunotherapy application. Mutations lead to tumor-specific replication and direct oncolytic applications. Because the vaccinia virus can include multiple genes it would be possible to simultaneously express toxic genes, multiple suicide genes, cytokine genes, costimulatory genes, HLA genes, and tumor antigens.

Compared to other replicating vectors such as herpes virus and adenovirus, the study of vaccinia as a tumor-directed vector is in its infancy. Over time the advantages of this vector may become more apparent, and its applicability may be more significant as the population ages and more cancer patients have not been vaccinated against smallpox. Further understanding of the biology of the virus will improve our ability to manipulate it to our advantage and enhance its potential as a vector for tumor-directed gene therapy.

11 Baculovirus-Mediated Gene Transfer: An Emerging Universal Concept

Kari J. Aireenne, Anssi J. Mähönen, Olli H. Laitinen, and Seppo Ylä-Herttuala

CONTENTS

11.1	Introduction	263
11.2	Baculoviruses	264
11.2.1	<i>Autographa californica</i> Multiple Nucleopolyhedrovirus and Baculovirus Expression Vector System	266
11.2.2	Preparation of Recombinant Baculoviruses	268
11.2.3	Transduction of Vertebrate Cells and Other Nontarget Cells	269
11.2.3.1	Mammalian Cells	269
11.2.3.2	Stem and Progenitor Cells	270
11.2.3.3	Avian Cells	270
11.2.3.4	Fish Cells	270
11.2.3.5	Other Non-Lepidopteran Hosts	270
11.2.4	Transduction Optimization	270
11.2.5	Baculovirus Hybrid Vectors	272

11.1 INTRODUCTION

First commercial gene therapy treatments based on an adenovirus serotype 5 were launched recently in China [1–3]. Owing to the tighter regulatory rules, the first gene-based medicine in the Western world is expected to enter markets at the earliest by 2008 [4,5]. The emerging success is, however, still shadowed by an overall limited clinical success and the appearance of fourth cancer case in the French trial of X-SCID, laying clouds especially on the use of integrating vectors in gene delivery [6,7]. Indeed, much still remains to be solved before gene therapy becomes a standard clinical practice and further development of vectors is necessary [8]. In this context, baculoviruses have raised increasing interest

because they have a long history as safe insecticides [9] and gene delivery tools in insect cells [10,11], and the long-lived dogma of incompatibility with vertebrate cells has been revised [12–14].

Baculoviruses are common in nature and even in our food, and have been known for hundreds of years [9,15]. Still, no diseases have been linked to baculoviruses in any organism outside the phylum *Arthropoda* [16]. Baculoviruses have been studied since 1920s as insecticides against forestry and agriculture pests [9,17] and, therefore, a lot of data are available about their biology [16] and biosafety [11,18]. The baculovirus expression vector system (BEVS) became a popular choice for recombinant protein production during the late 1980s and 1990s, with a large number of commercially available reagents [10].

It became evident already in early 1980s that baculoviruses can penetrate into nontarget cells nonproductively, including many human cell lines. No viral replication or gene expression could be detected [19,20]. However, in 1985, Carbonell et al. [21] reported a first successful transduction of mammalian cells by a recombinant baculovirus bearing a promoter active in target cells (Rous sarcoma virus [RSV] long terminal repeat promoter) as part of the recombinant baculovirus genome. In 1995, Hofmann et al. [22] confirmed these results. They were also the first to suggest baculovirus-mediated gene therapy. There was a 10-year gap between these two papers probably because Carbonell and Miller [23,24] later claimed that their initial findings of low-level gene expression in mammalian cells were due to pseudotransduction. During the late 1990s, the concept of baculovirus-mediated gene transfer was further verified and the list of suitable target cells is still continuously increasing.

The fact that baculoviruses are efficiently destroyed by complement [25] delayed the first successful *in vivo* applications of baculovirus-mediated gene transfer to the beginning of the new millennium [14], although the feasibility of these viruses in an *ex vivo* perfusion model was reported soon after baculoviruses were suggested as tools for gene therapy [25]. Several reports have also demonstrated the use of baculoviruses *in vivo* applications, especially in immune-privileged tissues such as brain, eye, or testis [26–31]. Indeed, baculoviruses offer many advantages compared with other viral vectors in terms of safety, high capacity for the incorporation of foreign DNA, and easy production (Table 11.1). This chapter provides an overview of the history as well as current status of baculovirus-mediated gene delivery. Future trends are also discussed. For a more detailed background on the biology of baculoviruses, the reader can refer to an excellent book, *The Baculoviruses*, edited by Miller [16] and a laboratory manual by O'Reilly et al. [10] describing recombinant protein production in insect cells by BEVS.

11.2 BACULOVIRUSES

Baculoviruses constitute a family of viruses, the *Baculoviridae*, including more than 600 known members [32–34], which

infect permissively only arthropod hosts. The double-stranded circular DNA genome (80–180kbp) of baculoviruses [34–36] is condensed into a nucleoprotein structure known as a core [37]. The core is located within a flexible rod-shaped capsid, averaging 25–50nm in diameter and 250–300nm in length [34,38–40] and can expand relatively freely to accommodate even very large DNA inserts [41]. The core and the capsid are known collectively as a nucleocapsid. Membrane-enveloped nucleocapsids are referred to as virus particles or virions [10].

Traditionally, baculoviruses are divided into two morphologically distinct genera: nuclear polyhedrosis viruses (NPVs) and granulosis viruses (GVs). However, recently an updated classification according to baculovirus genetic relationships has been suggested. Comparisons of 29 baculovirus genomes indicated that baculovirus phylogeny follows the classification of the hosts more closely than morphological traits. The updated classifications include four genera: alphabaculovirus (lepidopteran-specific NPV), betabaculovirus (lepidopteran-specific granuloviruses), gammabaculovirus (hymenopteran-specific NPV), and deltabaculovirus (dipteran-specific NPV) [42]. In the NPV group, virions that obtain an envelope from nuclear membrane are occluded within a paracrystalline protein matrix (occluded virions [OVs]), forming large (1–15 μm) polyhedral inclusion bodies (PIBs) containing multiple virions. NPVs are further distinguished on the basis of whether they contain a single nucleocapsid (SNPV) or multiple nucleocapsids (MNPVs) per envelope in the polyhedrin matrix [43]. In contrast to NPVs, GV has only a single virion embedded in a very small inclusion body [10].

Baculoviruses exist in two distinct forms that play different roles during natural life cycle of the virus (Figure 11.1). Occlusion-derived virions (ODVs) are responsible for horizontal transmission between insect hosts, whereas systemic spread within the insect and propagation in tissue culture is dependent on budded viruses (BVs) [16,44,45]. Structurally, BVs and ODVs differ by the origin and composition of their envelopes [46]. BVs acquire their envelopes by budding through the plasma membrane whereas envelopes of ODVs are derived from the nuclear membrane of the insect cell. They also differ in the mechanisms by which they enter the host cells. BVs enter the cells by adsorptive endocytosis [47],

TABLE 11.1

Advantages of Baculoviruses in Gene Delivery

Advantages

Easy and fast preparation at high titers (>10¹⁰ pfu/mL)
 Capability to transduce all type of cells from any origin
 High capacity for DNA inserts (>100kb)
 Safe, no replication in mammalian cells (risk group 1 agents)
 Little or low cytotoxicity even at a very high moi
 Viruses stable at 4°C protected from the light
 FDA approved production system
 Automated virus generation possible for a high-throughput applications
 (drug screening, expression cassette optimization, etc.)

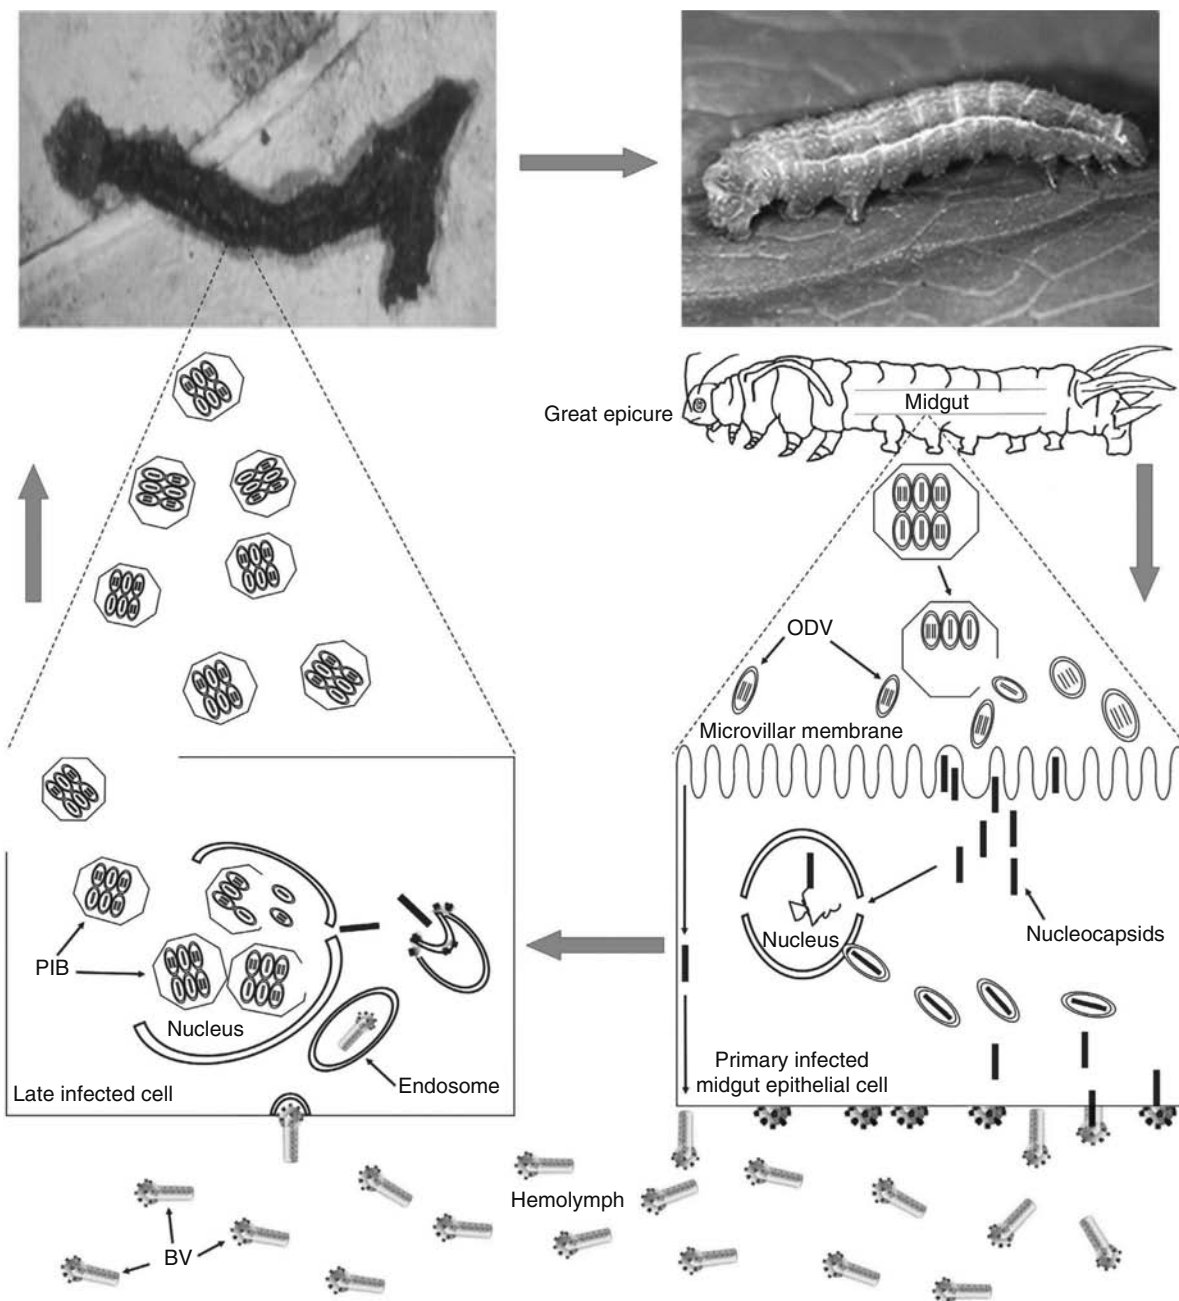

FIGURE 11.1 Life cycle of AcMNPV. Larva ingests virions containing PIBs with their nourishment. In the alkaline environment of the midgut, the PIBs break down and occlusion-derived virions (ODVs) infect primarily epithelia of the gut wall. ODVs fuse directly to the plasmalemma of epithelium and the nucleocapsids are transported into the nucleus. A minor proportion of nucleocapsids may travel through the cells in a process called transcytosis. The infection spreads through hemolymph inside the larva via BVs that contain an essential protein gp64 on their envelopes. Later in the infection, virions are packed into PIBs inside the nucleus of the infected cells. PIBs are released to the environment ready to infect the next hosts (horizontal infection) when cells lyse and larva dies. , PIB; , ODVs; , BV; , gp64 adhesion point in the plasma membrane of infected cells; , nucleocapsid.

but ODVs enter the midgut epithelial cells via direct membrane fusion at the cell surface [48,49]. PIBs are formed during late phase of natural infection by embedding the virions in the crystalline protein matrix, which is composed mostly of polyhedrin protein [50]. PIBs enable the horizontal infection of larva by contaminating the plant on which the

larva feeds [51]. The virions are protected from environmental factors within the PIB, but in the alkaline midgut of the larva, the crystalline polyhedrin matrix is solubilized [52] and the released virions enter the midgut cells by fusion with the membrane of the microvilli [53]. During the lytic cycle of infection, the cells release BVs from the basolateral area of

the midgut cells [54]. The spread of infection within the insect occurs from the midgut, through tracheal cells, to most tissues via the hemolymph [55–58]. Eventually, the larva dies and the PIBs that are produced in the very late phase of infection are released into the environment, and the cycle begins again. Most of the naturally occurring baculoviruses kill their target hosts within 4–7 days [17].

Baculovirus infection can be divided into early, late, and very late phases. Biologically these phases correspond to reprogramming the cell for virus replication (BV and PIB production). In the early phase (the first 6h), the virus prepares infected cell for viral DNA replication. This phase is also known as viral synthesis phase. Virus-specific RNAs can be detected in the cells by 30 min postinfection (pi) [59]. The late phase extends from 6 h pi to ~20–24 h pi. During this viral structural phase, late genes are expressed and the production of BVs starts around 12 h pi. Progeny nucleocapsids leave the nucleus and are transported onto the plasma membrane where they acquire their envelope. The occlusion-specific phase begins around 20 h pi. Production of infectious BVs decreases and packaging of virus particles into polyhedrin matrix begins, followed by the cell lysis [10]. The packaging into polyhedrin matrix (i.e., production of PIBs) does not usually take place with BEVS, because the polyhedrin gene has been deleted from most baculovirus genomes used in biotechnology procedures.

11.2.1 *AUTOGRAPHA CALIFORNICA* MULTIPLE NUCLEOPOLYHEDROVIRUS AND BACULOVIRUS EXPRESSION VECTOR SYSTEM

The prototype of the family *Baculoviridae* and the most extensively studied baculovirus is the *Autographa californica* multiple nucleopolyhedrovirus (AcMNPV). Its genome (~134 kbp) has been sequenced and predicted to contain 154 open reading frames [60]. Although the three-dimensional structure remains to be determined, the components of its cigar-shaped loosely enveloped virion are fairly well known [61,62]. The vp39 represent the major capsid protein of AcMNPV (Figure 11.2). It is randomly distributed over the capsid surface. The major envelope glycoprotein of the BV and ODV form is gp64 and p74, respectively. The gp64 is believed to be responsible for the formation of so-called peplomer structure at one end of the virion (Figure 11.2). The nucleocapsid of ODV and BV is similar but their envelopes differ in the composition (Figure 11.2). The differences in lipid and protein composition of BV and OV envelopes reflect different origin and functions during the virus life cycle [46]. Basic DNA-binding protein, p6.9, is shown to be present in the virions of several baculoviruses, including AcMNPV. It may become phosphorylated upon entry into the insect cells, which may result in unpackaging of the viral DNA [63,64].

FIGURE 11.2 Schematic illustration of the budded form of AcMNPV. (Modified from Funk, C.J., Braunagel, S.C., and Rohrmann, G.F., *The Baculoviruses*, Plenum Press, New York, 1997.)

FIGURE 11.3 Baculovirus penetration into a target cell. Baculovirus enters cell by endocytosis via attachment and activation of unknown receptors. Nucleocapsid escapes endosome in a pH-dependent process mediated by baculovirus major envelope glycoprotein gp64. Actin is involved in intracytoplasmic movement and nuclear entry of a large nucleocapsid. Nucleocapsid disassembly takes place in the nucleus, and the double-stranded DNA genome is exposed. Transient transgene expression is promoter dependent. See text for more detailed description. Authentic electron and confocal microscopy pictures represent virions from the corresponding steps of entry. Nucleocapsids are shown by white arrows.

AcMNPV enters insect cells by adsorptive endocytosis [47] (Figure 11.3). The role of the major envelope glycoprotein, gp64, is essential for viral entry. It mediates virus binding to the cell surface and pH-dependent escape of the AcMNPV capsid from the endosomes [65]. Glycoprotein gp64 is necessary and sufficient also for virus preparation, because it is needed for efficient virion budding from the insect cells [66]. The cellular receptors for AcMNPV attachment and entry still remain to be revealed [67–69].

The range of transfer plasmids and parent viruses available for the AcMNPV, and the characteristics (growth, expression level) of the cell lines supporting AcMNPV, have made it a standard for eukaryotic protein production. The most commonly used cell lines for AcMNPV are Sf-9 and Sf-21AE. They both originate from IPLB-Sf-21 cells, which were derived from *Spodoptera frugiperda* pupal ovarian tissue [70]. A cell line derived from *Trichoplusia ni* egg cell homogenates (BTI-TN-5B1-4 = High Five), however, has become a popular alternative to Sf cell lines due to the fact that these cells have been shown to produce up to 28-fold more secreted

proteins than any other insect cell lines [71–73]. These cell lines grow well in both monolayer and suspension cultures, and a serum-free culture medium can be used if desired.

To enable expression of a recombinant protein in insect cells, the gene for the desired protein is usually placed under a strong polyhedrin promoter (*polh*) of AcMNPV [10]. For other cells, a promoter active in the target cells, such as CMV (cytomegalovirus), RSV, or CAG (chicken β -actin promoter) must be used because *polh* is inactive in these cells. The *polh* is normally responsible for the synthesis of polyhedrin, which can constitute up to 50% of the total protein of the infected cell. Fortunately, polyhedrin is not essential to virus replication or infection in the cell culture [74]. However, the use of the *polh* promoter may be restricted in some cases by the fact that it is activated very late in the infection cycle at a point where the host cell machinery for posttranslational modifications is compromised. Problems with the *polh* promoter have been encountered, especially with proteins whose biological activity depends on proper glycosylation [75]. In such cases, the use of an alternative strong viral promoter that initiates

transcription earlier in the infection cycle (while the host post-translational modification pathways are still functional) could be useful. Indeed, Chazenbalk and Rapoport [76] were able to produce a more glycosylated and functional form of extracellular domain of the human thyrotropin receptor under a late basic protein promoter (*late*). However, engineered insect cells or virions are needed to mimic mammalian cell glycosylation of expressed proteins. While mammalian cells produce compositionally more complex N-glycans containing terminal sialic acids, insect cells mostly produce simpler N-glycans with terminal mannose residues [13,77]. Other promoters, which will be activated earlier than *polh*, include promoters for the p10 gene (*p10*), the major capsid protein gene (*vp39*), the basic 6.9-kD protein gene (*cor*), and the viral *iel* gene (*iel*). These promoters are available in a variety of baculovirus plasmids [10,78–80].

11.2.2 PREPARATION OF RECOMBINANT BACULOVIRUSES

Owing to the large size of baculovirus genome (80–180 kbp), a homologous recombination procedure was originally adopted to insert foreign genes into baculovirus genome, instead of conventional plasmid cloning techniques [81]. In practice, the target gene is subcloned into a transfer (donor) vector containing a suitable promoter, flanked by baculovirus DNA derived from a nonessential locus, such as the polyhedrin gene of AcMNPV. The viral DNA and transfer plasmid are then cotransfected into insect cells where the recombination events take place. Typically, 0.1%–1% of the resulting progeny is recombinant, which complicates their identification. If the target gene is inserted into the polyhedrin locus, altered plaque morphology of the recombinant viruses can be used for the identification of recombinant viruses. The cells in which the nuclei do not contain PIBs contain a recombinant virus. However, the detection of the desired PIB-minus plaque phenotype against the background of >99% wild-type parental viruses is difficult. Viral identification may be facilitated by the introduction of a *lacZ* cassette (β -galactosidase) along with the foreign gene, which enables the detection of the recombinant viruses according to a blue color [10]. Drug selection may also be used [82].

Several techniques have been developed to further facilitate and speed up the construction of recombinant baculoviruses [80,83]. By using a unique restriction site (*Bsu36 I*) at the polyhedrin locus, Kitts and coworkers [84] were able to linearize the double-stranded circular genome of AcMNPV. The linearization reduced the background of wild-type viruses and as a result, 10%–25% of the progeny viruses were recombinant. To obtain an even higher proportion of recombinants (85%–99%), Kitts and Possee [85] further modified the AcMNPV genome to enable *Bsu36 I* digestion to also remove an essential gene (ORF 1629) from the AcMNPV genome. Infective viruses will only be reconstituted by recombination with the transfer vector carrying the gene of interest, whereby an intact ORF 1629 will be restored to the genome. The system also enables a blue/white color selection of the recombinant viruses. However, it suffers

from the need of time-consuming plaque assays to purify the recombinant virus. A version of this system has been developed in which the target gene is amplified with specific primers using the polymerase chain reaction. This enables the ligase-free coupling of the linearized transfer vector and amplified gene in the mixture, which then can be used directly to transfect insect cells with cut viral DNA. The avoidance of cloning steps in *Escherichia coli* speeds up the construction of the recombinant viruses and simplifies manipulation of toxic genes [86,87]. To ease the manipulation of ORF 1629–deleted baculovirus genome, Je et al. [88] and Zhao et al. [89] have described a bacmid form of this virus that can be maintained in *E. coli*. These bacmids should also allow background-free virus preparation. However, generation of baculoviruses still relies on the inefficient homologous recombination in insect cells, and extraction and restriction enzyme treatment of the large ORF 1629–deleted viral genome (134 kbp) is troublesome.

Construction of the recombinant baculovirus genomes by direct cloning was first reported by Ernst and coworkers [90]. They introduced the *I-SceI* homing endonuclease site into the AcMNPV genome by homologous recombination. The new virus genome, called Ac-omega, can be cut with *I-SceI* meganuclease, and the target gene bearing compatible ends can be ligated straight to the linearized Ac-omega DNA under a polyhedrin promoter. A similar direct cloning system, Homingbac, utilizes *I-CeuI* homing endonuclease for the direct cloning of transgenes into *UDP-ecdyglycosyltransferase* locus of several baculovirus species. All Homingbac viruses were designed to retain the polyhedra phenotype so that they could be inoculated *per os* to insects [91]. Direct and directional cloning into baculovirus genome by *Bsu36 I* has also been reported [92,93]. Direct cloning is simpler than homologous recombination in insect cells, but owing to the normal background problems encountered with conventional cloning techniques, the need of plaque purification cannot be entirely avoided. In addition, handling of the large AcMNPV genome (134 kbp) makes the method inconvenient. Another *in vitro* technique based on the preparation of recombinant baculoviruses by *Cre-loxP* system has also been described [94]. The advantage of this method is a possibility to recover cloned inserts from baculovirus genome into *Cre/loxP* compatible plasmids. However, only up to 50% of the viral progeny are recombinants.

To avoid laborious and time-consuming plaque purification process, the genetic material can be introduced into the baculovirus genome in yeast or bacterial cells. Patel and coworkers [87] reported a novel method of propagating the viral genome by homologous recombination in the yeast *Saccharomyces cerevisiae*, where the appropriate recombinants can be more easily selected. Viruses are then obtained by transfecting insect cells. This method is rapid (pure recombinant virus within 10–12 days), and it ensures that there is no parental virus background. It also eliminates the need for time-consuming plaque assays, and multiple recombinants can be readily isolated. The major disadvantages of this system are the need of experience in yeast culturing and

the incompatibility of traditional transfer vectors with the system. An even faster, and currently the most popular, approach for generating recombinant baculoviruses uses site-specific transposition with Tn7 to insert foreign genes into bacmid DNA (virus genome) propagated in *E. coli* cells. The *E. coli* clones containing recombinant bacmids are selected by color (β -galactosidase), and the DNA purified from a single white colony is used to transfect insect cells [95]. The system has the same advantages as the yeast system but is faster (pure recombinant virus within 7–10 days) and easier to work with for those not familiar with the yeast cells. A variant of the transposon-based baculovirus generation system was published in 1995 [96]. The poor selection features of the original system have recently been overcome by a modified donor vector (pBVboost) and an improved selection scheme of the baculovirus bacmids in *E. coli* with a mutated levansucrase gene from *Bacillus amyloliquefaciens*. The new selection schema bypasses the disadvantages associated with the original transposition-based generation of baculovirus genomes in *E. coli* while retaining the simple, rapid, and convenient virus production [97,98]. Baculovirus generation in *E. coli* by genetically integrated cloning strategy (MAGIC) [99] or phage λ red system [100] has also been described.

11.2.3 TRANSDUCTION OF VERTEBRATE CELLS AND OTHER NONTARGET CELLS

Baculoviruses have extensively been studied in the past for their ability to infect nontarget cells for safety considerations with regard to their use as biological pesticides (see Section 11.2.8). Early work by Volkman and Goldsmith demonstrated that baculoviruses were able to enter certain cell lines derived from vertebrate species [20]. Thirty-five nontarget host cell lines, 23 of human and 12 of nonhuman vertebrate origin, were exposed to AcMNPV. However, no evidence of viral gene expression was obtained. This study was in accordance with the earlier reports showing uptake of AcMNPV by several vertebrate cell lines with no evidence of viral replication [19,101]. Carbonell and coworkers [21] were the first to show in 1985 that by constructing a recombinant baculovirus bearing a suitable promoter, marker gene expression in nontarget cells can be obtained. Because only a low level of marker gene expression was observed in the studied cells, it was claimed by the authors later (1987) that marker protein was carried into the cells with the virus and not actively expressed in the cells [23,24]. Many publications since Carbonell and coworkers' initial findings have, however, confirmed that AcMNPVs containing mammalian expression cassettes can enter vertebrate cells and express reporter genes under the control of suitable promoters. Indeed, a universal concept is currently emerging that by using the latest generation vectors and optimizing procedures (see below), any cell from any source can efficiently be transduced by AcMNPV. Ample lists of tested mammalian cells for the baculovirus-mediated gene delivery can be found from several articles [12,102–107].

11.2.3.1 Mammalian Cells

Hofmann et al. [22,107] were the first to demonstrate in 1995, a decade after the pioneering work by Carbonell and coworkers [21], that a recombinant AcMNPV containing the luciferase gene under a CMV promoter can efficiently drive transgene expression in human hepatocytes (Huh7 and HepG2), as well as in primary hepatocytes of human and rabbit origin. In accordance with these results, Boyce and Bucher [108] showed next year that a virus carrying *lacZ* reporter gene under the control of RSV promoter led to a high-level expression of the marker gene in human hepatocellular carcinoma line HepG2, as well as in primary rat hepatocytes. More recently, primary rat and human hepatic stellate cells (HSCs) and human hepatoma FLC4 cells were shown to be highly susceptible to baculovirus-mediated gene delivery [102,109]. These findings favor the potential of baculovirus vectors for liver-directed gene therapy.

A high-level expression of marker gene can be achieved not only in hepatic but also in a wide range of other cell lines [102,104,106,107,110–113]. Shoji et al. [110] transduced a panel of mammalian cells with a baculovirus vector carrying a marker gene in comparison with a replication-defective adenovirus vector. In this study, high-level luciferase activity was detected not only in human hepatocytes but also in other cell lines such as monkey kidney cells (COS7), porcine kidney cells (CPK), and human cervix carcinoma cells (Hela). Furthermore, the same level of marker gene expression was observed in these cells by both viruses, but as an advantage for the baculovirus, much lower cytotoxicity was associated with it than adenovirus at a high multiplicity of infection (moi). The inert nature of baculovirus in vertebrate cells compared with adenovirus was also demonstrated in cells such as Hela [114], SHSY-5Y (human neuroblastoma), and C3A (human liver) [115]. The use of CAG promoter in the study by Shoji and coworkers [110] resulted in a 10-fold higher level of luciferase gene activity than in the previous study with a CMV promoter [22]. This indicates the importance of the promoter and the expression cassette per se for successful transduction of target cells not only by baculoviruses but also by any other gene delivery vector [28,116–119]. High-level expression of T7 RNA polymerase was also directed by CAG in HepG2 and CPK cells, and lower expression was observed in some other cell lines [111]. Condreay et al. [106] demonstrated that recombinant baculoviruses containing green fluorescent protein (GFP) gene under the CMV promoter can transduce a wide range of mammalian cell types originating from different tissues. Cell lines of hepatic origin were transduced efficiently, as described earlier, but notable gene expression was also detected in cell lines derived from kidney tissue (Cos-7, BHK, CV-1, 293), and other nonhepatic cell lines such as keratinocytes (W12, primary human keratinocytes), bone marrow fibroblasts, and osteosarcoma cells (MG-63). The lowest efficiency of transduction and level of GFP expression was seen in cell lines of hematopoietic origin, such as THP-1, U937, K562, Raw264.7, and P388D1.

Adherent cells such as WI-38 (lung fibroblast), MCF-7 (gastric carcinoma), BGC-223 (breast carcinoma), and DMS-114 (small cell lung cancer) were found to be more permissive for baculovirus-mediated gene delivery than suspension cell lines such as P815 (mouse mastocytoma) or CNE (human nasopharyngeal carcinoma) in a study that included 20 different cell lines of human, mouse, and monkey origins [103]. Some human osteogenic sarcoma cells (U-2OS, Saos-2, and Saos-LM2) [105], prostate cancer cells (PC3) [120], and prostatic stromal cells (CHPSCs) [121,122] have proved to be good targets for baculovirus. Studies aiming to define pleiotropic effects of IE2 protein of human CMV revealed human primary cells (human foreskin fibroblasts [HFF] and human umbilical vein endothelial cells [HUVEC]) as particularly good targets for the baculovirus [123,124]. In line with this, efficient gene transfer has also been obtained in primary human and mouse pancreatic islet cells [125]. Recombinant baculovirus expressed the glycoprotein gB of pseudorabies virus (PrV) under the CAG promoter in various mammalian cell lines and produced specific antibodies in mice against PrV [126]. High levels of expression of PrV gB were observed in many porcine kidney cell lines such as CPK, SK-H, and CPK-NS, and in hamster kidney cells (BHK-21). High efficiency gene transfer into mouse, hamster, monkey, pig, and human kidney cells was reported also by Liang and coworkers [127].

The potential of baculovirus for therapeutic applications was tested by a virus containing a p53 tumor suppressor gene under the control of the CMV promoter together with an anti-cancer drug, adriamycin [128]. Greater than 95% of Saos-2 cells were killed by the combination of the recombinant virus (moi of 100) and adriamycin (35 ng/mL), suggesting that the combination treatment greatly enhanced apoptosis of the tumor cells. Overexpression of the human homolog of the *Drosophila* tumor suppressor *l(2)Tid* led to p53 independent inhibition of cell proliferation and induced apoptosis in human osteosarcoma cells [129]. Comparison between baculoviral and adenoviral vectors in cardiovascular cells supported AcMNPV as a potential vector for cardiovascular diseases such as restenosis [130]. To delay and reverse the degeneration of intervertebral disc disease, human Sox9 gene, an essential transcription factor for synthesis of type II collagen was expressed in rabbit vertebral pulp cells [131].

11.2.3.2 Stem and Progenitor Cells

Embryonic and adult stem and progenitor cells hold great therapeutic and research potential because they can, in principle, differentiate into any cell lineage in the body due to their high self-renewal capacity and plasticity [132–135]. Mesenchymal stem cells (MSCs) derived from blood of bone marrow and umbilical cord were efficiently transduced by AcMNPV. The growth of the MSCs was not compromised and the cells retained their plasticity by differentiating into adipogenic, chondrogenic, and osteogenic lineages. A trend similar to adenovirus transduction was observed that the transgene expression decreased as the MCS-derived progenitors differentiated toward the end-stage mature cells

[136–138]. Baculovirus-mediated expression of growth factors in rabbit articular chondrocytes proved the potential also to modulate the differentiation status of progenitor cells by AcMNPV for the cartilage engineering [139]. The efficacy of a baculoviral vector equipped with GFP under a human elongation factor 1- α promoter in human embryonic stem cells (hESCs) was up to 80% [140]. Transduction had no effect on hESCs growth, phenotype, or pluripotency. Extended transgene expression was achieved by a hybrid baculovirus carrying also *rep* gene and inverted terminal repeat sequences from AAV. However, the percentage of hESCs exhibiting stable EGF expression was only 2% [140].

11.2.3.3 Avian Cells

The suitability of baculovirus for gene delivery into avian cells was observed in virus-treated chicken primary myoblasts and whole-embryonic fibroblasts over 80% of cells expressing GFP after transduction [141]. Another study found the primary cells obtained from embryonic day 9 or day 15 chick embryo, or day 13 duck embryo, permissive for baculovirus transduction. Similar transduction efficacy was detected in all tested cells derived from different tissues of day 15 chick embryo (liver, heart, and lung). Duck cells seemed to be more permissive than chicken cells [142].

11.2.3.4 Fish Cells

Fish are subjected to many diseases and vaccination could be used to prevent infections. Therefore, five fish cell lines derived from tilapia, carp, salmon, and rainbow trout were studied for their ability to permit baculovirus-mediated gene delivery. As a result, a VSV-G pseudotyped baculovirus that contained the *lacZ* gene under CAG was shown to be capable of transducing all cells except rainbow trout gonad cells (RTG-2) [143]. Transduction of zebrafish embryos was demonstrated by Wagle and Jesuthasan [144]. By injecting virus into specific tissues and using right promoters, both the location and time of gene expression could be controlled. The results favor an idea of using AcMNPV for the functional genomics studies in zebrafish [145].

11.2.3.5 Other Non-Lepidopteran Hosts

Non-lytic and efficient gene delivery (up to 100% cells) was gained in fruit fly cells (*Drosophila* S2) transduced with a baculovirus containing gene of interest under the control of the promoter for the *D. melanogaster* heat-shock protein 70 [146]. Similar virus was also used successfully to study developmental biology in *Drosophila*, *Tribolium*, and *Xenopus laevis* embryos [147]. Recently, AcMNPV vector was reported to transfer and express EGFP in the larval and pupal honeybees [148].

11.2.4 TRANSDUCTION OPTIMIZATION

Baculovirus-mediated gene delivery can substantially be enhanced by optimized transduction conditions and vector design [98]. Although AcMNPV can enter any cell from any

origin, universal entry does not guarantee efficient gene expression. Correct intracellular traffic and nuclear entry is also vital (see Section 11.2.6).

Cell culture medium has significant impact on the successful cell transduction. It has been observed that, especially, the commonly used Dulbecco's modified Eagle's medium (DMEM) hinders baculovirus-mediated gene delivery [149,150]. This may also explain, along with possible clonal selection of cells lines, the published and partially contradictory results regarding susceptibility of different cell lines to baculovirus-mediated transduction by independent groups [150,151]. Systematic exploration of medium constituents suggested that HCO_3^- , rather than divalent cations such as Mg^{2+} , Ca^{2+} , or serum, exerts the inhibitory effect in a concentration-dependent manner [149]. Transient substitution of DMEM with PBS in transduction has been suggested as a solution to avoid DMEM associated problems. However, cells can be sensitive to cultivation in PBS [152]. Comparison of different standard culture mediums for transduction revealed that RPMI 1640, in general, gives the best results. Cells readily adapt to this medium without problems [150].

Several medium supplements have been reported to aid baculovirus-mediated gene delivery. Usage of histone deacetylase inhibitors (HDIs) like sodium butyrate or trichostatin A in culture medium usually markedly increases baculovirus-mediated gene expression [14,106]. The effect is supposed to be mainly due to the more exposed expression cassette structure [153]. These agents also enhance adenovirus- and retrovirus-mediated transgene expression *in vivo* and *in vitro* [14,154,155]. Interestingly, it was recently published that the U_s3 or $\text{U}_s3.5$ protein kinase of HSV could substitute HDI effect in U2OS cells [156,157]. Co-expression or baculovirus capsid display [151] of these kinases or their analogs might, thus, provide a useful tool to improve baculovirus-mediated gene expression. Microtubule interfering substances, such as nocodazole or vinblastine, augment baculovirus-mediated gene delivery because cytoplasmic transport and nuclear entry of baculovirus nucleocapsid seems to be hindered by intact microtubule network [40,158]. The HDI inhibitors and cytoskeleton interfering substances, however, are typically harmful to cells, which limits their use [159].

To obtain best results, transduction should also be performed in subconfluent cell culture. Established intercellular connections between cells grown to overconfluence disturb baculovirus penetration into cells. Disruption of the cell-cell junctions by a calcium chelator, ethylene glycol-bis(β -aminoethylether)- N,N,N',N' -tetraacetic acid (EGTA), significantly improved the transduction efficiency [160–162]. Baculovirus entry into cells or tissues with tight cellular junctions may thus require transient breakage of intercellular linkages.

Better results have also been achieved by modification of the standard transduction protocol. Extended incubation time (>4h) allows improved virus uptake, and transduction at temperatures under 37°C has been suggested to improve results by prolonging half-life of the virus in transduction [20,103,143,152,163]. In addition, since baculoviruses are not toxic to vertebrate cells, repeated exposure of cells with the

virus (supertransduction) can extend the otherwise transient transgene expression [164,165]. Although working with purified virus is recommended [27,98,166–169], it is possible to transduce vertebrate cells with a virus in the insect cell medium diluted at least 1:1 to the desired culture medium [103,152,170]. This is useful, especially, for the screening purposes [171].

Baculovirus envelope modification is yet another option to achieve enhanced gene delivery. The major envelope glycoprotein, gp64, has been harnessed for this purpose [172,173]. However, truncated vesicular stomatitis virus G transmembrane glycoprotein (VSV-G) [174] or a transmembrane region of neuraminidase [175] can also be utilized to display peptides or proteins on the baculovirus surface. Several reports of baculoviruses pseudotyped with intact VSV-G provide evidence that VSV-G is also able to enhance transduction efficiency of baculovirus in vertebrate cells *in vitro* and *in vivo* [29,68,112,176]. VSV-G has a broad host range because its entry into the cells seems to not depend on the presence of any specific receptor but a phospholipid component of the plasma membrane [177]. VSV-G mediates pH-dependent membrane fusion in endosomes [178], and has earlier been used to pseudotype and stabilize other enveloped viruses such as murine retroviruses and lentiviruses [179–181]. In baculovirus studies, VSV-G was cloned under the control of the *polh* promoter so that it was expressed in infected insect cells but not in vertebrate cells. The level of marker gene expression in HepG2 cells treated with a pseudotyped virus was 10-fold higher than in the same cells treated with a wild-type virus. Pieroni et al. [176] showed that VSV-G enhances the transduction efficacy of pseudotyped baculovirus also *in vivo*. VSV-G or measles virus receptor CD46 can complement the gp64 and, therefore, allows productive infection, replication, and propagation of the gp64 deleted baculovirus in Sf9 insect cells [182,183]. However, the virus propagation was inefficient and delayed as compared with the wild-type virus, but virions were similar in morphology to the wild-type viruses. A major problem of VSV-G, cytotoxicity [180,184,185], can be avoided by a baculovirus vector displaying in addition to gp64 only a 21-amino acid ectodomain, in conjunction with the TM and CTD domains, of VSV-G (VSV-GED) [186]. In accordance with VSV-G pseudotyping, the VSV-GED virus resulted in several folds higher transduction efficiency in several cell lines as compared to the control virus. Not only the number of transduced cells was increased but also the level of reporter gene expression was higher in the transduced cells. Enhanced gene delivery *in vivo* was also detected. VSV-GED has several advantages compared to the VSV-G pseudotyping and provides a novel tool to improve baculovirus-mediated gene delivery without compromising high viral titers. Other examples of reported beneficial molecules for virus surface modification include the mouse hepatitis virus S protein [68], extra copy of gp64 [68], avian influenza virus hemagglutinin [187], RGD-motif [188], tumor-homing peptides [189], a short peptide motif from gp350/220 of EBV [190], and avidin [191]. Avidin displaying virus, Baavi, provides versatile potential not only to vector targeting but also imaging (see Section 11.3),

being compatible with plethora of commercially available biotinylated molecules [192]. Pegylation is yet another possibility to modify baculovirus transduction efficacy [193].

Finally, the choice of promoter is important. CMV promoter is, in general, a good first choice to drive transgene expression using baculovirus vectors [194], but Chicken β -actin promoter has been shown to be more active in some cells [110]. The latter also suffers less from epigenetic silencing [195] and drive well expression in neurons as opposite to CMV [196,197]. Cell-type-specific gene expression has been achieved with tissue and organism-specific promoters [144,146,198–201]. Enhancers can be used to boost promoter activity. Examples include the cytomegalovirus enhancer [199,200,202] and the homologous region sequence (hr1) of AcMNPV [203]. The Woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) was very recently recommended to be included in all baculovirus expression cassettes [150]. The WPRE-bearing virus showed remarkable better transgene expression in all tested cell lines. In some cells, the impact was comparable to earlier-mentioned and well-demonstrated sodium butyrate effect but having an advantage of being nontoxic. Transactivator strategy has also been applied successfully to baculoviruses to drive efficient and cell-specific transgene expression [163,204].

11.2.5 BACULOVIRUS HYBRID VECTORS

BEVS has become a popular choice for a virus-like particle (VLP) generation in vaccine production and for a basic research [205]. Indeed, the extraordinary capacity of AcMNPV to carry foreign DNA (no known limit for foreign DNA, but over 100kbp tolerated) allows construction of recombinant viruses bearing also large expression cassettes [10,206–208]. This is a valuable property for many purposes and not least for a hybrid vector construction, as shown by several authors. Palombo and coworkers [209] constructed a baculovirus-adenovirus (Bac-AAV) hybrid vector to prolong the transient nature of baculovirus-mediated transgene expression. The idea was to use the natural integration capacity of AAV to carry the transgene cassette into a defined region (chromosome 19) of the host cell genome [209]. β -galactosidase and hygromycin resistance gene excision from the baculovirus backbone vector and a subsequent integration into the genome of 293 cells was shown to occur with significant frequency. However, integration into the desired region occurred only in a fraction of the clones, and nonspecific integration and multiple insertions of the marker gene were detected. The Wang group has applied a similar strategy to flank an expression cassette with the AAV inverted terminal repeats to improve and extend gene expression in neural cells [200,210], to treat cancer [211], and to transduce hESCs [140].

A system for the production of gutless adenovirus vectors (FD-AdVs) that does not require helper adenoviruses was described by Cheshenko and coworkers [207]. The helper virus was replaced by the baculovirus-adenovirus hybrid vector (Bac/Ad) containing a Cre recombinase-excisable copy

of the packaging-deficient adenovirus genome. 293-Cre cells were transfected with the FD-AdV plasmid containing a transgene cassette, packaging signals, and two copies of the inverted terminal repeats, and were followed by transduction by the Bac/Ad. High titer FD-AdV virus preparations (10^8 pfu/mL) were attained. However, the system has to be further improved to avoid generation of replication-competent viruses during a large-scale production. Yap et al. [111] constructed a recombinant baculovirus carrying a cDNA of the bacteriophage T7 RNA polymerase under the control of the CAG promoter. High-level expression of this enzyme in various mammalian cell lines was observed after the baculovirus transduction. A plasmid bearing the entire poliovirus genome under the T7 promoter yielded a high titer of infectious poliovirus in the HeLa cells after prior transduction with the baculovirus.

To efficiently propagate and study hepatitis B virus (HBV) and hepatitis C virus (HCV) in cultured cells, recombinant baculoviruses carrying the HBV [212–216] and HCV [206,217,218] cDNAs under mammalian promoters have been prepared. The control of the gene expression in both the HCV minigenome and the full-length HCV construct was also investigated [219]. In addition, Tet-off and ecdysone/ponasterone-inducible (pon) systems were compared to control the gene expression. The tetracycline-controlled system gave a low basal activity and was highly inducible in almost 100% of HepG2 cells. Hepatitis-baculovirus hybrid vectors, thus, represent a simple and highly flexible system for studying the effects of antivirals or cytokines on HBV [220] and HCV production, and for the understanding of their replication and pathogenesis at the molecular level.

To investigate biology of the human cytomegalovirus (HCMV), genes encoding immediate early proteins of the HCMV were cloned into baculoviruses under the CAG promoter [221]. These viruses provided a new strategy for efficient isolation of the HCMV viruses with mutations in essential genes. In another study, a hybrid baculovirus was used to carry woodchuck hepatitis virus (WHV) pregenome under CMV promoter into WC-3 woodchuck hepatoma cells to study the effect of adenovirus superinfection on WHV replication [222].

11.2.6 ENTRY MECHANISMS INTO THE VERTEBRATE CELLS

The BV form of AcMNPV enters cells by adsorptive endocytosis in a multistep process including virus attachment, cellular entry (endocytosis), vesicular transport, endosomal escape, intracytosolic transport, nuclear entry, capsid disassembly, and gene expression (Figure 11.3). The exact molecular mechanisms leading to infection of insect cells, or transduction of vertebrate cells, remain still poorly understood. Results from both the insect and vertebrate cells hint involvement of clathrin-mediated endocytosis in the virion uptake [40,47,223]. Very recent observations in vertebrate cells suggested also involvement of macropinocytosis, and caveolae route, in baculovirus entry [224,225]. Indeed, several endocytic routes may be involved depending on cell type and culture conditioning [226].

van Loo et al. [40] showed that baculoviruses can also transduce nondividing cells and that the mechanism of the viral capsid transport into the nucleus before uncoating is apparently identical to that of insect cells (Figure 11.3) [227]. Pig kidney cells (Pk1) were arrested in S phase with aphidicolin, a reversible blocker of DNA polymerase, to show that the arrested cells can be transduced similarly as untreated mitotic cells. Baculovirus capability to transduce dormant cells has been verified by independent studies [228,229].

Some studies have suggested presence of specific binding sites for the baculovirus uptake into insect cells. However, the precise nature of these cell surface receptors is still unknown [47,223]. AcMNPV binding studies revealed existence of 3.1×10^{10} binding sites with avidity of $2.3 \times 10^{10} \text{ M}^{-1}$ in Sf21 cells [47] in line with the results obtained in High Five cells [223]. The affinity of AcMNPV against unknown receptors was in a similar range also in other insect cell lines but the amount of available binding sites varied between the studied cells. Attachment seemed to be limited by diffusion and large virion size [223]. In vertebrate cells, both receptor and nonspecific charge-mediated viral uptake have been suggested for the still speculative receptors [22,67,68]. The effect of the titer and virus competition studies in the cell culture suggested that gene transfer into hepatocytes might be due to the asialoglycoprotein receptor [22]. However, study in Pk1 cells, which do not express this receptor, did not support this conclusion [40]. Contrary to this specific receptor hypothesis, baculoviruses were reported to enter several cell lines by absorptive endocytosis, which does not require any interaction with a high-affinity receptor but rather interaction with a heterogeneous cell surface motifs [67]. Electrostatic charges were shown to be important. Negatively charged epitopes at the cell membrane appeared to be critical for baculovirus-cell interactions and the subsequent entry. Heparan sulfate proteoglycan seemed to be an important docking motif. Enzymatic removal of heparan sulfate groups from the cell surface caused a significant reduction in transduction [67]. The mode of baculovirus entry into the target mammalian cells was further studied by constructing recombinant baculoviruses encoding gp64 (extra copy), VSV-G, mouse hepatitis virus S protein, or GFP to compare susceptibility of various cell lines to these recombinant baculoviruses [68]. Increased amounts of gp64 or foreign envelope protein (VSV-G, MHVS) on the virus surface (envelope) caused higher expression than the control virus in several mammalian cell lines. Furthermore, this study indicated that phospholipids, such as phosphatidic acid or phosphatidylinositol, on the cell surface played an important role in the transduction of mammalian cells by baculovirus, whereas heparin and heparan sulfate did not. The published results are thus contradictory, and further studies are needed to resolve the exact nature of baculovirus receptors. However, the receptors may well represent a general cell surface motif such as heparan sulfate, phospholipid, integrin, or lectin because baculovirus can penetrate to plethora of cells. Indeed, as discussed in previous chapters, current data suggest that AcMNPV has a universal entry capacity.

The virion attachment on the cell surface, as well as pH-dependent escape of the AcMNPV nucleocapsid from the endosomes, is mediated by the major envelope glycoprotein, gp64 [65]. The precise vesicular routing beyond virion entry, leading to endosomal escape, is currently not known. Because AcMNPV is able to penetrate dozens of cells, and of different origin [20,102–105,142–144,147], gp64 has raised recently a lot of interest in pseudotyping and stabilizing of other enveloped viruses such as lentiviruses (HIV [230–233] and FIV [234,235]) or human respiratory syncytial virus (HRSV) [236,237]. The noncytotoxic nature of gp64 is a major advantage compared to VSV-G in virus production and transduction [186].

AcMNPV infection induces a series of actin rearrangements in insect cells, and actin plays an important role also in transduction of vertebrate cells although no viral replication takes place in these cells [20,238]. The major capsid protein of AcMNPV, vp39, may have a role on the nucleocapsid intracytoplasmic movement by hastening it [239]. The minor capsid protein, p78/83 [240], may assist on this, and has an important role in mediating nuclear actin accumulation and assembly vital for virus progeny generation [241–243]. Contrary to actin, microtubules are not essential to transduction. Disintegration of microtubules by nocodazole or vinblastine enhanced baculovirus-mediated gene delivery in vertebrate cells, suggesting that microtubules may pose a mechanical barrier for nucleocapsid movement toward and entry into the nucleus [40,158]. Indeed, the intracytoplasmic movement and nuclear entry are those steps in which baculovirus entry into vertebrate cells seems to be mostly restricted [244,245].

Disassembly of the viral nucleocapsid and exposure of nucleoprotein core take place in the nucleus. Phosphorylation of the basic viral protein, p6.9 (VP12), may control the disassembly according to studies performed in insect cells [64,246,247]. The p6.9 functions like a histone in the condensation of the viral DNA. The basic protein is substituted for host cell histones after disassembly and viral genome is thus under epigenetic control of the host cell [141,248,249].

11.2.7 TOWARD THERAPEUTIC APPLICATIONS

11.2.7.1 Gene Therapy

Current evidence suggests that baculoviruses provide also an effective tool for gene delivery *in vivo* (Table 11.2). The first attempts of *in vivo* gene transfer with baculovirus were performed in the liver parenchyma of rats and mice [25]. Several attempts were also undertaken to inject baculoviruses directly into systemic and intraportal circulation [25]. These experiments resulted in undetectable transgene expression, suggesting that the virus was somehow inactivated by serum components. This led to several studies in immune-compromised animals. When Hofmann et al. [107] injected a β -galactosidase expressing baculovirus directly into the liver parenchyma of C5-deficient immunocompromised mice, a few transduced hepatocytes were detected around the injection site. They also injected recombinant baculoviruses into the Huh7-derived

TABLE 11.2

Summary of the Preclinical Data of Baculovirus-Mediated Gene Transfer *in Vivo*

Study	Target Animal	Positive Organ/Tissue	Positive Cell Types	Notes	References
Hoffmann et al., 1998	C-5 deficient mice	Liver	Hepatocytes		[107]
Airenne et al., 2000	Rabbits	Adventitia	Fibroblasts Smooth muscle cells	Delivery by collar devise	[14]
Sarkis et al., 2000	Nude mice, BALB/c mice, and Sprague–Dawley rat	Brain	Striatum: astrocytes, corpus callosum, ependymal layer, and neuronal cells		[28]
Haeseleer et al., 2001	Mice	Retina Corneus	Retinal pigment epithelial cells Retinal inner nuclear layer Corneal endothelial cells Ganglion cell layer Muller cells Lens epithelium Photoreceptor cells		[27]
Hüser et al., 2001	Neonatal Wistar rats	Liver parenchyma	Not determined	The first report of a complement protected BV	[252]
Kircheis et al., 2001	Complement deficient A/J mice	Liver Spleen Kidney Lungs	Not determined	Delivery through tail vein	[250]
Pieroni et al., 2001	DBA/2J, BALB/c, and C57BL/6 mice	Quadriceps femoris muscle	Myofibers	Transgene expression mouse strain desendant	[176]
Lehtolainen et al., 2002	Normal Wistar rat	Hindbrain Forebrain Subarachnoidal space Spleen Heart Lung	Cuboid epithelium of the choroid plexus Endothelial cells of brain microvessels	Very high transduction rate in choroid plexus cells (76 ± 14%)	[26]
Abe et al., 2003	BALB/c female mice	Intramuscular, intranasal, and intradermal (administration route)	Not determined	Vaccine against influenza virus Intranasal route most efficient in vaccination	[270]
Tani et al., 2003	BALB/c mice	Cerebral cortex Mouse testes Seminiferous tubules	Astrocytes Pyramidal cells Basal and sertoli cells	A synthetic protease inhibitor to protect BV from the complement	[29]
Facciabene et al., 2004	BALB/c female mice	Intramuscular, intranasal, and subcutaneous (administration route)	Not determined	Vaccine against hepatitis C virus. Only intramuscular administration led to clear humoral response	[271]
Li et al., 2004	Adult male Wistar rats	Striatum, cerebral cortex, substantia nigra, retina, visual cortex, lateral geniculate nucleus, and superior colliculus	Neurons	Axonal transport explain virus spreading to distant tissues	[201]
Laitinen et al., 2005	Female Wistar rats	Brain	Cuboid epithelium of choroids plexus	Multipurpose simultaneous transgene vector allowing expression in mammalian, insects, and bacteria	[254]
Hoare et al., 2005	MF-1 mice	Liver	Parenchymal cells	Complement inactivation by soluble complement receptor type 1 prior virus treatment allowed successful portal vein administration	[251]

Räty et al., 2007	Male Wistar rats	Liver Kidney Lung Brain Spleen	Tubular epithelial cells of the kidney	Several administration routes were compared and viral biodistribution was studied by noninvasive SPECT/CT imaging modality	[345]

human hepatocarcinomas generated in nude mice (T-cell deficient) and got low gene transfer efficiency. A systemic baculovirus gene vector delivery into complement-deficient Neuro2a tumor-bearing A/J mice resulted in transgene expression primarily in liver, spleen, and kidney, but significant expression was also found in the tumor [250]. Pegylation of baculovirus was reported to enable brain transduction in mice after intravenous application. GFP expression was also detected in liver, spleen, lung, heart, and kidney [193]. Intraportal application with a complement inactivator led to some hepatic expression of *Lac Z* marker gene in MF-1 mice [251]. In contrast to other related reports, this study also reported toxicity associated to a high dose systemic administration of baculoviruses. Injection of decay acceleration factor (DAF)-displaying complement-resistant baculovirus into the liver parenchyma of complement-sufficient neonatal Wistar rats caused an enhanced expression of the marker gene suggesting that generation of complement-resistant vectors could improve the gene transfer efficiency *in vivo* [252]. However, direct intrahepatic injection of the complement-resistant AcMNPV-DAF- β gal vector in adult rats resulted only in single positive cells distant from the injection site.

Delivery methods that allow gene transfer in the absence of serum, or to the sites where viruses are not exposed to the complement, have led to more successful experiments in immune-competent animals. BALB/c mice, nude mice, and Sprague-Dawley rats were injected with recombinant baculovirus directly into the striatum of brain [26,28]. Marker gene expression was detected in the striatum, the corpus callosum, and the ependymal layer, indicating the ability of baculoviruses to transduce neural cells *in vivo*. Transduced cells were identified mainly as astrocytes with only a few positive neurones. No difference was detected between the three species or between the cobra venom factor (CVF) (an inhibitor of the complement system) treated and untreated groups, suggesting immune-privileged nature of the brain. Transduction efficiency, tropism, and biodistribution of the baculoviruses after local delivery into the brain have also been studied in comparison to adenoviruses in BDIX and Wistar rats [26]. In this study, baculoviruses were found to transduce cuboid epithelium of the choroid plexus cells very efficiently ($76\% \pm 14\%$). A clear difference was observed with the adenovirus vector when injected into the corpus callosum; adenoviruses did not transduce the choroid plexus cells, whereas ventricular ependymal lining and cells in the corpus callosum were transduced with a high efficacy. Adenovirus injection into the striatum resulted in an effective transduction near the injection site and in the corpus callosum. Both viruses lead to transgene expression in endothelial cells of brain microvessels throughout the forebrain [26]. AcMNPV's high tendency to transduce choroid plexus cells was verified by other studies conducted in rat brain [186,253,254]. Transgene expression could be detected also in the walls of lateral ventricles and in subarachnoid membranes when the vector was pseudotyped with the truncated VSV-G molecule (VSV-GED) [186].

Wang and coworkers demonstrated advantage of using a tissue-specific hybrid promoter in rat brain. The promoter of

human platelet-derived growth factor β -chain and synapsin-1, fused to enhancer of CMV immediately early promoter, drove efficient neuron-specific gene expression [199,204]. Astrocyte-specific gene expression was achieved by glial fibrillary acidic protein promoter [200]. Driven by neural-specific promoter, transcriptionally targeted transduction was detectable not only in neurons in injection sites but also in remote target regions. Axonal transport of the baculovirus vector was suggested to explain the results [201]. An expression cassette flanked with the ITRs of AAV boosted and extended transgene expression in rat brain [210]. The strength of a promoter could also be improved by a chimeric transactivator strategy [204]. As a step forward to real therapy, astrocyte-specific baculovirus was recently used to treat malignant glioma. A virus expressing A-chain of diphtheria toxin effectively suppressed tumor development in a rat C6 xenograft model [211]. Efficient transduction of intervertebral disc, an encapsulated and avascular immune-privileged tissue, was reported in rabbit [30]. Gene-delivery efficacy of nucleus pulposus cells compared favorable to reported results with adenovirus and retrovirus vector. In another study, lumbar intrathecal injection into the cerebrospinal fluid was used to transduce rat dorsal root ganglia cells [31].

In a different approach, carotid arteries of New Zealand white rabbits were successfully transduced by recombinant baculoviruses using a collar device. This system allowed gene delivery with minimal exposure to complement [14]. Transient expression in the adventitial cells was observed with an efficacy and duration comparable to adenoviruses. Recombinant baculoviruses have also been tested for direct administration into a mouse eye by subretinal injections. A strong expression of the marker gene in retinal pigment epithelial cells was reported by this study [27]. Intravitreal injection of the virus resulted in the marker gene expression in the corneal endothelium, lens, retinal pigment epithelial cells, and retina. The ocular tissue contains areas where antigens are not subjected to the complement pathway and therefore makes it a good target for baculovirus-mediated gene therapy. High gene delivery efficacy was observed also in immune privileged mice testis [29].

Direct injection of recombinant baculoviruses into the quadriceps femoris muscle of BALB/c and C57BL6 mice resulted in a transient expression of β -galactosidase. Expression levels were 5- to 10-fold higher when VSV-G pseudotyped baculoviruses were used [176]. The authors also used C5-deficient mice where a higher and more sustained gene expression (up to 178 days) was observed than in BALB/c and C57BL6 mice, suggesting a different gene transfer efficiency between the different mouse strains and the importance of the complement activity.

11.2.7.2 RNAi

Gene silencing by RNA interference (RNAi) is a powerful approach for a loss-of-function studies in fundamental biological questions [255,256]. It provides also new therapeutic platform to treat common diseases [257]. The facile and high throughout-compatible preparation of baculoviruses [97,254]

as well as their inert nature [114,115] make baculoviruses as attractive alternatives for RNAi delivery in vertebrate cells. Nicholson and coworkers were the first to show that a baculovirus-delivered U6-based short hairpin RNA (shRNA against lamin A/C) performed well in Saos2, Hepg2, Huh7, and primary human HSCs [258]. In another study, a hybrid HI promoter efficiently suppressed target gene expression by up to 95% in cultured human NT2 neural precursor and C6 rat glioma cells, and by 82% in rat brain [202]. Suppression of porcine arterivirus [259], HBV [260], HCV [261], and influenza virus A and B [262] replication by baculovirus-mediated shRNA delivery provides a proof of principle of baculovirus as a potential vehicle for RNAi-mediated antiviral therapy. A related strategy, taking advantage of a baculovirus-delivered ribozyme against HIV-1 U5 gene, was successful to inhibit HIV-1 replication substantially *in vitro* [263].

11.2.7.3 Vaccination

BEVS has shown to be useful in a subunit vaccine production [205]. A cervical cancer vaccine, Cervarix (GlaxoSmithKline PLC), against the two most prevalent cancer-causing types of the human papillomavirus (HPV 16 and 18), was recently approved for a clinical use in woman aged 10–45 years old in Australia and Europe, and it is expected to be launched soon in USA too. This bivalent HPV-16/18 VLP vaccine [264] is the first BEVS-based product for clinical use having an exceptional market potential. Another example of an advanced baculovirus based subunit vaccine is the influenza vaccine, FluBlok (Protein Sciences Corporation), which has already shown HS efficacy in clinical trials [265–267]. FluBlok uses recombinant HA proteins derived from current circulating influenza viruses that are selected by the World Health Organization and the Center for Disease Control on an annual basis [268]. There are several well-recognized disadvantages in the standard use of embryonated eggs for vaccine production such as a slow vaccine generation time (about 6 months), possible disrupt of the supply by avian influenza virus, safety concerns due to live flu virus, and need to adapt all new influenza variants for high-yield growth. BEVS avoids all these and allows moving a flu vaccine into full production in about 6–8 weeks from the time the target strain is identified [269]. FluBlok is expected to reach markets during 2008–2009 flu seasons.

In addition to subunit vaccines containing recombinant proteins produced in insect cells, baculovirus-mediated gene delivery, baculovirus display of desired antigens, or infected insect cells per se may prove to be usable for vaccination too [172,173,205]. Induction of specific antibodies was observed in mice that were inoculated intranasally or intramuscularly with a virus encoding PrV glycoprotein B. Higher levels of antibodies were detected in serum after intramuscular rather than intranasal inoculation [126]. Although intramuscular or intraperitoneal immunization elicited higher antibody titers, protection from a lethal challenge of the influenza virus was only achieved by intranasal application of hemagglutinin encoding baculovirus [270]. Better immune response against E2 glycoprotein of HCV

and carcinoembryonic antigen (CEA) was gained in mice with VSV-G pseudotyped virus [271]. Intramuscular application was also found in this study to give the best response. In accordance, a VSV-G pseudotyped baculovirus expressing murine telomerase reverse transcriptase induced antitumor immunity in a murine glioma model after direct injection into muscle [272].

Lindley and coworkers [273] reported a novel use of the baculovirus gp64-display system [172,173] as an efficient method to produce monoclonal antibodies against desired antigens. Immunization with a whole virus eased and speeded up antibody production by eliminating the need for laborious purification of a target antigen before immunization. Furthermore, the immunostimulatory nature of virions alleviated the need for other adjuvants [274,275]. Same strategy was used to generate monoclonal antibodies against human peroxisome proliferator-activated receptors and the amino-terminal domain of human hepatocyte nuclear factor 4 α 1/ α 2/ α 3 [276,277]. This method might also be useful for direct vaccination with desired displayed antigens, as suggested by Tami and coworkers [278]. In support of this, baculovirus-displayed proteins have been proven to elicit efficiently antigen-specific responses and vaccination potential in mice against bovine herpes virus 1 protein [279], Rinderpest virus and *Peste des petits ruminants* virus [280], malaria [281], and acute respiratory syndrome-associated coronavirus (SARS-CoV) [282–284]. Furthermore, surface-displayed hemagglutinin may provide an alternative method as an influenza vaccination [187,285]. A virus that both displayed and expressed *Plasmodium falciparum* circumsporozoite protein (CSP) was superior in inducing anti-CSP immune responses [286]. This study showed also that baculovirus transduction not only induced efficient antibody responses but also triggered maturation of professional antigen presenting dendritic cells (DCs) leading to specific antibody and CD4(+) and CD8(+) T-cell responses against CSP in mice after i.m. vector injection. DC induction by AcMNPV was detected also in human monocyte-derived DCs [287] and in mouse bone marrow-derived DCs [288].

Vaccination with infected cells is still an interesting additional possibility. Lyophilized insect cells infected with interferon- β eradicated subcutaneous tumors of UV2237m fibrosarcoma and K-1735M2 melanoma in syngenic mice, inhibited tumor growth and hepatic metastasis in syngenic and orthotopic model of the CT-26 murine colon cancer, and was effective in immunotherapy against occult brain metastasis [289,290]. In another study, fixed and sonified insect cells containing Japanese encephalitis virus (JEV) proteins were used to detect T-cell responses of volunteer donors who had experienced subclinical JEV infection [291]. This approach has applications in the preliminary screening of potential vaccine antigens. When mice received virions or infected insect cells bearing the fusion protein gp64-site A of a foot and mouth disease virus (FMDV), a specific and protecting immune response to FMDV was elicited [274]. Whole cell immunization protocol was used also in brucellosis vaccine study [292].

11.2.8 SAFETY

Extensive safety testing of baculoviruses has been conducted, which has led to their classification onto the lowest biohazard level [11]. These studies have revealed that nucleopolyhedroviruses are harmless to and unable to replicate in microorganisms, noninsect invertebrate cell lines, vertebrate cells, vertebrates, plants, and nonarthropod invertebrates. These trials have included long-term carcinogenicity and teratogenicity tests, tests in primates, and tests in humans [18]. Many different mammalian species have been studied, including rats, mice, dogs, guinea pigs, monkeys, and humans. In these tests, baculoviruses were administered by oral, intravenous, intracerebral, intramuscular, and topical routes. No toxicity, allergic responses, or pathogenicity associated with the baculoviruses were detected [293]. The safety of baculoviruses is also underscored by the fact that we are exposed everyday to baculovirus particles present in large numbers in our environment and food. Yet, no diseases have been linked to baculoviruses [15,294].

11.2.8.1 Restricted Replication

The safety of baculoviruses is secured at several levels of restrictions in baculovirus infectivity [295]. The polyhedrin matrix is essential to horizontal transfer of the virions by protecting them from the environment. The alkaline midgut of insects facilitates the dissolution of the polyhedrin matrix, leading to primary infection of the larva (Figure 11.1). Organisms such as birds and mammals that lack such alkaline conditions in their digestive tract or other potential points of entry, such as respiratory tract, are not infected by ODV [296–298]. Tissue or cell-type specificity may create the second level of restriction, although the baculovirus host range does not appear to be limited at the point of entry into the target cells [20,68]. This is particularly true for AcMNPV. The subsequent steps following the virus entry by adsorptive endocytosis may be much more important [151,158,245]. Although escape from the endosomes certainly creates barrier, it was found that nucleocapsids seemed to enter into the cytoplasm even in the cells in which no marker gene expression was detected [151]. The block in transduction of vertebrate cells by AcMNPV seems, thus, to lie in the defective intracytosolic transport or entry of the nucleocapsid into the nucleus [158,244]. This is in agreement with the known ability of gp64 to mediate pH-dependent membrane fusion in endosomes [65]. Finally, if the nucleocapsid reaches the nucleus, strictly guided molecular mechanisms that cover the expression of the baculovirus genome remain in place. Indeed, baculoviruses propagate only in insect cells and are inherently unable to replicate in mammalian cells [104,238,299,300]. This is an advantage when baculoviruses are used for gene therapy, because risks related to the rise of replication-competent viruses during the virus production can be avoided. Replication-competent viruses are the major concerns with most of the current main stream gene delivery vectors based on human pathogens [301].

11.2.8.2 Guided Viral Gene Expression

Although AcMNPV DNA does not replicate or persist in mammalian cells [238], baculoviral early genes are transcribed by host DNA polymerase II [302,303]. Furthermore, a product of early gene (baculovirus transactivator IE1), which is able to activate several early, late, and very late viral promoters, was demonstrated to be functional in mammalian cells [304,305]. Adenoviral proteins were also capable of transactivating a heterologous insect virus promoter in mammalian cells [306]. In addition, the baculoviral early-to-late promoter, which activity is dependent on baculoviral early gene expression, drove gene expression cell type dependently in some mammalian cells [307]. So, it is not surprising that detectable mRNA levels of baculoviral genes have been recently reported in some vertebrate cells [245,308,309]. However, the relevance of the detected viral gene expression in safety terms remains to be studied further because these results were based on indirect or sensitive PCR-based methods. The extent and timing of the viral transcription, known to be important for productive infection in insect cells, and most importantly, evidence of any translation of viral transcripts, remain mainly to be resolved. The few studies concerning these issues this far have been able to show some translation of the viral mRNA (IE2) only in HepG2 cells [229,310].

11.2.8.3 Genome Size

The large size of the baculovirus genome (~134 kbp) raises a theoretical concern of homologous recombination of it (or parts of it) into the target cell genome. In the worst scenario, this might lead to malignancy of the target cell as reported in the case of naturally integrating retrovirus and AAV vectors [7,311–315]. However, integration of AcMNPV genomic fragments into the mammalian genome has been shown to take place *in vitro* only in the presence of selection pressure [106,316]. In these studies, Chinese hamster ovary (CHO) cells, which were stably transduced by selection pressure with recombinant baculoviruses, expressed GFP at least 25 passages [106]. Analysis of the baculovirus-derived DNA indicated that DNA derived from the viral vector had stably integrated into the transduced CHO cells [106]. Integration into the CHO genome occurred as small fragments (5–18 kb) via illegitimate recombination [316]. Two of the clonal cell lines maintained starting levels of the GFP expression over a 5 month period with and without selection. The two remaining clones, however, showed a loss of the marker gene expression. Baculoviruses can, thus, be used for the preparation of stable cell lines. No evidence of integration of AcMNPV genomic fragments into the target cell genome has been found without concomitant antibiotic selection pressure [238,317].

11.2.8.4 Immune Response

One of the biggest challenges in gene therapy is the immune response of the host. The host defense mechanisms function both at the cellular level by generating cytotoxic T-cells and at

the humoral level by generating antibodies against foreign antigens. Cellular immunity eliminates the transduced cells, whereas humoral immunity protects against the repeated administration of the vector [176,318,319]. The host may recognize not only the vector and the transgene product but also the foreign DNA, which makes the vector design even more challenging [320]. However, the eye, nervous system, and reproductive organs possess immune-privileged regions [321] and, therefore, provide good targets also for the baculovirus-mediated gene therapy [26,27,29–31].

As discussed earlier, immune responses against baculoviruses were suggested as a reason for no detectable transgene expression when mice and rats were treated with systemic, intraportal, or direct injections into the liver parenchyma [25]. Therefore, the influence of untreated and heat-inactivated serums from different species was tested for baculovirus transduction efficiency. The results indicated that the classical complement (C) cascade inactivates baculoviruses rapidly and the extent of inactivation varies from one species to another [25,322]. Incubation of baculoviruses in the serum of either C3- or C4-deficient guinea pigs did not cause any significant neutralization of the baculovirus, suggesting that C3 and C4 components are essential [25,322]. In line with these findings, the direct injection of recombinant baculoviruses into C5-deficient mice resulted in a higher and longer-lasting expression of the marker gene than that in mice, which were not complement deficient [176]. In *ex vivo* experiments that excluded the C system, detectable levels of the marker gene expression were found in human liver segments perfused by the baculovirus vectors [25,107]. More detailed investigations have demonstrated that the classical pathway of the C system and assembly of the very late C components are essential for the inactivation of the baculovirus in human serum, indicating the presence of IgM or IgG antibodies against baculoviruses [322]. These antibodies are most probably part of the innate self/nonself pattern recognition immune system detecting antigens without a known history of immunization [286,323,324]. Involvement of the alternative C pathway in baculovirus inactivation has also been suggested [251].

A couple of efforts have been taken to protect baculovirus from inactivation by the complement system [325,326]. The treatment of human serum with functional blocking agents (CVF, anti-C5 monoclonal antibodies) against the components of the C-cascade increased vector survival significantly in a dose-dependent manner *in vitro* [322]. Soluble complement receptor type 1 (sCR1), a potent inhibitor of both the classical and alternative C pathways, increased baculovirus survival in human serum in a dose-dependent manner [327] and reduced intraportal application associated toxicity in mice [251]. A complete baculovirus survival was achieved by the soluble complement receptor at concentration of 100 µg/mL of serum [327]. Incorporation of the complement-regulatory protein DAF into the viral envelope was also shown to improve gene transfer efficiency in neonatal Wistar rats *in vivo* [252]. Synthetic inhibitor of complement (FUT-175) was also effective [29]. Pegylation [193] and VSV-G pseudotyping [29] may also protect baculoviruses from the complement attack.

Baculoviruses have been shown to stimulate antiviral activity in mammalian cells by promoting cytokine production. Baculovirus exposure resulted in the activation of TNF- α , IL-1 α , and IL-1 β expression in the primary hepatocyte cultures and production of interferons (IFNs) in some mammalian cells [328,329]. Kupffer cells were present in the primary hepatocyte cultures and were most probably responsible for the cytokine production [328]. The IFN-stimulating activity of the baculoviruses required live virus [329]. Contribution of the toll-like receptors for eliciting a strong innate immune response in mice was first suggested in a study that showed an AcMNPV-induced secretion of TNF- α and IL-6 as well as increased expression of activation ligands (CD69 and mature macrophage Ag receptor) in murine RAW264.7 macrophages [270]. Further studies revealed an important role of the toll-like receptor 9 and MyD88-dependent signaling pathway on activation of the immune cells via baculoviral DNA [330]. Role of viral DNA on promoting humoral and CD8+ T-cell adaptive responses as well as inducing maturation of dendritic cells and the production of inflammatory cytokines (IFN- $\alpha\beta$) against coadministered antigen was further supported by studies of Herva-Stubbs and coworkers [275]. However, other viral components and recognition pathways are also involved on the priming of the immune system [275,330]. The induction of antiviral effects (cytokine production) in vertebrate cells is also cell-type dependent. No cytokine production was detected in HepG2, Huh7, BHK, or L929 cells while IFN synthesis in dendritic, macrophage, and SMMC-7721 cells was evident [331,332]. No correlation existed between AcMNPV transgene expression and induction of INF production [332]. In accordance with these studies, baculovirus-mediated perivascular gene transfer was found to result in immune responses [14]. Interestingly, however, only a modest microglia response was seen in rat brain after the baculovirus transduction whereas the adenovirus gene transfer led to a strong microglia response [26].

11.3 FUTURE ASPECTS

The genuine advantages of baculovirus vectors (Table 11.1), and the recent advances in vector design as well as in transduction optimization, certainly make AcMNPV a powerful vector for a universal gene delivery into any cell from any origin *in vitro* [97,98,254]. However, despite the profound existing knowledge about the baculovirus safety, biology, and factors important for efficient cell transduction *in vitro*, further demand for vector development and studies concerning AcMNPV behavior, especially *in vivo*, still exists. These issues need to be addressed before clinical trials with baculovirus vectors can be launched. Common challenges shared with all gene therapy vectors such as truly transcriptionally and positionally targeted gene delivery also largely remain to be resolved.

An ideal gene therapy vector should transduce only the desired target cells with a high efficacy. Therefore, a strong interest in developing targeted gene delivery vectors has emerged [333–339]. As a first step toward targeted

baculovirus transduction, Ojala and coworkers [340] described baculovirus vectors displaying either a functional single chain antibody fragment (scFv) specific for the carcinoembryonic antigen or the synthetic IgG-binding domains derived from protein A of *Staphylococcus aureus*. Display of the targeting moieties on the viral surface was achieved through fusion to the N-terminus of gp64 (Figure 11.2) [341]. Specific binding of the gp64 fusion viruses to mammalian target cells could be demonstrated by fluorescence and confocal microscopy. However, no enhancement of the viral entry or gene transfer into the mammalian cells could be observed by monitoring GFP expression. Indeed, it is well known that a specific ligand–receptor interaction does not necessarily guarantee efficient transduction of the target cells [333,342]. Correct internalization, escape from endosomes, transport of the genetic material into the nucleus, and efficient transcription and translation are required as well [150,151,158,226,343,344]. The first baculovirus showing also enhanced gene expression beyond specific binding was based on avidin display on virus surface. Displaying of this biotin binding protein on virus provided a flexible tool for virus targeting [191] and biodistribution imaging [253,345]. More recent papers have described other targeting moieties enabling also enhanced gene expression. Examples include SARS-CoV S protein (lung cells A549, NCI-H520, HFL-1, and MRC-5) [282], a peptide motif of EBV (B-cells Raji, HR1, B95–8, BJAB, and DG75) [190], an RGD-motif derived from coxsackievirus A9 and human parechovirus (A549 lung cells) [188] or FMDV [346], RGD tumor homing peptides LyP-1, F3, and CGKRK (human breast carcinoma cells MDA-MB-435 and HepG2 hepatocytes) [189]. The true targeting of baculoviruses, however, is hampered by the extreme tropism of baculovirus, which is mediated by the gp64 envelope glycoprotein. The gp64 is vital for virus budding, attachment, and endosomal escape, and must, thus, also exist as an intact form in the virus envelope to guarantee efficient virus generation [341,346]. A first step forward for a successful pseudotyping of baculovirus without concomitant native (genomic) gp64 expression was published by Kitagawa and coworkers [183]. In this paper, a measles virus receptor (CD46) pseudotyped gp64-null baculovirus was prepared in Sf-gp64 cells stably producing gp64 or by transfecting insect cell with a recombinant viral genome (bacmids). However, titers of the pseudotyped viruses were low and revertant viruses that had incorporated the gp64 gene were generated after passaging in Sf-gp64 cells. Further method development is, thus, needed for efficient generation of truly targeted baculoviruses.

Further knowledge on molecular mechanisms behind viral cellular entry will create the basis for further engineering of the baculoviruses, allowing better possibilities for cell/tissue-specific entrance also *in vivo*. It is also important to learn more about host response and biodistribution of viral particles after different administration routes *in vivo*. Indeed, a first study using magnetic resonance imaging (MRI) for

virus particle biodistribution determination was performed with a baculovirus [253]. This study confirmed the high tropism of baculoviruses against choroids plexus cells in the ventricles of rat brain. Single-photon emission computed tomography (SPECT/CT) was also used recently for baculovirus biodistribution studies [345]. This study revealed new aspects of baculovirus trafficking in an immune competent rat model after i.f., i.p., i.m., and i.c.v. administration. The results suggested virus spread via the lymphatic system and extensive accumulation of virus particles into the kidneys, especially after i.p. administration, was observed. Transduction of kidney was confirmed by reverse transcriptase–polymerase chain reaction and immunohistochemistry. Baculovirus may, thus, be beneficial for the treatment of kidney diseases. These studies show that MRI and SPECT/CT can provide useful and important information of vector behavior in an immune-competent animal in a noninvasive way.

Current baculovirus vectors allow only transient transgene expression, which is desirable in the treatment of cancer [4] or cardiovascular disorders [347,348]. However, more prolonged expression is needed for the treatment of genetic diseases [349]. AAV baculovirus hybrid vectors have shown some success in this regard [140,200,209–211]. A strategy based on EBV episomal replication elements (OriP/EBNA-1) was also recently reported to prolong baculovirus-mediated gene delivery [350]. The use of episomal maintenance for the extension of transgene expression has the advantage of avoidance of possible insertional mutagenesis problems [351–353]. Controlled and inducible gene expression will be highly desirable in vectors capable of sustained gene expression [354–356].

A novel system where the fusion protein (enhanced GFP) is displayed in large quantities on the surface of the baculovirus capsid without compromising the viral titer or functionality is thus far used in virus entry mechanism studies [158,229] but has also potential to open remaining intracellular blocks hindering baculovirus transduction [244]. The system is based on the production of the desired peptides or proteins as either C-terminally or N-terminally linked fusion proteins with the baculovirus major capsid protein, vp39 (Figure 11.2). As the penetration of the baculovirus into mammalian cells and the release of the viral capsid into the cytoplasm seems to be a general phenomenon, the concept of baculovirus-mediated therapy may be further extended, with the possibility of using baculovirus capsid as a shuttle to transport also therapeutic proteins directly into the cells as an alternative to traditional protein transduction strategies [357].

In conclusion, the latest advances in baculovirus technology have further strengthened the concept of a baculovirus-mediated gene delivery with many advantages compared to current gene therapy vectors (Table 11.1). Baculoviruses are especially useful for large expression constructs allowing the use of multigene strategies. Inherent safety, together with the ease and speed of production of these vectors, creates a powerful and universal concept to test different gene delivery constructs also in a high-throughput setup.

ACKNOWLEDGMENTS

We thank Ms. Minna Kaikkonen, Ms. Johanna Laakkonen, and Ms. Emilia Makkonen for comments regarding the manuscript; Dr. Jani Rätty for graphics in Figures 11.1 through 11.3, Dr. Susan E. Rice Mahr for the photograph of infected larva, and Dr. Franklin Dlott for the photograph of healthy Alfalfa looper in Figure 11.1. We also thank Dr. Maija Vihinen-Ranta and Ms. Johanna Laakkonen for the EM and confocal pictures in Figure 11.3.

Gene therapy is defined as the delivery of genetic material for a therapeutic purpose. Because of their nature, bacteria have essentially been used as vaccination vectors. Current gene therapy, through nucleic acid vaccination in prophylactic or therapeutic purposes, brings the hope to monogenic/polygenic diseases, cancer, and ischemic heart disease [1]. DNA vaccines are eukaryotic expression vectors encoding one or several antigens with/without additional genes encoding for modulatory functions. With improving plasmid purification/dosages, antigen-presenting cells (APCs) targeting, and technologies for modulation of immune responses, substantial progress has been made in the past decade in overcoming the major inadequacies of first-generation gene-transfer vectors.

To induce an efficient immune response, effective antigen proteins or DNA delivery technologies are required. In addition, the vectors must protect the therapeutic DNA vaccine from degradation and clearance by the host immune system. A variety of viral and nonviral delivery systems are available for basic and clinical research. Viral vectors derived from retroviruses, adenoviruses, lentiviruses, poxviruses, parvoviruses, and herpesviruses are the most frequently used [2]. Apart from those, naked plasmid DNA or its combination with compounds increasing the efficiency of cell membrane penetration (cationic lipids, lipoplexes etc.) has also been used [3,4]. Moreover, gene transfer can also occur from bacteria to a very broad range of recipients that include yeast [5] and plants [6], and several laboratories have reported a relatively high frequency of functional gene transfer from bacteria to mammalian cells [7–14].

Because of their nature properties, bacterial vectors are particularly suited for gene transfer in APCs. They will naturally elicit an immune response which can be beneficial as the bacteria will have a built-in adjuvant effect [15]. The key is to

match the correct (and safe) dosage, vector, and adjuvant response with the desired immune reaction. Typically, a bacterial infection will innately lead to APC cytokine (TNF- α , IL-1, IL-6) release [16] and attract other APCs and polymorphonuclear leukocytes to the site of infection [17]. Surrounding tissue is at risk during the digestion of the foreign bacteria as APCs and polymorphonuclear leukocytes also release microcidal agents (lysozyme, bactericidal/permeability-increasing protein, acid hydrolases, nitric oxide, and oxygen free radicals) that can damage nearby endothelial cells [18,19] and thus cause potential undesired side effects (resulting from cytokine release). However, tempering these reactions while delivering a specific antigen is the goal of bacterially mediated immunomodulation.

12.1 LIVE OR ATTENUATED BACTERIA

The history of bacterial vaccine development began with the use of bacillus Calmette–Guérin (BCG) vaccine against tuberculosis (TB) by Albert Calmette and Camille Guérin at the Pasteur Institute (Lille, France) in 1927 [20] and continued with the development of the currently licensed Ty21a vaccine for typhoid [21]. With the progress of modern molecular biology, these bacteria can be processed to retain their adjuvant role in mounting immune response and carry desired antigens, proteins, or plasmid DNA as prophylactic/therapeutic vaccines. Several experimental tools exist to further influence the antigen delivery process in precision and flexibility [7,22]. To date, extensive research has been conducted using different live, live attenuated as well as killed bacterial strains as vectors. Live bacterial vaccines can be regarded as a self-limiting organism stimulating an immune response to one or more expressed antigens. The use of live bacteria to induce an immune

response to itself or to a carried vaccine component is an attractive strategy. Advantages of live bacterial vaccines include their mimicry of a natural infection, intrinsic adjuvant properties, and their possibility to be administered orally [23]. However, the utilization of live bacteria to infect the host may potentially be associated with pathologies. Therefore, attenuation of bacteria virulence was developed in order to balance the pathogenicity/reactogenicity and preserve the ability to elicit a protective immune response. Attenuation of the pathogenic bacterial strains can be achieved through abrogation of virulence factors [24,25], metabolic crippling [26], or intracellular replication-deficient [27] by directed mutagenesis using recombinant DNA methods. These include attenuated *Listeria monocytogenes* and commensal *Bifidobacterium longum* representing Gram-positive bacteria, and Gram-negative bacteria such as attenuated *Yersinia* spp., *Shigella* spp., *Salmonella* spp., and apathogenic *E. coli* [7,28,29]. A variety of attenuated mutant strains of *Salmonella* and *Shigella* deleted in genes for cell wall synthesis [9,30] and genes for RNA/DNA precursor synthesis [31,32] have already been used for bactofection. Auxotrophic mutants of *Salmonella* and *Shigella* defective in aromatic acid biosynthesis [33,34] have been studied as vaccine carriers as well. However, attenuations of the live bacterial pathogenicity may influence the overall performance of the strain, i.e., the efficacy of DNA delivery or the immunogenicity of the vaccine [23,35]. Even though the applications of live attenuated bacterial vaccines are extensive and has lead to more than 2000 published papers, only very few of the promising candidates have survived the licensing process and become registered [36] reflecting the difficulty in developing a commercial live vaccine. Furthermore, human clinical trials using *S. typhimurium* (VNP20009) have shown dose-limiting toxicity despite extensive attenuation [37]. As an alternative approach, nonliving bacterial components/lysate or whole bacterial cells have been used for both human and animal mucosal immunization and been shown to provide humoral and cellular responses. In addition, the bacterial ghost (BG) system [38], which is a non-living bacterial envelope made from protein E-mediated lysis of Gram-negative bacteria in combination with antigen packaging. Since this BG system do not involve host DNA or live organisms, they exhibit improved potency with regard to target antigens compared to conventional approaches, they are versatile with regards to DNA or protein antigen choice and size. Killed but metabolically active (KBMA) vaccines are based on bacterial nucleotide excision repair mutants, and are inactivated by photochemical treatment with a synthetic highly reactive psoralen known as S-59 [39]. The KBMA vaccine approach is based on the hypothesis that the increased sensitivity of *uvr* mutant strains to photochemical inactivation is correlated with randomly distributed, infrequent psoralen crosslinks, leaving intact the ability of a population of inactivated bacteria to express its genes, while preventing productive growth and the ability to cause disease in the immunized host. Another strategy of killed-bacteria is to use formalin to fix the bacterial vectors but retain the ability of delivery antigen or protein [40–42].

12.2 MECHANISMS OF GENE TRANSFER BY BACTERIAL VECTORS

The first step of gene transfer by bacterial vectors lies in the entry of the delivery vehicle uptake by host target cells (Figure 12.1). The bacterial cell is typically confined to spherical or cylindrical shapes between 1 and 5 μm which can innately target the phagocytic cells. When professional phagocytic cells such as macrophages or dendritic cells are targeted, this entry is likely to happen through phagocytosis. This contact will activate these phagocytic cells, i.e., the APCs. Gram-negative cells contain lipopolysaccharide (LPS), whereas Gram-positive cells possess lipoteichoic acid. These and other features (unmethylated cytosine–phosphate–guanine [CpG] dinucleotides [43–45], peptidoglycan [46], flagellin [47], and bacterial lipoproteins [48]), the so-called pathogen-associated molecular patterns (PAMPs), naturally influence bacterial uptake and act as natural adjuvants to improve APCs activation

FIGURE 12.1 Strategies of bacteria vectors in vaccinations. Different strategies are undertaken by the bacterial vectors in delivering the DNA vaccines. (1) After bacterial vectors penetrating into the mammalian cells, the vectors are destructed or undergo lysis in the cytoplasm of target cells. The plasmid carrying therapeutic gene (○) is released and get into the nucleus and expressed by the eukaryotic transcription and translation machinery (⊕). (2) The passenger antigen (⊕) is expressed within the bacterial compartment and delivered into the target cells. These nonsecretory antigens can only be released into the cytoplasm of target cell upon the phagosomal lysis of vector. Further antigen processing and presentation will happen essentially in APCs. (3) Bacterial vector do not enter the eukaryotic cell, but express and secrete the therapeutic transgene in the intercellular space. (4) The bacterial vector can escape from lysosomal/phagosomal lysis. The transgene is expressed after penetrating into the cytoplasm of target cell by the prokaryotic transcription and translation machinery and the expressed antigenic protein is being secreted into the cytoplasm.

through binding to receptors of the Toll-like receptor (TLR) family [44,49]. In the case of non-phagocytic cells such as those of the intestinal epithelium, there are two major strategies for bacteria to gain entry into a eukaryotic cell [50,51]. For certain genera such as *Salmonella* or *Shigella*, contact between the bacteria and the host results in the secretion by the bacteria of a set of invasion proteins that triggers intracellular signaling events. For example, upon the contact of *S. typhimurium* with host cells results in activation of a specialized protein secretion system (type III), which leads to cytoskeletal rearrangement, membrane ruffling, and bacterial uptake by pinocytosis [50]. For other genera such as *Yersinia* or *Listeria*, binding of a single bacterial protein to a particular ligand on the host cell surface is necessary and sufficient to trigger entry by a zipper-like mechanism. After internalization, the bacteria are localized in the phagosomal vacuoles and are targeted for degradation. Therefore, escaping from the vacuolar compartment is essential to the delivery DNA vaccines.

Shigella spp. and *L. monocytogenes* can disrupt the endosomal/lysosomal membrane, escape into the host cell's cytoplasm, and spread from one infected cell to an adjacent one by exploiting the cell's actin polymerization for intracellular motility [52,53]. This process of phagosomal escape is particularly well understood and exploited in vectors based on bacteria replicating in the cytosol [10,54]. In *L. monocytogenes*, the pore-forming cytolysin listeriolysin O (LLO), which is encoded by *hly*, plays an essential role in the escaping step. Strains with mutations in *hly* that inactivate the pore-forming activity of LLO are unable to escape from the primary phagosome [55,56]. Once spreading to the cytosol, wild-type *L. monocytogenes* will replicate [57]. An attenuated *L. monocytogenes* strain has been engineered to undergo self-destruction in the cell cytosol by production of a phage lysine under the control of the promoter of *actA*, which is preferentially activated when the bacteria are in the cytosol [10,27]. Another bacterial vector taking advantage of the pore-forming activity of the LLO protein is the invasive *E. coli* [11,40]. In addition to the *hly* locus from *L. monocytogenes* encoding the LLO protein, the *inv* locus encoding the invasin protein from *Yersinia pseudotuberculosis* has been inserted into this bacterium [11]. Invasin binds to β 1-integrin expressed at the surface of mammalian cells and this binding is necessary and sufficient for entry of the whole bacterium into the mammalian cell [51]. Therefore, invasin expression restricts the tropism of these bacteria to non-phagocytic cells expressing β 1-integrin [58,59], while invasin-negative recombinant *E. coli* can be used to target professional phagocytic cells [41,42]. In the case of bacterial delivery vectors that remain in the lysosome/phagosome, such as *Salmonella*, the mechanism of delivery remains unclear [12].

Another interesting approach might be used in bacterial delivery systems [7]. Bacteria are not used for the gene transfer but the proteins secreted by bacteria persist in the target tissues. More recently, the utilization of double-stranded RNA (dsRNA or RNA interference, the so-called RNAi) to silence target genes has potential therapeutic applications that are widely acknowledged [29,60]. Recent progress in this strategy

was made by using nonpathogenic bacteria to induce gene silencing in target cells, both *in vitro* and *in vivo*. Bacteria-mediated induction of RNAi was established by demonstrating target-specific gene silencing after transfer of double-stranded RNA from *E. coli* in the nematode *Caenorhabditis elegans* [61,62]. Another example of bacteria-mediated RNAi transfer for functional genomics is postulated by Xiang et al. who developed an siRNA delivering system using nonpathogenic *E. coli* engineered to transcribe shRNAs from a plasmid containing the invasin gene *inv* and the LLO gene *HlyA*, which encode two bacterial factors needed for successful transfer of the shRNAs into mammalian cells. Upon oral or intravenous administration, *E. coli* encoding shRNA against CTNNB1 (catenin β -1) induce significant gene silencing in the intestinal epithelium and in human colon cancer xenografts in mice [63,64]. Another *in vivo* study carried out by Zhang et al. using attenuated *S. typhimurium* to deliver STAT3-specific RNAi, bacterial vector could preferentially home to tumor tissues, inhibit tumor growth, and extend the survival in experimentally induced mice [65]. In the light of these results obtained previously, the delivery of dsRNA or eukaryotic expression plasmids encoding siRNAs into mammalian cells can be envisaged in the near future.

12.3 APPLICATION OF BACTERIAL VECTORS

12.3.1 INFECTIOUS DISEASES

At the end of the nineteenth century, killed bacteria started to be first used as vaccination against infectious disease. In early twentieth century, killed *Salmonella typhi* was used both in England and Germany by the end of the First World War. However, it is only until 1960 that well controlled field trials of two forms of killed *S. typhi* vaccine provided unequivocal evidence of their considerable but incomplete protective effect [33,66].

Mucosal membranes remain the most frequent portals of entry of pathogenic microorganisms. Mucosal immunization with whole formalin killed *Pseudomonas aeruginosa*, *Branhamella catarrhalis*, nontypable *Haemophilus influenzae*, or *Streptococcus pneumoniae* results in enhanced homologous bacterial clearance from the lung of immune animals challenged with live bacteria [67]. This has prompted studies aimed at the development of intranasal or enteral vaccination protocols in the protection of mucosa. Furthermore, following the attenuation of bacterial pathogenicity and carrying antigen-expressing plasmids, those bacterial vectors exploit more flexible strategies in infectious disease (Table 12.1). For example, attenuated strains of *Yersinia* spp., *S. enterica* serovar *typhi* and *Typhimurium*, *Shigella* spp., and *L. monocytogenes* have been successfully applied as DNA delivery vectors against certain infectious diseases mainly of bacterial and viral origin. Antigens were derived from viruses such as HIV, measles, hepatitis B, hepatitis C, herpes simplex 2, cytomegalovirus, human papillomavirus 16, and pseudorabies. Similarly, a variety of bacterial antigens from *L. monocytogenes*, *Mycobacterium tuberculosis*,

Chlamydia trachomatis, *Brucella abortus*, *Pseudomonas aeruginosa*, and *Clostridium tetani* were exploited through bacteria-mediated DNA transfer. Antigens from eukaryotic pathogens such as *Penicillium marneffeii* were also delivered using bacterial DNA carriers [29].

Oral administration in mice of an attenuated *Yersinia enterocolitica* carrying a eukaryotic expression plasmid encoding *Brucella* genes elicited humoral and cellular responses. This immune response, in conjunction with potential cross-reacting antibodies against LPS of both *Yersinia* and *Brucella*, induced protection against a *Brucella* challenge [68].

In earlier studies by Pasetti et al., intranasal vaccination of *Salmonella typhi* or *Shigella flexneri* 2a carrying plasmids encoding fragment C (Frag C) of tetanus toxin could elicit higher titers of Frag C antibodies than those induced by intramuscular inoculation of bacteria carrying a prokaryotic expression plasmid in which the expression of the same antigen was inducible *in vivo* [31,32]. Those pioneer studies demonstrated that bacteria can serve as a vehicle for the delivery of foreign antigens to the systemic immune system and intranasal

inoculation is sufficient to induce an immune response against both the live vector and heterologous antigen as oral inoculation [69]. Another set of studies exploited *S. typhimurium* as a gene delivery vector, when β -galactosidase was used as a transgene, specific cytotoxic T-lymphocytes (CTLs) and T-helper (Th) cells, mainly of the Th1 type, as well as specific antibodies could be detected after a single oral vaccination [34]. A very similar immune response was elicited by *S. typhimurium* vectors expressing two virulence factors of *L. monocytogenes* (LLO and ActA) [70]. These vaccines could protect the mice from a lethal challenge with *L. monocytogenes* and partially protective after single dose [71]. β -galactosidase as well as a fusion antigen of the *P. aeruginosa* outer membrane protein with the fimbriae was administered orally or nasally. Multiple nasal administrations were necessary to obtain a T-cell response in the spleen compared with a single oral one [13,71]. Specific IgGs were observed in the gut, saliva, and serum after oral administration, whereas nasal administration gave rise to antibodies in the lungs, saliva, and serum, with hardly any antigen-specific IgA detected [71]. Independently,

partial protective responses against *Chlamydia* were obtained in the lungs of mice after oral administration of *Salmonella* encoding the major outer membrane protein of *Chlamydia trachomatis* [13]. To increase the immunogenicity of the expression plasmid, Galen et al. showed that the vaccination of engineering of cytolysin A hemolysin (ClyA) fused to the encoded antigen, domain 4 (D4) moiety of *Bacillus anthracis* protective antigen (PA), lead to a higher titer of anti-PA IgG production [72]. For parasitic infection, Gomez-Duarte et al. demonstrated the immunogenicity of *S. typhi* secreting *Plasmodium falciparum* sporozoite surface protein (SSP-2) and the cytokine responses from nasal immunization in mice [73]. Furthermore, the same group developed a prime-boost strategy consisting of nasal mucosal delivery of *P. falciparum* circumsporozoite surface protein PfCSP exported from a *S. typhi* followed by an intradermal PfCSP DNA boosting. The mice in the prime-boost group developed higher frequencies of IFN- γ -secreting cells [74]. Shen et al. reported the use of *L. monocytogenes* carrying IL-12 cDNA to manipulate host immune responses against *Leishmania* major-infection [75], which is the first demonstration that a gene introduced into a host by *Listeria* works to modulate the murine host immune response against infections *in vivo*. More recently, attenuated *S. typhimurium* vaccine encoding *Helicobacter pylori* UreB gene and mouse IL-2 gene was constructed and tested in mice model which showed the protective effect against *H. pylori* infection [76] which may contribute to the development of a human-use *H. pylori* DNA vaccine to treat peptic ulcer.

In the past decade, developing a measles vaccine that can be administered in the presence of maternal antibodies has posed a great challenge. *A. S. flexneri* and *S. Typhi Ty21a* were employed as DNA vaccine encoding measles antigens. Intranasal immunization with the *Shigella* carrier as well as intraperitoneal immunization with the *Salmonella* carrier resulted in strong, boostable measles-specific cellular immune responses albeit weak humoral responses in mice [30,77]. Another priority for the global health issue is to develop an effective vaccine to treat/prevent HIV infection. The overwhelming number of HIV transmissions takes place via mucosal surfaces and hence the mucosal immunity stimulated by HIV vaccine plays a vital role in protection against HIV. Shata et al. demonstrated *S. typhimurium* Δ aroA carrying an HIV-1 envelope (Env) DNA vaccine administered to mice stomach and led to Env-specific CD8⁺ T cell responses, both in mucosal and systemic lymphoid tissue. By contrast, intramuscular vaccination with the naked Env DNA vaccine induced systemic CD8⁺ T cells only [78]. Likewise, oral immunization with an HIV glycoprotein (gp120) DNA vaccine via *S. typhimurium* Δ aroA induced strong systemic and mucosal CD8⁺ T-cell responses [78]. In addition, *S. flexneri* Δ aroA Δ iscA was employed to deliver a DNA vaccine encoding gp120 [79]. Intranasal immunization of mice elicited strong CD8⁺ T-cell responses comparable to those induced by intramuscular injection of the plasmid or intraperitoneal immunization with a recombinant vaccinia-env vector. When *S. enterica* serovar *Typhi Ty21a*, *S. enterica* serovar *Typhimurium* Δ aroA and *S. flexneri* Δ asd were compared in

the intranasal mouse model, *Shigella* induced the strongest gp120-specific CD8⁺ T cell responses, followed by *S. enterica* serovar *Typhimurium* and *Ty21a*, respectively. In a side-by-side study [80], Karpenko et al. compared the efficacy of naked DNA vaccines alone, attenuated bacteria, and virus-like particles (VLPs) as carriers for DNA delivery in inducing immune responses against an HIV polypeptide antigen. For this purpose, mice were immunized intramuscularly with naked DNA plasmid or with encapsulated VLPs containing the eukaryotic HIV-polypeptide CTL-immunogen (TCI) expression plasmid or immunized mucosally with attenuated *Salmonella* carrying the identical plasmid. The artificial VLPs and the recombinant *Salmonella* vaccine both induced HIV-specific immune responses superior to those obtained after vaccination with naked DNA alone. Compared to VLPs as delivery vectors, *Salmonella* vaccination revealed slightly higher humoral and cellular immune responses [80]. Finally, Xu et al. proposed the use of an attenuated *Shigella* defective in LPS-O-antigen synthesis and carrying an HIV gag DNA vaccine as a boost, after priming by intramuscular DNA injection [81]. Gag specific T-cell responses were detected in the spleen and lungs and the prime/boost strategy resulted in a dramatically increased T-cell response in the lungs [81]. Another group in Japan by Tsunetsugu-Yokota et al. also demonstrated that an oral *Salmonella* vaccine carrying HIV gag potentiated the intestinal CTL responses in nasally primed mice with gag p24 and cholera toxin adjuvant [82].

Bacterial vaccines also bring some hope to the treatment of chronic viral hepatitis disease. Oral vaccination with *S. typhimurium* encoding a hepatitis B virus surface antigen (HBsAg) proved to induce stronger CTL responses in Balb/c mice than recombinant HBsAg vaccination [83]. The same research group also showed that a single administration of these bacteria vaccine to transgenic mice expressing HBsAg in the liver led to loss of expression of the antigen in hepatocytes [84]. This loss of HBsAg was accompanied by hepatic flare that subsided after 3 weeks, while the suppression of HBsAg expression continued in the absence of overt liver pathology for the remaining duration of the experiment (12 weeks). This single administration of the recombinant bacteria induced CTLs, Th1 T cells, and HBsAg-specific IgG2 subclass antibodies as further proof that immune tolerance against the viral antigen had been broken. A similar *S. typhimurium* was also used in bacteria-mediated DNA vaccination against the non-structural region 3 (NS3) of hepatitis C virus in HLA-A2.1 transgenic mice [85]. A single oral administration induced A2.1-restricted CTLs, INF- γ -producing T cells, and resistance against a challenge with NS3-expressing vaccinia virus [85].

Other DNA vaccinations mediated by bacteria include vaccination against influenza [86,87] with *Listeria* or a recombinant strain of *S. flexneri*, vaccination against herpes simplex virus-2 by attenuated *S. typhimurium* [88], vaccination against human papillomavirus type 16 by *S. typhimurium* [89,90], vaccination against influenza virus by *S. flexneri* [87], and vaccination against pseudo-rabies virus using either nonpathogenic *E. coli* administered intramuscularly [91] or a swine-adapted strain of *S. choleraesuis* [92].

TB is evolving as the leading killer of young adults worldwide among all the single infectious agents nowadays. The recent increase in TB patients especially in developing countries is caused among others, by pandemic HIV, war and political instability, drug resistance, and increasing poverty. The BCG vaccine has been effective in controlling childhood TB but does not confer protection against adult TB of endogenous or exogenous infection. Therefore, efforts are being made to develop alternative weapons to fight TB infection. Miki et al. [93] reported protective cellular immunity against *Mycobacterium tuberculosis* using the *L. monocytogenes* $\Delta 2$ strain DNA vaccine encoding *M. tuberculosis* antigens. Parida et al. [94] employed the *S. enterica* serovar *Typhimurium* Δ aroA strain as DNA vaccine carrier for the delivery of the *M. tuberculosis* Ag85A antigen. Comparative animal studies in mice were performed using the intranasal as well as the oral route for the application of the *Salmonella* vaccine carrier. To this end, bactofection was superior to vaccination with naked DNA as monitored by the bacterial load in different organs after intravenous challenge with *M. tuberculosis*. The immune response as monitored by IL-2 and IFN- γ levels was higher after administration of the vaccine carrier by the intranasal compared to the oral route.

12.4 CANCER IMMUNOTHERAPY

Cancer is the second leading cause of death in industrialized countries. Since increasing number of patients are suffering from different forms of cancer, traditional cytotoxic chemotherapy is often not curative or durably responsive when tumor cells are disseminated. Cancer immunotherapy is a promising approach due to its potential eradication of disseminated tumor cells. Vaccines against cancer face a difficult challenge as their targets are usually tumor-associated self-antigens that are poorly immunogenic, undergo mutations, and often suppress immune responses at the cellular level. Therefore, targeting specific tumor antigen, inducing *in vivo* effective CTL responses, and breaking self-tolerance should be the main aims when developing cancer vaccines.

Anecdotal case reports from more than 200 years ago describe tumor regression in patients with severe bacterial infections [95]. Application of bacteria in cancer therapy was pioneered independently by Friedrich Fehleisen and William B Coley in the late 1800s and early 1900s [96,97], leading eventually to immunomodulation for the treatment of cancer. Many more recent studies have now shown the potential of genetically engineered bacteria as tumor-targeting vectors in human cancer therapy (Table 12.2). Among the bacterial

vectors designed for cancer vaccine, *Salmonella* strains have essentially been used to deliver DNA for therapeutic applications in oncology. In the first instance, “model” tumor antigens such as β -galactosidase was encoded in eukaryotic expression vectors carried by strains of *Salmonella* [98,99]. Oral administration of these bacterial strains delivery of DNA vaccines encoding the model tumor antigens protected the mice against challenges with fibrosarcoma [98] or renal carcinoma [99]. In addition, when real murine/human tumor antigen/epitope was expressed in *Salmonella* vector, the tumor protective effect still could be demonstrated in neuroblastoma [100–102], melanoma [103,104], and adenocarcinoma [105,106].

Attacking the tumor’s vasculature has been documented as an effective strategy to inhibit tumor growth/metastasis. This antiangiogenic intervention has been anticipated in *Salmonella* expressing vascular endothelial growth factor receptor (FLK-1 or Fra-1) [107–111]. Recently, Endoglin (CD105), a co-receptor in the TGF- β receptor complex that is overexpressed on proliferating endothelial cells in the breast tumor neovasculature, was delivered by attenuated *S. typhimurium*. In a prophylactic setting, a pronounced CD8⁺ T-cell response was induced which effectively suppressed dissemination of pulmonary metastases in mice [112,113]. Another strategy used the delivery of the endogenous angiogenic inhibitor, thrombospondin-1 (TSP-1), by *S. choleraesuis* demonstrated to be effective for the treatment of primary and metastatic melanomas [114]. Platelet derived growth factor receptor beta (PDGFR β) expressed by a *Salmonella* vaccine also showed the suppression of angiogenesis *in vivo* and reduction of tumor stromal cell proliferation [115]. Combined application of cyclophosphamide with a DNA vaccine targeting PDGFR β not only completely inhibited the growth of different tumor types but also led to tumor rejections in mice [116]. Legumain is highly upregulated on macrophages in many tumor tissues and consequently applicable for tumor therapy. Immunization of mice with *Salmonella* vaccine encoding for Legumain induced a robust CD8⁺ T-cell response against tumor-associated macrophages and in turn led to a suppression of tumor angiogenesis, tumor growth, and metastasis by profoundly altering the tumor microenvironment [117]. Emergence of acquired multidrug resistance (MDR) remains a major challenge in the treatment of cancer following chemotherapeutic drugs and thus MDR gene serves an alternative cancer vaccine target. *Salmonella* vaccine against MDR-1 have also inhibited tumor growth and metastasis in preclinical studies [118]. This also enabled the further combination of targeting MDR-1 with tradition cytotoxic therapy in effective treatments of cancer.

It has been shown that the immune responses mediated from bacteria-delivering DNA vaccines can be dramatically improved by modifying the expression vectors or co-expression of immunostimulatory molecules. Optimization of the bacterial vectors carrying DNA vaccine was shown to be achieved by different means. (1) The expression levels of delivered antigen can be enhanced by adding a posttranscriptional regulatory

acting RNA elements. In experimental murine model, the antitumor effect can be further augmented by boosting with antibody–cytokine fusion protein boost that targets IL-2 to the tumor microenvironment [101]. (2) Antigen-fusion to ubiquitin can also increase antigen processing and effective presentation in order to break peripheral T cell tolerance to a self-antigen [119,120]. (3) Co-expression of invariant chain leads to preferential presentation in the context of MHC class II molecules [104]. (4) Expression of CD40L [121] alone or co-expression of CD40L/antigen [120] upregulated the expression of Fas, B7–1, and B7–2 molecules and improved antigen presentation to T cells. (5) Fusion of cytokine gene into DNA vaccine produced immune-modulatory effects, such as IL-2 [122], IL-4/IL-18 [123,124], GM-CSF/IL-12 [125], IL-12/VEGFR2 (or FLK-1) [126], IFN- γ [127], IL-18 [128] (or combined FRA-1) [128,129], CCL21 with apoptosis protein inhibitor (survivin) [130], NKG2D ligands [131,132]. (6) Co-expression of LLO in addition to tumor antigen caused lysosomal escape and the antigenic epitope to be presented onto MHC class I complex [41,42,58]. (7) From the experience in bacterial vaccine against HIV infection [81,82], the use of prime-boost strategy to enhance and prolong CTL responses is also applied in the field of cancer vaccine, such as primed by naked DNA vaccine and boosted by bacterial vaccine or primed by bacterial vaccine boosted by antigen-loaded DCs [99].

Hypoxic or necrotic regions are characteristic of solid tumors in many murine and human tumors, including the majority of primary tumors of the breast and uterine cervix. The limitation of cancer gene therapy approaches in solid tumor treatment is the delivery vectors, which achieve specific high-level expression within tumor tissues or the tumor environment following systemic or parenteral administration. Accordingly, gene therapy for solid tumors that exploits and targets gene expression in hypoxic tumor cells is currently being investigated [133]. It is known that certain species of anaerobic bacteria, including the genera *Clostridium* and *Bifidobacterium*, can selectively germinate and grow in the hypoxic regions of solid tumors after intravenous injection [134,135]. In such cases, bacteria proliferate between tumor cells and thus the therapeutic gene is not introduced into the tumor cell, but rather the therapeutic protein is produced in the tumor. Candidate bacterial vectors for gene introduction include species of *Bifidobacterium*, *Clostridium*, and *Salmonella*. *Bifidobacterium* is a normal bacterial flora in the intestine, and is the nonpathogenic. *B. longum* transformed with plasmid containing the gene for human endostatin, a potent inhibitor of angiogenesis, has been shown to affect liver tumor growth inhibition in Balb/c mice [136,137]. In the study by Theys et al. described that *C. acetobutylicum* expressing murine-TNF- α is a possible tool for cancer therapy [138]. The use of anaerobic bacterial vaccine for the selective delivery of prodrug-activating enzymes also has been proved to be efficient in preclinical studies [139–142].

In these studies, the *E. coli* enzyme cytosine deaminase (CD) [140,142,143] and nitroreductase [139] were expressed

in *Clostridium* and were shown to convert the nontoxic prodrugs 5-fluorocytosine and CB1954, respectively, into toxic compounds capable of diffusing in the tumors and killing the cancer cells through a bystander effect. Using a similar principle, a strain of *Clostridia* was engineered in which a radioresponsive promoter drove the expression of TNF- α [144]. Gram-negative *Salmonella* have also been proposed as oncolytic agents. In contrast to obligate anaerobic bacteria such as *Clostridia* and *Bifidobacteria*, *Salmonella* are facultative anaerobic bacteria and have the potential to colonize oxygenated small metastatic lesions as well as large tumors with a hypoxic centre. The anaerobic bacteria per se also could exert oncolytic effect and thus potentiate the cytotoxic chemotherapy. In the study by Lee et al., *Salmonella choleraesuis* in combination with cisplatin acted additively to retard tumor growth and extensively prolong the survival time of the mice bearing hepatomas or lung tumors. This enhanced antitumor immune responses, manifested by increased infiltrating neutrophils, CD8⁺ T cells, and apoptotic cells in the tumors, represents a promising strategy for the treatment of primary and metastatic tumors [145]. Dang et al. assessed 26 different strains of anaerobic bacteria systemically for their proliferative capacity to grow within avascular compartments of transplanted tumors, one (*Clostridium novyi*) appeared particularly promising [146]. This research group also demonstrated that intravenous injection of *C. novyi-NT* can potentiate the treatment effect from selected anti-microtubule agents [147] or radiotherapy [148] in animal models without excessive toxicity. Another study carried out by Cheong et al. demonstrated the *C. novyi-NT* plus a single dose of liposomal doxorubicin enhanced the tumor eradication effect [149].

One study applied this bacterial delivery of prodrug-activating enzyme into clinical setting [150]. Nemunaitis et al. used *Salmonella* vector expressing *E. coli* CD in the therapy of chemotherapy-refractory colorectal cancer patients. Although the study was a pilot study with only three participating patients, the results are very promising and point towards the potential of this procedure [150]. An earlier study published by Toso et al. applying *Salmonella* vaccine (VNP20009) in clinical cancer patients with metastatic melanoma demonstrated that *Salmonella* vaccine could be safely administered intravenously to human. The maximum tolerated dose was found to be 3×10^8 cfu/m², with thrombocytopenia, anemia, persistent bacteremia, hyperbilirubinemia, diarrhea, vomiting, nausea, elevated alkaline phosphatase, and hypophosphatemia as the dose-limiting toxicities. Some tumor colonization was observed upon injection of highest tolerated dose. However, no clinical antitumor effects were seen in their study [37]. Altering the kinetics of infusion failed to improve response or colonization in a small number of subsequently treated patients [151]. Another phase I trial of systemic administration of *Salmonella* vaccine to dogs with the spontaneous tumor model showed acceptable toxicity results in detectable bacterial colonization of tumor tissue and significant antitumor activity in tumor-bearing dogs [152].

12.4.1 OTHER GENETIC DEFICIENCIES

Although most studies using bacteria for various gene therapy-related procedures developed for the treatment of infectious or neoplastic diseases, expectations have been put into the usage of bacterial vaccine in other clinical entities like inflammatory diseases, genetic deficiencies, or vascular diseases.

Inflammatory bowel disease (IBD) is a significant health-care problem and the pathogenesis is complex and relies on the interaction between three essential factors: genetic susceptibility, intestinal bacteria, and the gut mucosal immune response. The traditional treatment by immunomodulation strategies usually lacks organ specificity and results in unpleasant side effects. As an alternative, administration of an engineered *Lactococcus lactis* secreting IL-10 led to local production of the anti-inflammatory cytokine and prevented the development of colitis in different mouse models [153]. This strain was also modified to carry a mutation disabling the thymidylate synthase, resulting in a strain dependent on the availability of thymine or thymidine in the local microenvironment, which was less likely to accumulate in the environment [154]. Another bacterial vector used is the invasive *E. coli* [11], expressing invasins from *Yersinia* and LLO from *Listeria* and carrying a eukaryotic expression plasmid expressing TGF- β 1 [155]. Oral administration of these bacteria led to a significant reduction of the severity of experimental colitis in mice, with vector-specific transcripts detected in colonic and extra-colonic tissues such as the lungs, liver, and spleen. Further modification of the CMV promoter replacing by the inflammation inducible IL-8 promoter has shown the improved expression of TGF- β 1 in the inflamed colon without extracolonic expression and affecting the therapeutic effects [155].

Bacterial vectors are capable of transferring a functional gene copy into target cells (airway epithelium) in various models of monogenic diseases like cystic fibrosis (CF). Fajac et al. have shown that *E. coli* expressing invasins and LLO is able to deliver GFP gene into normal or CF airway epithelial cells [156]. A major problem of this study was the unsatisfying selectivity of gene transfer. Krusch et al. have used *L. monocytogenes* to deliver CF transmembrane conductance regulator (CFTR) to mammal cells indicating the possibilities of bacterofection usage in the treatment of inherited disorders [157]. Invasive strains of *E. coli* are also capable of transferring CFTR into target cells (airway epithelium) in CF [156,158,159]. These results demonstrate that bacteria allow the cloning, propagation, and transfer of large intact and functional genomic DNA fragments and their subsequent direct delivery into cells for functional analysis.

In the last years several studies have indicated the possibilities of VEGF in the therapy of ischemic heart disease. In the study by Celec et al., *E. coli* vectors, which produce angiogenic factors, VEGF, proved to induce neovascularization in experimental animals [160]. This strategy provides a new modality for experimental angiogenesis and may be applicable in ischemic diseases. On the contrary, VEGF may also be served as the target in arteriosclerotic diseases. Vaccination

against VEGFR2, carried by *S. typhimurium*, led to inhibition of angiogenesis, slowing down the progression of preexisting advanced atherosclerosis, and increased neointima formation. These results indicate the significant role of VEGFR2 (+) cells in cardiovascular diseases and DNA vaccination targeting these cells may contribute to the development of novel therapies against atherosclerosis [161].

12.5 EMERGING TECHNOLOGIES

One of the problems encountered when trying to transfect mammalian cells with large DNA molecules is the possibility of mechanical breakage of these large molecules during the purification process. In that context, the utilization of bacteria to transfer large DNA molecules would simplify the procedure. The delivery of bacterial artificial chromosomes was first demonstrated into HeLa cells using an invasive *E. coli* [162]. Direct DNA transfer of up to around 1 Mb was demonstrated and as the bacterial vector is equipped with an inducible recombination system, modifications of the bacterial artificial chromosome sequences should be possible. More recently, efficient transfer of an α -satellite DNA cloned into a P1-based artificial chromosome was stably delivered into the HT1080 cell line and efficiently generated human artificial chromosomes de novo [159]. In the same report, a 160 kb construct containing CFTR gene was transferred into the same cells, where it was transcribed and correctly spliced [159]. In a study in mice, large DNA molecules carrying the viral genome of the murine cytomegalovirus (MCMV) were transferred using *E. coli* and *S. typhimurium* as delivery vectors [163]. This transfer led to a productive virus infection that resulted in elevated titers of specific anti-MCMV antibodies, protection against lethal MCMV challenge, and strong expression of additional genes introduced into the viral genome. Thus, the reconstitution of infectious virus from live attenuated bacteria presents a novel concept for multivalent virus vaccines launched from bacterial vectors.

The second issue in bacterial vector therapy is to monitor the delivery efficiency after vaccination. Soghomonyan et al. demonstrated that using *Salmonella* (VNP20009) expressing HSV-thymidine kinase reporter gene was able to selectively localize within murine tumor models and to effectively sequester a radiolabeled nucleoside analogue, and thus could be analyzed by quantitative autoradiography and positron emission tomography (PET). The ability to noninvasively detect *Salmonella* vectors by PET imaging has the potential to be conducted in a clinical setting, and could aid in development of these vectors by demonstrating the efficiency and duration of targeting as well as indicating the locations of tumors [164].

It is clear that each vector interacts with the elements of the innate immune system in complicated ways that can impact both the quantity and quality of immune responses elicited by the vector. The immune system can normally respond to bacterial vector and passenger antigen stimulation but mechanisms of immune regulation in hosts will be started to induce self-tolerance. The past 10 years have witnessed

a renaissance in the field of active mechanisms of immune regulation, and much of this points to a particular group of T cells, currently described as CD4⁺ CD25⁺ Foxp3⁺ regulatory T (Treg) cells which play a suppressive role in antitumor vaccinations [165]. Several studies have demonstrated the adjuvant effects with affecting Treg cells obtained from additional gene co-expressing in bacterial vectors. Hussain et al. demonstrated that the Treg cell inhibition is responsible for the differences in vaccine-mediated antitumor responses and less Treg cells was found in the mice vaccinated with *Listeria* vector expressing LLO and antigen [166,167]. Furthermore, Nitcheu-Tefit et al. showed that the incorporation of LLO in the *E. coli* vaccine can affect Treg cell inhibitory function and may have important implications for enhancing antitumor vaccination strategies in humans [168]. By the increasing number of studies regarding the role of Treg cells in cancer patients [169,170], there is a clear rationale for developing bacterial vaccines to manipulate these regulatory influences and augment antitumor immunity.

12.6 BIOSAFETY ISSUE

The ideal bacterial vaccine has to meet the balance between the biosafety and immunogenicity. There is no single bacterial vector approved for human utilization in gene therapy despite the extensive research that has been conducted or still is undergoing in the field of DNA vaccination. The development of candidate vaccine focuses mainly on immunological aspects, e.g., to the induction of the desired immune response against the delivered antigen. However, the lack of relevant animal models during the preclinical development phase makes it hard to predict the immune response and hence the outcome of clinical trials with candidate bacterial vectors.

For bacterial gene therapy two major types of safety issues can be distinguished [171]. The first issue involves the safety of the bacterial strain chosen to deliver the genetic material of interest, e.g., the risks associated with the release of the non-recombinant bacterium. The second involves the risks that are associated with the delivered foreign genetic material. Several guidelines have been developed by the competent regulatory authorities that address these issues resulting in an extensive documentation necessary to characterize the strains and also to characterize the impact on the environment [171].

The main concerns about the safety of bacterial vaccine strains are reversion to virulence, the establishment of systemic infections, horizontal gene transferring, or translocation to organs others than the side of administration of the vaccine [23,172]. A further concern is whether the delivered bacteria could have a negative impact on the indigenous microflora or establish a permanent colonization of the intestine. Also the unintentional transfer of the bacterial cells to other individuals is a point of concern, especially, if they are shed into the environment and are capable of surviving in environments other than the intestines. Additional safety issues that have to be considered are the sequence of the therapeutic gene and the way in which the recombinant strain is constructed. Bacteria-mediated DNA vaccine integration is very unlikely but may

potentially cause mutagenesis if the plasmid insertion reduces the activity of a tumor suppressor or increases the activity of an oncogene. Previous integration by Ledwith et al. study has shown that the probability of any DNA molecule integrating randomly into the chromosome, however, is quite low following intramuscular DNA injection [173].

Upon modifying the immune responses of DNA vaccines by co-administration of genes encoding immunostimulatory cytokines, these vaccines need to be tested either in animal species that respond to the encoded human cytokine or to use expression of analogous animal genes to avoid of chronic inflammation or generalized immunosuppression. It has been demonstrated that the vaccination with live bacterial vaccines could induce the formation of auto-reactive anti-DNA antibodies, and several authors have tried to assess the possibility that vaccination has an impact on the generation of auto-immune responses [174]. However, the relation between vaccine and autoimmunity remains obscure and subsequent publications did not support this theory of generating autoimmune reactions. However, this remains an important point, especially when a bacterial vaccine expresses a real tumor antigen, which is usually a self-antigen.

12.7 FUTURE DIRECTION AND CONCLUSION

As more and more antigens are identified for various infectious diseases or cancer, bacterial vectors will offer a shuttle for introducing the newly identified antigens to the immune system. Furthermore, it should be possible to coordinately express more than one antigen at a time (i.e., a panel of disease specific antigens) to mount a complete immune response against a particular disease in one particular administration. Although the experience from LLO and Invasin expressed in bacterial vaccine has greatly improved the antigen delivery and intracellular processing, one obstacle most likely still hindering gene delivery is the intracellular trafficking of gene cargo to the nucleus. Current systems might be able to efficiently enter the cell cytoplasm and release genetic cargo, but the use of designed mechanisms for facilitating nuclear transport has not been investigated thoroughly. Also, the dosage, location of vaccination, or optimal prime/boost strategy in bacterial vaccine therapy still need to be further defined.

In summary, bacterial vectors in gene therapy seems to be a valuable tool with a specific niche of application, mostly in immunotherapy.

13.1 INTRODUCTION

Polyelectrolyte complexes of nucleic acids with polycations (polyplexes) are investigated as promising delivery vectors for a variety of nucleic acid therapeutics. In particular, polyplexes capable of responding to environmental changes or stimuli by altering their properties and behavior seem to promise a significant improvement of the efficacy of the delivery process. Variety of external and endogenous stimuli can be utilized to improve overall efficiency of polyplexes. While the external stimuli are by nature physical (ultrasound, heat, magnetic field, light), the endogenous ones offer a wider variety ranging from simple chemical stimuli to complex biochemical stimuli. Irrespective of its nature, a given stimulus can improve polyplex efficiency by one of three distinct mechanisms. First, a stimulus can be used to facilitate spatial and temporal control of the release of nucleic acids from the polyplexes. Examples of successfully used stimuli to release nucleic acids from polyplexes include pH gradient and redox potential gradient [1–3]. Second, a stimulus can be used to alter properties of polyplexes and thus allow overcoming selected barriers. This approach is relatively less investigated than the first one and can be based on both external and endogenous stimuli (heat, ultrasound, pH gradient, redox potential gradient). An example of such an approach is to use hyperthermia to improve transfection activity [4–7]. Third, a stimulus can be used to favorably alter physiological properties of target tissues to increase the efficiency of polyplexes. This

approach creates potential risks as well as benefits and is limited to external stimuli such as acoustic cavitation [8–11]. Here, we discuss the properties and current state of the art of polyplexes responsive to redox potential gradients.

13.2 REDOX-RESPONSIVE POLYPLEXES

One of the several stimuli, which has been utilized for improving the efficiency of nucleic acid delivery, is the redox potential gradient existing between extracellular and intracellular environments. The existence of a high redox potential gradient between oxidizing extracellular space and the reducing environment of subcellular organelles has been exploited by incorporating disulfide bonds into the structure of the delivery vectors to provide them with the capability to release the therapeutic nucleic acids selectively in the subcellular reducing space. The original interest in gene delivery systems controlled by redox potential gradients was guided by the need to transiently enhance stability of the vectors during the delivery. Although both polyplexes and lipid-based delivery systems [12–17] have been developed that are controlled by redox potential gradients, this chapter focuses exclusively on the polyplex vectors.

13.2.1 BIOLOGICAL RATIONALE

A redox potential gradient exists between extracellular environment and various subcellular organelles in normal as well

as pathological states. Disulfide bonds present in the structure of polyplexes are readily reduced in the reducing intracellular environment, while they are generally preserved in the oxidizing extracellular space. The intracellular reduction of disulfide bonds in polyplexes is most likely mediated by thiol/disulfide exchange reactions with small redox molecules like glutathione (GSH) and thioredoxin; either alone or with the help of redox enzymes. GSH (L- γ -glutamyl-L-cysteinylglycine) is the most abundant intracellular thiol present in millimolar concentrations inside the cell but only in micromolar concentrations in the blood plasma [18]. GSH has multiple direct and indirect functions in many critical cellular processes like synthesis of proteins and DNA, amino acid transport, enzyme activity, metabolism, and protection of cells [19]. GSH also serves as a reductant by functioning to destroy free radicals, hydrogen peroxide, and other peroxides. It also functions as a storage form of cysteine. The intracellular GSH concentration is an additive function of both its oxidized (GSSG) and reduced form (GSH). The GSH redox ratio ([GSH]:[GSSG]) is maintained and determined by the activity of GSH reductase, NADPH concentrations, and transhydrogenase activity. The redox state of the GSH/GSSG couple is often used as an indicator of the overall redox environment of the cell. In contrast to other redox systems in the cell, it is important to realize that not only the [GSH]:[GSSG] ratio, but also absolute concentrations of GSH and GSSG are important for the estimation of the redox state of the cell [20]. This is because the Nernst equation for the reduction potential of the GSH/GSSG couple depends on $[GSH]^2/[GSSG]$. The GSH concentration and redox ratio ([GSH]:[GSSG]) are different in various subcellular compartments, supporting different roles of this redox molecule in the different compartments [21]. Because of the different GSH levels in various subcellular organelles, the local GSH concentration and [GSH]:[GSSG] ratio are important for predicting the location and rate of the disulfide reduction.

The majority of GSH is usually found in the cytosol (1–11 mM), which is also the principal site of GSH biosynthesis [22–24]. The most reducing environment in the cell is usually found within the nucleus, where it is required for DNA synthesis and repair and to maintain a number of transcription factors in reduced state [25–27]. The nuclear GSH levels are typically greater than those found in the cytosol and can reach up to 20 mM [21,27,28]. Another major pool of GSH in the cell is found in mitochondria (~5 mM) [29,30]. Both mitochondrial and nuclear GSH pools are at least partially independent of the cytosolic pool. In contrast to the reducing environment found in the nucleus and mitochondria, the endoplasmic reticulum (ER) is more oxidizing than the cytosol [31,32]. The ratio [GSH]:[GSSG] typically ranges from 1:1 to 3:1, which is relatively low compared with the overall ratio in the cell (usually >30:1). Whereas the above concentrations can serve as a general guideline when assessing the influence of redox environment on the polyplexes, one should keep in mind that the redox state of the cell is not static. It depends on a variety of factors including the stage of the cell cycle and biological status of the cell in general [20].

Despite numerous studies, the redox state of endosomes and lysosomes remains a contested issue. Even though some evidence suggests the possibility of endosomal and lysosomal reduction of disulfide bonds [33–37], recent report provides evidence that both the endosomal and lysosomal environments are oxidizing (similar to ER) and disulfide reduction proceeds rather inefficiently [38]. As a way of explaining the previous observations of disulfide reduction in endosomes, it was suggested that such reductions in endocytosed macromolecules could have proceeded in Golgi [39]. As acknowledged by the authors of the study on the oxidizing environment in endosomes and lysosomes, however, one cannot exclude the possibility that a small subset of lysosomes could be reducing or that only some disulfides within certain proteins could be susceptible to endo/lysosomal cleavage. Because redox polyplexes typically contain a large number of disulfides, it is unlikely that the limited reducing potential of endo/lysosomes plays an important role in their subcellular trafficking. The subcellular distribution of reducing capability and current understanding of subcellular trafficking of polyplexes therefore suggests that intracellular reduction of disulfide bonds in redox-sensitive polyplexes proceeds preferentially in the cytoplasm and nucleus (Figure 13.1).

Whereas the reducing nature of the intracellular environment is a well-established fact, the presence of reactive oxygen species and absence of a redox buffer means that the extracellular space is predominantly oxidizing ([GSH] ~1.5 μ M; [GSH]:[GSSG] ~7:1) [18]. Despite the oxidizing nature of the extracellular environment, however, the presence of redox-active thiols in numerous proteins on the cellular plasma membrane suggests that at least the microenvironment of the cell surface can support disulfide reductions [39–41]. The redox activity of the plasma membrane is closely correlated with the levels of redox enzymes at the plasma membrane [42–44]. The maintenance of the thiol groups is mediated by the transfer or shuffling of hydrogens and electrons between the cysteine thiols of these surface proteins [45]. The total levels of redox-active thiols on the surface of cells range from ~4 to ~30 nmol per 10^6 cells [45,46]. Whereas the intracellular reducing environment has been widely utilized in gene delivery, the reducing microenvironment of the plasma membrane received considerably less attention. To our knowledge, there has been only one report describing an attempt to utilize the cell membrane thiols to improve gene delivery by increasing cellular uptake of DNA [47] and one report proposing to utilize the cell surface reduction as a trigger to disassemble thin DNA films [48]. Whether the reducing potential of the plasma membrane is sufficient enough to have any significant, negative or positive, effect on the activity of gene delivery systems, however, remains to be investigated [39].

13.2.2 PREPARATION METHODS OF REDOX-RESPONSIVE POLYPLEXES

Vast majority of the reported redox-responsive polyplexes contains reducible disulfide bonds in the structure of the polyplexes. There are only a few examples of polyplexes in which

FIGURE 13.1 Schematic representation of subcellular trafficking of redox-responsive DNA polyplexes. (Adapted from Oupicky, D., et al., *Expert Opin. Drug Deliv.*, 2, 653, 2005.)

the disulfides are associated with the nucleic acid [49]. The introduction of disulfide bonds into polyplexes is relatively simple. Three different methods are primarily employed in achieving this task (Figure 13.2) and are reviewed in this section: (1) polycations containing disulfide bonds are synthesized first and used to prepare the polyplexes; (2) oligocations containing two or more thiols are used to prepare the polyplexes, which is followed by DNA-template polymerization within the polyplexes leading to high-molecular weight reducible polymers; (3) disulfide-containing cross-linkers are used to cross-link pre-formed polyplexes. Although each of the three main methods has its own set of advantages and disadvantages, the recent trends seem to favor the first method in which the disulfide-containing polycations are synthesized first and then used to formulate the polyplexes.

13.2.2.1 Synthesis of Disulfide-Containing Polycations

There has been an increased interest in recent years in the synthetic methods of preparing disulfide-containing polycations. Synthesizing polycations containing the disulfide bonds already before polyplex formation (as opposed to creating the

disulfides after the polyplexes are formed) allows not only better characterization of the polymers, but also a more diverse and controlled placement of the disulfide bonds (Figure 13.2A). Historically, probably the first example of a polycation with disulfides in the backbone intended as gene delivery carrier has been described by Balakirev et al. [50]. The authors prepared a cationic derivative of lipoic acid and its polymerization via opening the 1,2-dithiolane ring provided the desired reducible polycation.

Among the most readily available methods for synthesis of reducible polycations is to react oligo- and polyamines with commercially available disulfide-containing cross-linkers. Such approach was applied to the synthesis of reducible polycations based on low-molecular weight poly(ethylenimine) (PEI) and a variety of oligoamines such as spermine or pentaethylene hexamine [51–54]. Because of the multivalent nature of the polycations used and random nature of the cross-linking, the synthesized reducible polycations are usually branched or hyperbranched polymers. While these features to some extent reduce the definition of the product, the simplicity of the reactions offers the possibility to synthesize small polycation libraries and fast screening of numerous polycations [52].

FIGURE 13.2 Methods of preparation of disulfide-containing polyplexes. (A) Polyplexes are prepared using polycations containing disulfide bonds, (B) DNA-template polymerization: Polyplexes are prepared using oligocations containing two or more thiols followed by DNA-template polymerization within the polyplexes, and (C) polyplexes are prepared and then cross-linked using disulfide-containing cross-linkers.

Another versatile synthetic approach to reducible polycations relies on mild oxidation of thiol groups introduced into the structure of oligo- and polycations. Oxidation of thiol-containing polycations offers tremendous versatility as virtually any polycation can be thiolated. In particular, peptides are especially well suited for this approach as thiol groups can be introduced with unprecedented control. Cationic peptides containing cysteine terminal groups have been polymerized into linear polypeptides via oxidation of the thiol groups with a mild oxidizing agent such as dimethylsulfoxide [55–58]. Reducible cationic polypeptides were prepared not only based on a single peptide, but also on a combination of several peptides with different amino acid sequences, thus offering an easy way of preparing polymers containing multiple biological functions [59–61].

While easy availability and potential inherent biological activity made peptide-based polycations among the most attractive for preparation of redox-sensitive polyplexes, recent reports also indicate increased interest in new types of synthetic reducible polycations.

Synthesis of well-defined analogues of reducible linear PEI by oxidation of α,ω -bisthiol-oligoethylenimines has been described by Park and colleagues [62]. The synthesized

reducible PEI shows reduced cytotoxicity and comparable transfection activity when compared with control nonreducible PEI. The synthesized reducible PEI represent better defined polymers in comparison with earlier attempts to prepare reducible PEI by random cross-linking of PEI oligomers [51,52].

In a search for efficient polymer carriers of nucleic acid therapeutics, methacrylate- and acrylate-based polycations have been widely investigated due to convenient synthesis by free-radical polymerization and the possibility to optimize their properties by copolymerization of a number of ionic and nonionic comonomers [63]. Poly(2-dimethylaminoethyl methacrylate) (PDMAEMA) emerged as one of the most promising polycations in this class [63–68]. Substantial cytotoxicity, however, impeded PDMAEMA prospects in gene delivery and prompted the development of biodegradable DMAEMA alternatives [66]. While synthesis of reducible polypeptides by oxidation of terminal thiol groups has been reported by numerous investigators, the traditional way of preparing methacrylate polymers by free-radical polymerization leads to polymers with high polydispersity and with poorly defined end-group chemistries; both of which severely limit the possibility of synthesizing the necessary

FIGURE 13.3 Synthetic approach to reducible polycations via RAFT polymerization demonstrated on the example of DMAEMA. (From You, Y.Z. et al., *Biomacromolecules*, 8, 2038, 2007; You, Y., et al., *J. Control. Release*, 122, 217, 2007.)

thiol-terminated polymers. Two recent studies report, for the first time, a synthesis of reducible PDMAEMA copolymers using reversible addition-fragmentation chain transfer (RAFT) polymerization and their use in gene delivery [69,70]. RAFT polymerization is an exceptionally versatile tool for the synthesis of α,ω -functionalized polymers of narrow molar mass distributions and it has opened new possibilities for the synthesis of previously unattainable (meth)acrylate copolymers [71–74]. RAFT polymerization is arguably more versatile with respect to monomer choice than other living free-radical polymerization techniques as it can be applied to virtually any type of monomers without the necessity of protecting functional groups. Reducible PDMAEMA was synthesized as shown in Figure 13.3. Difunctional RAFT agent (BTBP) was used in an AIBN-initiated radical polymerization of DMAEMA to obtain α,ω -dithioester-functionalized oligomers (1). The terminal dithioester groups of (1) were converted into thiol groups by aminolysis with hexylamine. Final reducible PDMAEMA (3) was synthesized by oxidation of the terminal thiol groups of (2) (Figure 13.3). Reducibility of the synthesized PDMAEMA was confirmed by treatment with dithiothreitol (DTT), which resulted in the decrease of molar mass to values similar to the original dithiol-DMAEMA oligomer [69,70].

Reducible poly(amidoamine)s (PAAs) emerged as yet another recent example of the increased interest in reducible polycations. PAAs are a family of water-soluble and biodegradable polymers obtained by the polyaddition of primary or secondary aliphatic amines to bisacrylamides (Figure 13.4). The first example of PAAs containing disulfide linkages along their backbones synthesized by the stepwise polyaddition of 2-methylpiperazine to *N,N'*-bis(acryloyl)cystamine

FIGURE 13.4 Examples of synthesized reducible PAAs. (From Emilietri, E., Ranucci, E., and Ferruti, P., *J. Polym. Sci. Pol. Chem.*, 43, 1404, 2005; Lin, C. et al., *Bioconjug. Chem.*, 18, 138, 2007; Christensen, L.V. et al., *Bioconjug. Chem.*, 17, 1233, 2006.)

and *N,N'*-bis(acryloyl)-(L)-cystine was reported by Ferruti et al. [75]. Synthesis of a small library of reducible PAAs suitable for use in gene delivery was reported in several recent publications by Kim and Feijen by Michael addition reactions of different oligoamines with the cystamine bisacrylamide linker [76–78]. All the reducible PAAs were shown to be reduced to low-molecular weight products after disulfide reduction.

Alternative strategy aimed at reducing the affinity of polycations to nucleic acids upon cellular internalization uses polymers containing disulfide bonds in the side chain. For example, quantitative substitution of amino groups of PLL with 3-(2-aminoethylthio)propionyl residues resulted in the reducible disulfide bonds located in the side chains of the polycation. Release of DNA from such polyplexes was observed upon treatment with DTT and GSH [79]. More recently, biodegradable poly(β -amino ester) with disulfide side chain was synthesized and used as an efficient gene delivery carrier [80]. Finally, an interesting example of redox-responsive polyplexes in which the disulfide reduction leads to a disassembly of necklace-like rotaxane structures was reported by Ooya et al. [81].

13.2.2.2 DNA Template-Assisted Polymerization

The second method of introducing disulfide bonds into the structure of polyplexes relies on the use of cationic molecules containing at least two thiol functionalities and their oxidation *in situ* (Figure 13.2B). When polyplexes are formed using this method, the local concentration of the thiol groups increases substantially, which leads to an easy aerial oxidation without the need for any additional oxidizing agent. This approach, also called DNA template-assisted polymerization, has been widely explored using short cationic peptides containing multiple cysteine residues by Rice and colleagues. The original studies were performed with peptides consisting of several lysines and different number (1–5) of cysteines [82]. Using peptides with three and more cysteines resulted in the formation of polyplexes stabilized by disulfide cross-links. The general applicability of this approach was confirmed for peptides with various amino acid sequences as well as peptides containing additional nonpeptide functionalities like poly(ethylene glycol) (PEG) and carbohydrates [58,83–87].

Direct comparison was conducted of the properties of DNA polyplexes prepared either by using the DNA-template-assisted polymerization or by using pre-formed reducible polypeptide [58]. A cationic peptide with a sequence derived from the HIV-1 Tat was used in those studies. Even though some differences were reported in the physical properties of the two types of polyplexes, no major effect of the preparation method was observed on the transfection properties of the polyplexes.

Similar approach has been applied by Kataoka et al. to the formation of disulfide-stabilized polymer micelles/polyplexes for delivery of various nucleic acids [88–91]. In this alternative approach, thiol groups are introduced into the cationic blocks using standard chemical methods such as use of Traut's

reagent and *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP), and the cross-linking disulfide bonds are then formed *in situ* by aerial oxidation as above.

13.2.2.3 Polyplex Cross-Linking Using Low Molecular Weight Reducible Cross-Linkers

Probably the simplest way of providing polyplexes with stabilizing disulfide bonds is to use commercially available disulfide-containing cross-linking agents (Figure 13.2C) [53,92–94]. For example, complexes of DNA with poly(L-lysine) (PLL) were efficiently and reversibly stabilized by cross-linking with dimethyl-3,3'-dithiobispropionimide (DTBP) via unpaired amino groups of PLL [92,93]. These low-molecular weight cross-linking agents can also be used in the DNA-template copolymerizations with DNA-condensing cationic molecules to form linear reversible polycations [95]. This approach, despite its simplicity, has not found a widespread use because of the need for excess cross-linkers due to competing hydrolysis, poor reproducibility, and difficulties to analyze the extent of the reaction in the obtained polyplexes.

13.2.3 BIOLOGICAL ACTIVITY AND MECHANISM OF ACTION

The studies of the redox-responsive polyplexes focused mostly on their *in vitro* properties with only limited amount of data available on the *in vivo* behavior and properties. Here, we will discuss the properties of redox-sensitive polyplexes that we believe represent the main advantages for their use and the rationale for further development.

13.2.3.1 Physicochemical Properties of Redox-Responsive Polyplexes

Physicochemical properties are known to affect biological properties of polyplexes. Changes in the physicochemical properties caused by the reduction of disulfides in the polyplexes are therefore likely to be reflected in changes of biological activity. The most obvious consequence of the reduction of disulfides in polyplexes is a decrease of the affinity between the nucleic acids (e.g., DNA) and the polycations. This in turn results in a faster and easier polyplex disassembly and DNA release. While polyplexes based on linear reducible polycations show only quantitative changes in the disassembly with disulfide reduction [56,60,77], cross-linked polyplexes typically exhibit full stabilization against disassembly (i.e., DNA release), which is then reversed after reduction [53,93]. Introduction of disulfide bonds into polycations usually increases their hydrophobicity, although no evidence suggests that this change has any influence on activity of the polyplexes [48,75,96]. For the reduction-induced changes in properties to have any effect on biological activity of polyplexes, they must occur on the same timescale as the extracellular and subcellular steps of delivery. Available evidence clearly points out that the disulfide reduction in the polyplexes proceeds with high rates and is typically completed within 1 h (usually faster) at

GSH concentrations found in the cytoplasm [50,62,80]. Conversely, the reduction rates at GSH concentrations typically found in blood plasma are almost negligible. This means that, unlike many polyplexes based on hydrolytically degradable polycations, the redox-responsive polyplexes show a significant spatial selectivity of their responses, and that the rates at which the responses to reducing environment occur can realistically influence the delivery process.

13.2.3.2 *In Vitro* Properties of Redox Polyplexes

The easy intracellular reversibility of disulfide bonds in the redox-sensitive polyplexes proved to be an advantageous feature for efficiently delivering a variety of nucleic acids, including plasmid DNA, mRNA, antisense oligonucleotides, and siRNA. The reduced affinity between the nucleic acids and polycations upon the intracellular reduction of disulfide bonds is believed to enhance availability of the nucleic acids for their biological function. Due to the subcellular compartmentalization of the GSH, it may be even possible to improve the selectivity of cellular delivery by controlling the location of the redox-induced disassembly. Indeed, based on the current knowledge, we predict that most likely RNA-based therapeutics will benefit from a potential to improve the selectivity of delivery based on GSH levels and subcellular distribution.

The intracellular reduction of disulfides within the polyplexes has been clearly demonstrated in numerous studies. The reduction is believed to increase the rates of polyplex disassembly and thus promote better availability of the delivered nucleic acids for transcription/translation machinery (Figure 13.1). It is reasonable to hypothesize that changes in intracellular GSH concentrations will manifest themselves in altered activity of the redox polyplexes. The anticipated relationship between the extent and rates of intracellular degradation and transgene activity then offers a real opportunity to modulate polyplex activity in disease states associated with altered cellular redox state. Available evidence suggests that indeed artificially changing cellular GSH levels leads to changes in polyplex biological activity, albeit the differences are often small. Most of the published data were obtained with DNA polyplexes. In general, increasing the cellular GSH levels by incubating the cells with a membrane-permeable derivative of GSH leads to an increase in transfection activity of redox DNA polyplexes [50,56,77,94]; supporting the notion that increasing the GSH concentration leads to increased disulfide reduction and improved DNA availability. A recent report, however, shows a significant decrease of transfection activity after artificial increase of GSH levels in prostate carcinoma PC-3 cells [57]. These results suggest that an optimum intracellular GSH concentration might exist for each cell line that will result in the highest transgene expression; and that a straightforward relationship between intracellular GSH concentrations and polyplex activity could be an oversimplified view. If increasing the GSH concentration leads to enhanced transfection activity, then, depleting intracellular GSH by inhibiting its *de novo* synthesis would be expected to have an opposite effect. Most of the available reports confirm this

hypothesis by demonstrating a small decrease in DNA transfection of redox polyplexes after incubating cells with buthionine sulfoximine (BSO), which inhibits γ -glutamylcysteine synthetase necessary for cytosolic GSH biosynthesis [50,56,57,77,94]. Similar effect of GSH inhibition on the reduction of activity was confirmed also for siRNA redox polyplexes [97].

As already mentioned, delivery of plasmid DNA has been by far the most investigated application of the redox-sensitive polyplexes. Number of studies in a variety of cell lines showed transfection activities comparable or better than those observed for PEI and commercially available lipid formulations [51,55–57,60,76,77,79,82,83,90]. The benefits of the redox-sensitive polyplexes for efficient delivery have been demonstrated also for mRNA. Unlike DNA, only cationic lipids were successfully used to efficiently deliver mRNA. High intracellular stability of polyplexes based on high-molecular weight polycations was believed to be responsible for the extremely low mRNA expression [98]. In comparison, polyplexes formed using smaller polycations could mediate relatively high levels of gene expression. Recent studies document that using redox-sensitive polyplexes results in a high mRNA activity, even when high-molecular weight polycations are used (Figure 13.5) [56,57]. These results suggest that cytosolic reduction of the disulfide bonds in the polyplexes results in an increased bioavailability of mRNA.

Recently published studies confirm the applicability of redox-sensitive polyplexes also for efficient delivery of small nucleic acids such as siRNA and antisense oligonucleotides [49,57,97,99]. Similar to mRNA, siRNA acts in the cytoplasm and thus its delivery is significantly simplified by not needing to traverse the nuclear membrane to initiate its action. One can hypothesize that the reducing environment leads to environmentally triggered release of siRNA in the cytoplasm. This was clearly demonstrated by an efficient silencing of human vascular endothelial growth factor (VEGF) in PC-3 cells [97]. The redox polyplexes exhibited much higher RNAi activity against VEGF expression than control PEI polyplexes (~50% vs. ~20% silencing). Further evidence of the advantageous use of redox polyplexes for siRNA delivery was demonstrated by the ability of high-molecular weight, reducible, histidine-rich polycations to deliver siRNA targeted against neutrophin receptor p75^{NTR} in primary cultures of adult rat dorsal root ganglion cells [57]. While the redox polyplexes showed a complete knock-down, PEI polyplexes caused only around 60% knock-down in expression, which was attributed to the restricted availability of the siRNA in the cytoplasm.

Efficiency of a different approach to deliver siRNA using redox-sensitive polyplexes was demonstrated by the ability of disulfide-linked conjugates of siRNA with membrane-penetrating peptides to cause efficient silencing in a wide variety of cell lines [99]. Cytoplasmic delivery of antisense oligodeoxynucleotides (ODN) using redox-sensitive polyplexes also was reported recently [49]. The authors synthesized redox-sensitive polyion complex micelles composed of polycations and a PEG-ODN conjugate bearing a disulfide

FIGURE 13.5 (See color insert following blank page 206.) Histidine-rich RPCs mediate efficient delivery of mRNA. linkage between the PEG and ODN segments and demonstrated enhanced cytoplasmic delivery of ODN.

13.2.3.3 Decreased Toxicity of Reducible Polycations

The toxicity of polycations such as PEI is a well-known phenomenon [100–102]. Available data on cytotoxicity of the reducible polycations and their DNA polyplexes show that all the reducible polycations exhibit only minimal toxicity when compared with control nonreducible polycations [56–58, 76–78]. In fact, the observed cytotoxicity is often similar to that obtained for low-molecular weight degradation products of the reducible polycations. The observed low cytotoxicity of the disulfide-containing polycations is most likely a direct consequence of the reduced binding affinity for the intracellular membranes and vital proteins and nucleic acids after rapid intracellular reduction and subsequent decrease of molecular weight of these polycations. The available results also suggest that significant contribution to the cytotoxicity of polycations originates from their intracellular action and that direct destabilization of the plasma membrane may not be the major contributor to the polycation toxicity [60].

13.2.3.4 *In Vivo* Properties of Redox Polyplexes

The studies reported so far focused on two aspects of the *in vivo* behavior of redox-sensitive polyplexes, namely on the stability of their disulfide bonds in plasma circulation [61,93,94] and on the hepatic transfection efficiency [85,91].

Although blood plasma environment is generally oxidizing, reduction of disulfide bonds can potentially occur due to the presence of low concentrations of cysteine and GSH. Premature reduction of disulfides in the polyplexes prior to their arrival at the target cells could severely compromise their transfection activity as evidenced by experiments with polyplexes pre-incubated with reducing agents before *in vitro* transfection experiments [56]. The compatibility of redox-sensitive polyplexes with plasma environment was tested with two formulations. First, polyplexes based on reducible polypeptide prepared from Cys(Lys)₁₀Cys were stabilized by surface cross-linking with multivalent HPMA copolymers and their extended plasma circulation was confirmed in mice [61]. Second, PLL/DNA polyplexes were cross-linked with disulfide-containing cross-linker and sterically stabilized by PEG [93]. The polyplexes then exhibited significantly extended plasma circulations times, which increased with increasing cross-linking density. This was documented by an increase in the amount of the polyplexes remaining in the circulation 30 min after intravenous injection compared with non-cross-linked controls. Almost 40% of the injected dose (ID) was found in circulation for highly cross-linked polyplexes, 27% for intermediately cross-linked polyplexes, whereas only 5.8% of control non-cross-linked polyplexes remained in circulation 30 min postinjection [93]. These findings were recently confirmed for disulfide cross-linked PEI polyplexes, although the improvement in the plasma circulation was not as substantial due to the absence of PEG in the polyplex formulations [94].

Nevertheless, the area under the plasma concentration–time curve for 0–60 min increased to 2435% ID/mL min for the highest cross-linking degree tested, compared to 766% ID/mL min for the control polyplexes. These observations indicate that the reduction-mediated destabilization of the polyplexes in blood plasma is not significant, if any, within the timeframe observed and that redox-sensitive polyplexes are suitable for systemic application. These results also are supported by previous studies on long-circulating liposomes containing disulfide bonds [103].

In vivo transfection efficiency of redox-sensitive polyplexes was evaluated using hepatocyte-targeted formulations [85]. The polyplexes were prepared using three thiol-containing peptides with different functions: (i) hepatocyte targeting, (ii) blocking nonspecific RES recognition, and (iii) DNA condensation. The structure of the DNA-condensing peptide was varied to modulate the metabolic stability of DNA in the liver. Four different peptides based on L- or D-amino acids and containing either cysteine or penicillamine residues were studied. It was found that positively charged polyplexes exhibited higher metabolic stability in the liver than negatively charged polyplexes. Replacing L-amino acids with D-amino acids also resulted in significantly increased metabolic half-life of DNA in the liver, while using sterically stabilized disulfides by replacing cysteine with penicillamine had no influence on metabolic stability. This suggests that disulfide reduction proceeds readily in the hepatocytes and is not the rate-limiting step of hepatic metabolism of DNA. Finally, the redox-sensitive polyplexes were able to mediate prolonged expression of transgene (secreted alkaline phosphatase) *in vivo*, which peaked at day 7 postinjection and returned to baseline levels by day 12.

Recent report indicates suitability of the redox polyplexes for delivering VEGF gene to ischemic myocardium to achieve tissue regeneration [104]. VEGF gene delivery can reduce myocardial infarct size through cardiomyocyte regeneration, enhancement of cardiomyocyte viability, and neovascular proliferation. Using a rabbit infarct model, the author showed that the redox-responsive polyplexes produce higher VEGF concentrations than controls. The best formulation showed VEGF expression nearly fourfold higher than the luciferase control and twofold higher than a lipid-based positive control at half the transfection amount [104].

14.1 INTRODUCTION

The completion of the Human Genome Project [1] is a step towards understanding the genetic basis of disease and will doubtless provide more information on the interplay between genes and ill health. Genes are nucleic acid materials which serve as repositories for the amino acid sequences of the cell's work horses, the proteins. Proteins in turn control cell physiology and cell biochemistry. Mutated genes can give rise to nonfunctional proteins or pathogenic proteins and ultimately disease. Such disease-causing genes may be used as therapeutic targets in gene therapy. Gene therapy is important not just because it is an alternative means of treating disease but also because it offers the hope of treatments for currently incurable diseases such as cystic fibrosis, sickle cell anemia, and cancer. Such diseases are either hereditary or acquired and can be

either monogenetic in origin (due to the mutation of a single gene) or originate from the malfunctioning of more than one gene. Examples of monogenetic diseases are cystic fibrosis [2], sickle cell anemia [3], and severe combined immune deficiency disease [4]. The exact genetic basis of diseases such as cancer is more complex and typically is the result of multiple mutations. In gene therapy, the therapeutic exogenous gene encodes for the replacement copy of the missing or faulty gene (Figure 14.1). Alternatively, as in the treatment of certain cancers, the therapeutic gene may encode for an enzyme capable of specific activation of a pro-drug [5], or encode for a therapeutic protein [6].

Another aspect of gene therapy is the use of genes as vaccines. Genes used in the prevention of infectious diseases are genes encoding for specific antigens which will

FIGURE 14.1 Replacement gene therapy. A therapeutic plasmid could give rise to a therapeutic protein which either replaces a non-functional protein from a mutated gene or has a therapeutic effect.

ultimately produce prophylactic antibodies [7]. Gene therapy is also possible using small interfering RNA sequences (siRNAs) to effect gene silencing. These materials inhibit translation and the disease-causing protein is no longer expressed (Figure 14.2).

Although it is possible to combat diseases with gene therapy, the current paucity of marketed gene therapeutics hints at the fact that reducing this concept to practice is rather problematic. One key difficulty lies in the delivery of the therapeutic gene or siRNA [8–10]. The gene therapeutic, if administered for the treatment of a disease such as cancer or cystic fibrosis must evade degradation by extracellular nucleases, resist deactivation by other extracellular components, and traverse both the plasma and nuclear membranes intact in order to access the transcription locus and produce the therapeutic protein. Each of these stages is fraught with a huge potential for failure and to achieve effective gene therapy these transport barriers must be overcome with the aid of delivery systems. It is in the delivery of genes that polymers and dendrimers are applied. Delivery systems fall into two main classes: viruses and synthetic compounds (nonviral systems). Nonviral gene delivery

FIGURE 14.2 Exogenous siRNAs are incorporated into the RNA-induced silencing complex (RISC). The RISC is a large protein-siRNA complex which targets RNA transcripts for degradation. Binding of the siRNA is in the double-stranded form but unwinding of the strand yields a single-stranded antisense template to guide recognition of the target mRNA. The RISC precursor complex (~250 kDa) is transformed in the presence of ATP into the active 100 kDa complex that can endonucleolytically cleave the substrate mRNA in regions homologous to the siRNA template. The cleaved mRNA fragments are released and the RISC complex can bind and process the next mRNA molecule.

systems may be prepared from polymers, lipids, or dendrimers [8]. This chapter is concerned with the delivery of genes and other nucleotides using polymers and dendrimers (Figures 14.3 and 14.4).

Polymer- and dendrimer-based gene therapeutics comprise of anionic DNA electrostatically bound via its phosphate groups to amine polymers or dendrimers (Figures 14.5 and 14.6). These amine polymers and dendrimers are protonated at physiological pH and thus possess a positive charge and the electrostatic complexes are termed polyplexes in the case of polymers and dendriplexes in the case of dendrimers (Figures 14.5 and 14.6). Polyplexes or dendriplexes present as particles of 40–1000nm in size [11,12] and colloidal particles are obtained largely by the manipulation of dendrimer/polymer DNA charge ratio [11,12].

Gene therapy is not a brand new concept as the first gene therapy clinical trial took place in May 1989 [13]. The trial involved cancer patients and retroviral gene transfer into

human somatic cells in an *ex vivo* approach. Cells were harvested, infected with the gene of interest, and then reconstituted back into the patients. This clinical trial signaled the start of a long journey and 2 years later the first nonviral gene therapy clinical trial was conducted [14]. Generally viral vectors are thought to have superior transfection efficiencies over that seen with nonviral vectors [15,16] and as such the former have been most frequently investigated in clinical trials [17]. However, serious safety issues have been associated with the use of viral vectors over the last 5 years such as insertional mutagenesis with retroviral vectors [18] and a fatal response to the use of adenoviral gene delivery [19]. These events make the hunt for safe, effective, and preferably nonviral gene transfer systems even more important than was previously thought. This notwithstanding, the commercial launch of the viral gene medicine, Gendicine, in China is highly encouraging [20]. This gene therapeutic comprises an adenovirus carrying the p53 apoptosis causing

FIGURE 14.3 Examples of some cationic gene (polymers 1–4) and siRNA (polymer 5 only) delivery polymers. 1, chitosan; 2, linear poly(ethylenimine) (PEI); 3, branched PEI; 4, poly(L-lysine); 5, polyvinyl ether. Various derivatives of polymers 1–5 have also been used to deliver other nucleotides for gene therapy.

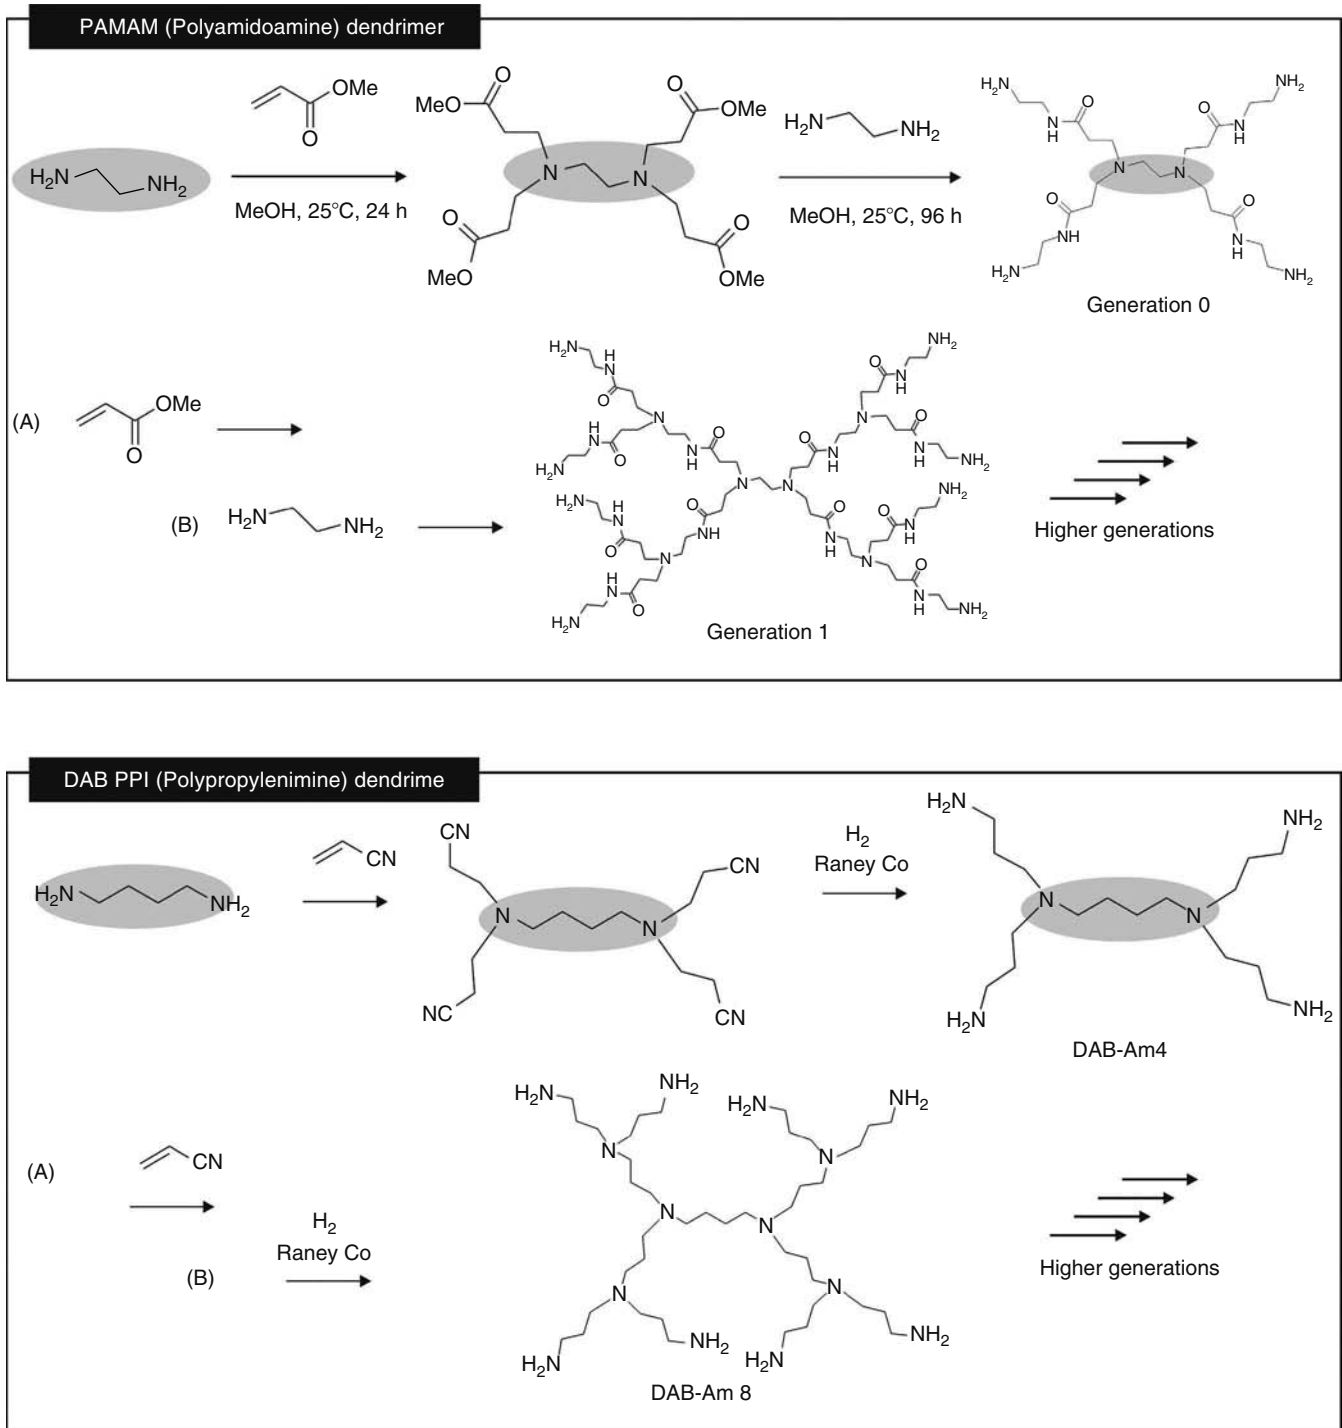

FIGURE 14.4 Convergent synthesis of polyamidoamine and poly(propylenimine) dendrimers; these dendrimers are active as gene transfer agents.

gene and it is injected locally into the tumor for the treatment of head and neck cancers. At the time of writing, this particular form of gene therapy was only licensed for use in China. The fact that viruses are largely not amenable to systemic delivery (e.g., used in intravenous injections) also militates against their widespread use. This limitation is especially important when considering the treatment of cancer, for example, as micro metastases may only be combated with

the use of systemically active therapeutics. Metastasis is the event that leads to a cancer patient's death.

Currently gene therapy research is focused on achieving biodegradable gene delivery options that offer specificity of targeting to the desired cells on systemic administration, transfection efficiencies on par with viruses, and possibly long-term gene expression by sustained release mechanisms; this is the desire although we are not there yet [8,9].

Before considering the various carriers (polymers and dendrimers) in detail, it is thus pertinent to first review the biological barriers to delivery encountered by DNA medicines.

14.2 BIOLOGICAL BARRIERS TO GENE DELIVERY

Nucleic acids, unless significantly chemically modified, tend to be rapidly degraded in tissues or in the systemic circulation [21]. The package of nucleic acids within synthetic particles made from cationic lipids, polymers, or dendrimers [8,9,22,23], which complex DNA or oligonucleotides, via electrostatic interactions, limits the extracellular degradation of nucleic acids. The complexation process leads to a nanoparticle and an excess of the cationic carrier ensures that the nanoparticle carries a positive charge at physiological pH. This cationic nanoparticle encounters a number of biological barriers before locating the nuclei of its target cell types.

FIGURE 14.6 Dendriplex formation on electrostatic binding of genes and dendrimers. (A) Water soluble poly(propyleneimine)G3 dendrimer, (B) atomic force microscopy image of poly(propyleneimine)G2 dendrimer–DNA dendriplexes (dendrimer, DNA weight ratio = 5:1). (C) molecular modeling simulation of (from left to right) poly(propyleneimine)G2 dendrimer–DNA binding and poly(propyleneimine)G3 dendrimer–DNA binding. (Adapted from Schatzlein, A.G. et al., *J. Control. Rel.*, 101, 247, 2005.)

Most of the work on the biological barriers to gene transfer has been carried out on polyplexes as opposed to dendriplexes and hence much of the evidence supporting the presence of these biological barriers is drawn from the polyplex literature. In mechanistic terms it appears that dendriplexes and polyplexes behave in a similar manner and differences between the mechanism of action of polyplexes and dendriplexes, at the cellular level at least, appear to be subtle rather than profound. However, some differences in

the biodistribution of gene expression have been noted, for example, when polyplexes are compared to dendriplexes produced from low-molecular weight dendrimers; the latter produce superior tumoricidal results when incorporated in a cancer gene medicine [6].

The biological barriers faced by nucleic acid medicines may be broadly classed as being of an extracellular and intracellular nature (Figure 14.7). Examples of the extracellular barriers to gene delivery include susceptibility to enzymatic

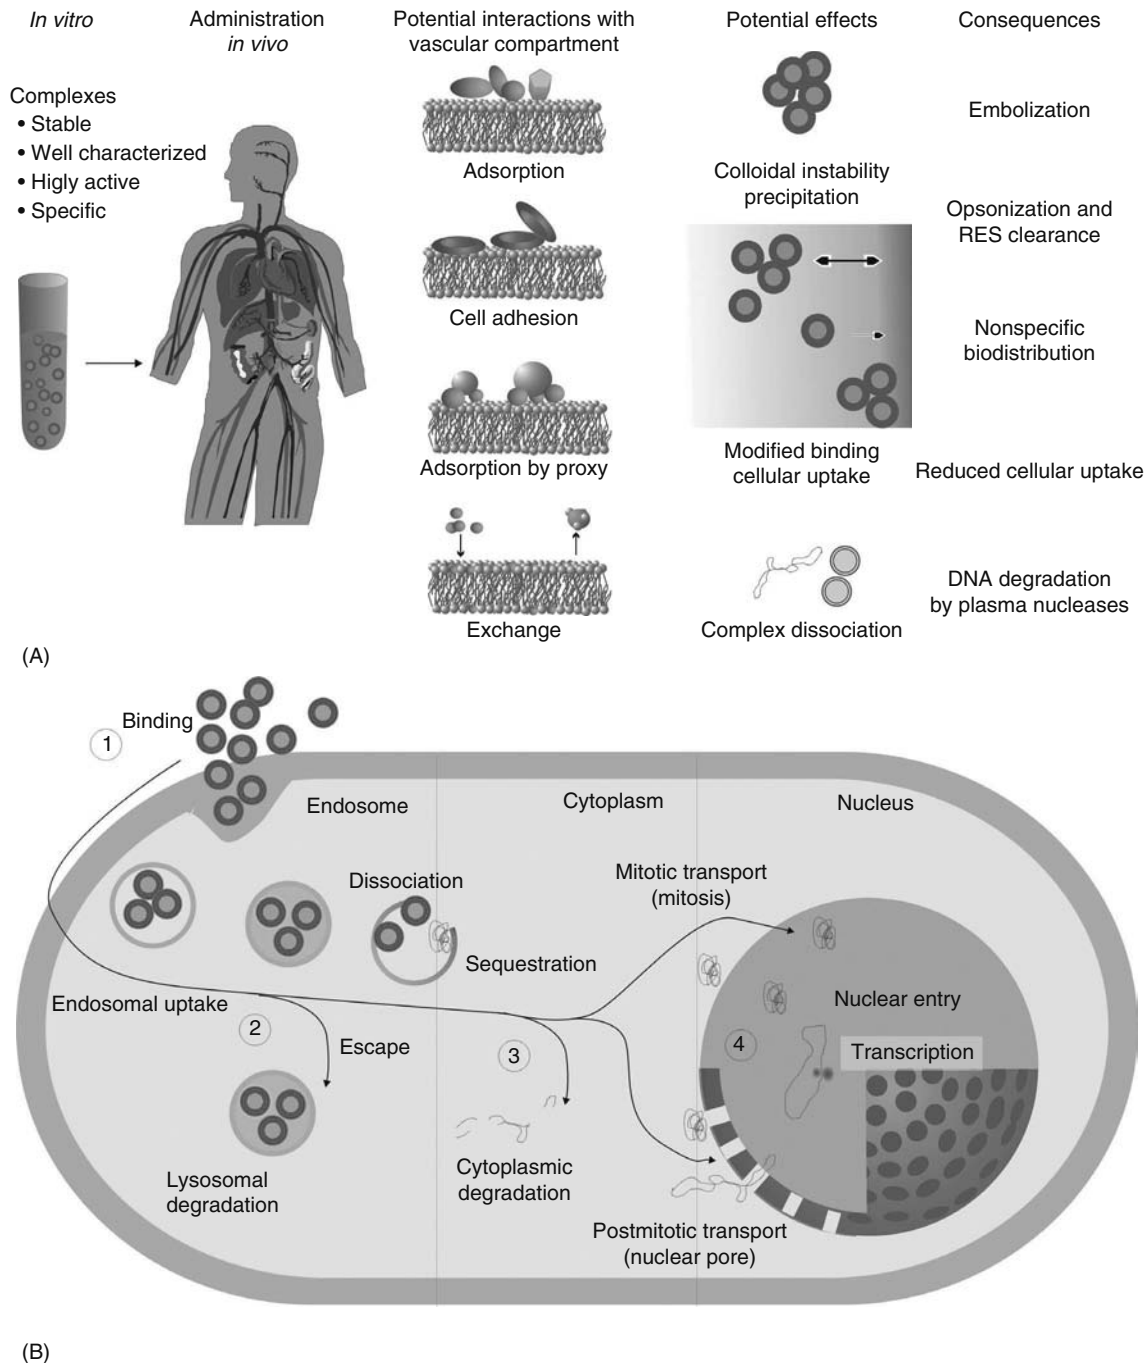

FIGURE 14.7 (A) Extracellular barriers to the delivery of therapeutic genes. (B) Intracellular barriers to the delivery of therapeutic genes. (Reproduced from Uchegbu, I.F. and Schatzlein, A.G., *Polymers in Drug Delivery*, CRC Press, Boca Raton, 2006. With permission.)

degradation by nucleases in the serum and extracellular fluid [24], the presence of a mucus coat on certain cell surfaces [25], such as those required to be breached in the treatment of cystic fibrosis, vulnerability to inactivation by interactions with blood components [26], the possibility of recognition and elimination by immunological defense systems [27], and the possibility of uptake by nontarget organs and tissues [28]. Once inside the cell, the intracellular barriers to gene expression come into play and these include entrapment and degradation within the endosomes and lysosomes [29,30], vulnerability to cytoplasmic nuclease enzymatic attack [31], and the relative impenetrability of the nuclear membrane [32,33]. Once safely inside the nucleus the genes are transcribed to produce mRNA which is in turn transported to the cytoplasm and eventually translated into the therapeutic protein. The biological barriers described above must be overcome in order to achieve a clinically relevant level of gene expression.

14.3 EXTRACELLULAR BARRIERS TO GENE DELIVERY

14.3.1 INTERACTIONS WITH PLASMA AND BLOOD COMPONENTS

Upon entering the systemic circulation, the injected exogenous gene will be enzymatically degraded by the nucleases present in the serum [24]. However, upon incorporation of the gene within polyplexes or dendriplexes [34,35], the gene does acquire some resistance to degradation by serum nucleases [36]. The polyplexes then need to travel to their target site of action. One factor that is crucial in allowing the polyplexes to travel unhindered to their target site is their particle size [37]. A colloidal (<500nm) particle size is ideal. On intravenous injection of colloidal polyplexes, there is an interaction with serum proteins which leads to polyplex aggregation and an increase in particle size [26,28,38]. This size increase is thought to hinder transport through the fine capillaries and tissues and result in polyplexes being entrapped within the first capillary bed encountered, that of the lung [26,28].

Exogenous gene expression is predominantly observed in the lung following intravenous administration of polyplexes [26,28]. It is clear that if polyplexes are to be targeted to tissues other than the lung, the polyplexes must resist aggregation prior and subsequent to *in vivo* application [26,28,39]. However, most polyplexes tend to aggregate at physiological salt concentrations and are also bound by electrostatic attractions to negatively charged blood components such as serum proteins and blood cells [26,28]. Specifically, when negatively charged serum proteins are bound to the polyplexes, charge neutralization occurs, leading to an increase in polyplex particle size [28]. Such an increase in the size of the polyplex not only results in gene expression occurring predominantly in the lung but also ultimately reduces the level of gene transfer in a target region distal to the lung [26]. One other possible consequence of polyplexes interacting with serum proteins is that the polyplexes may then be cleared from the blood by the macrophages of the reticuloendothelial system (in the liver

spleen and bone marrow) in common with other intravenously injected particulates [27]. Polyplex aggregation may be suppressed by the covalent attachment of poly(ethylene oxide) moieties to the polyplex [26].

Unless they have been administered locally polyplexes and dendriplexes need to travel in the vascular compartment to reach the appropriate organ/site of action. If the target site lies in the parenchyma the particles then need to extravasate and travel through the interstitium to finally reach the target cells. While this is obviously not trivial further challenges exist. When the positively charged synthetic vector systems are administered *in vivo*, the nonspecific nature of electrostatic interactions leads to promiscuous interaction of the particles with biological surfaces, macromolecules, and cells. In the process complexes may be destabilized [40].

14.3.2 UPTAKE BY THE TARGET CELL

Even if the uncomplexed and naked therapeutic gene manages to evade devastation by the serum nucleases it still needs to gain entry to the cell and the first barrier to penetration into the cell is posed by the inherent nature of the gene. DNA faces significant difficulty in entering the cells due to its hydrophilic nature, large size, and polyanionic character. The surface charge of the cell membrane is negative [41] and it is envisaged that this cell surface will repel the approach of the large anionic DNA molecule. Polyplexes can assist in facilitating DNA uptake as they usually carry a positive charge [8]. Via this positive charge, the polyplexes are able to interact with the anionic surface charge of the cells and facilitate endosomal uptake into the cell [42]. Additionally, binding and uptake of the poly(amidoamine) dendrimer Superfect depends on cellular membrane cholesterol [43], as does the binding of lipoplexes [44], and any uncomplexed dendrimer present in the formulation also interacts with membranes although it is not clear whether the ability of the uncomplexed dendrimer to interact with membranes [45–47] is relevant for the uptake and intracellular processing of dendriplexes.

However, the electrostatic binding to the anionic cell surfaces is of a nonspecific nature and can often lead to inefficiency in transfection when complexes are given by an intravenous route due to electrostatic interactions with nontargeted cells. These nonspecific interactions must be suppressed if gene expression with the exogenous gene is to be targeted to particular cells. In order to increase the specificity of uptake into the target cells, homing devices are incorporated in the vector/DNA complex. Examples of such homing devices used to increase the specificity of recognition by the desired target cells include ligands such as galactose [48], *N*-acetyl galactosamine [49], antibodies [50], and transferrin [51]. These ligands will obviously be more efficient if the nonspecific interactions with blood components and cells are reduced. A commonly used strategy to reduce nonspecific interactions is the shielding of cationic surface charges using poly(ethylene oxide) moieties [26,49].

Additionally certain extracellular barriers to gene transfer are disease-specific [52]. In cystic fibrosis patients, barriers

such as the thick mucus which coats the cystic fibrosis lung epithelium and the lack of specific receptors that may be exploited for receptor-mediated uptake have been cited as some of the key barriers to transfection with mucus being a formidable barrier for the gene delivery particle to traverse [53]. Generally, although not specifically applied to polyplexes, strategies to overcome these barriers such as the use of mucolytic agents have had limited success [54].

14.4 INTRACELLULAR BARRIERS TO GENE DELIVERY

Upon arrival in the cell the exogenous gene is once again faced with a number of hurdles which prevent it reaching the nucleus, the site of transcription. The polyplex is usually taken up by endocytosis and DNA must escape from the endosome in order to avoid degradation, traverse the cytoplasm intact, and in turn cross the nuclear membrane to gain entry to the nucleus (Figure 14.7B).

14.4.1 ENDOSOMAL ESCAPE

If the gene fails to escape from the endosome the net result is a reduction in gene expression [37]. Some polyplexes can facilitate endosomal escape [55,56]. Cationic polyplexes prepared from cationic polymers such as PEI, by virtue of their high level

of amino groups, are believed to act by buffering the acidic contents of these vacuoles [55–57]. The accompanying increase in the pH prevents the action of the degradative enzymes and eventually enables a rupture of the endosome due to an increase in the ionic and latterly water content of the endosome [29,55–59]. The ionic content of the endosome is increased by an energy-driven influx of chloride ions and protons in response to the intraendosomal buffering by the polymer. This hypothesized mechanism of action by polyamines is termed the proton sponge hypothesis. There is now good evidence that poly(amidoamine) and poly(propyleneimine) dendrimers also exploit their inherent buffer capacity to disrupt endosomes [59].

One of the newer strategies to facilitate endosomal escape is the use of an amine polymer with the amine shielded by a poly(ethylene oxide) substituent. An acid cleavable linker between the amine function and the poly(ethylene oxide) moiety enables intracellular cleavage of the poly(ethylene oxide), amine bond, releasing the amine function to facilitate endosomal escape (Figure 14.8) [49].

Peptides, although not strictly polymers, are also able to promote endosomal escape of gene transfer systems and a description of their actions is included for completeness. Fusogenic peptides undergo a pH-triggered conformational change on entering the endosomes which leads to membrane destabilization and the release of entrapped DNA [30,60]. Examples of endosomolytic peptides are the viral peptides

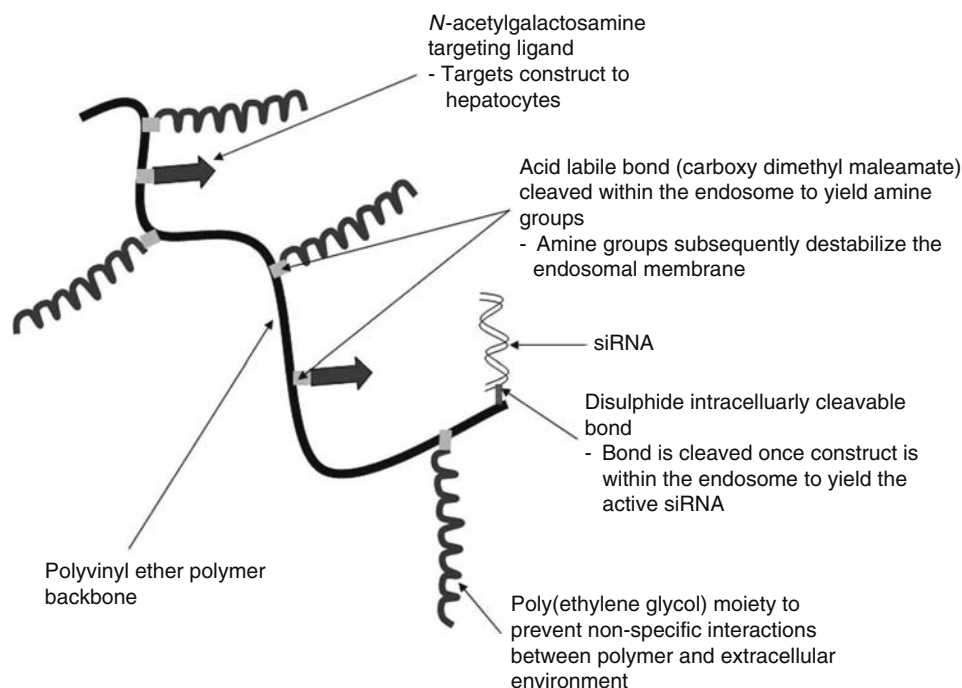

FIGURE 14.8 Schematic representation of the “dynamic polyconjugates” used to target anti-apolipoprotein B siRNA to hepatocytes. Both the polymer bonds of poly(ethylene oxide) and *N*-acetylgalactosamine are acid-cleavable carboxy dimethyl maleamate bonds, destined to be cleaved within the endosome. This water soluble conjugate is designed to be taken up, via the galactose units, by the asialoglycoprotein receptor on the hepatocytes; endosomal cleavage of the acid labile maleamate bonds will subsequently release the *N*-acetylgalactosamine and poly(ethylene oxide) groups to reveal amines. The free amine groups are now available to disrupt the endosome and finally cleavage of the disulphide bonds results in release of the siRNA moiety. (Redrawn from Rozema et al., *Proc. Natl. Acad. Sci. U S A*, 104, 12982, 2007.)

such as the amino terminal domain of the influenza virus hemagglutinin HA2 subunit [30] and the synthetic mimics of amphiphilic anionic viral peptides [60].

14.4.2 STABILITY IN CYTOPLASM

After escaping from the endosomes, DNA may be sequestered in the cytoplasm and subjected to the onslaught of cytoplasmic nucleases [31]. Microinjected plasmid DNA injected into the cytoplasm undergoes rapid degradation by cytoplasmic nucleases with an apparent half-life of 50–90 min [31]. The cytoplasm is a hostile environment for the exogenous gene as was exemplified by one study which reported that transgene expression was observed in 13% of the cells when 10,000 copies of naked DNA were microinjected into the cytoplasm whereas less than 10 copies of naked DNA were needed to induce the same level of gene expression when DNA was microinjected into the nucleus [61]. It is possible that polymeric gene delivery systems which protect DNA from nuclease degradation [62,63] may protect DNA from intracytoplasmic degradation.

14.4.3 NUCLEAR IMPORT

Assuming that DNA remains stable within the cytoplasm, there is still a requirement for DNA to enter the nucleus for transcription to occur and breaching the nuclear barrier is undoubtedly the most formidable challenge of all. The transport of DNA from the cytoplasmic medium into the nucleus is limited by the presence of the nuclear envelope. In dividing eukaryotic cells, nucleocytoplasmic transfer of DNA can occur when the nuclear envelope breaks down during mitosis [15]. Cells in the nondividing phase however are normally resistant to nucleocytoplasmic transfer of plasmid DNA [15]. In nondividing cells the nucleocytoplasmic exchange of molecules occurs through the nuclear pore complexes (NPC) that span the nuclear envelope [64]. Hence, the nuclear envelope acts like a molecular sieve enabling small aqueous molecules of up to 9 nm in diameter (<17 kDa) to diffuse freely through the NPC [64–67]. However, larger molecules of up to 25 nm (>41 kDa) such as plasmid DNA and larger DNA fragments undergo a sequence-specific active transport process involving multiple cellular components [64–67].

Although there is very little direct evidence that polymers actually assist the translocation of DNA or oligonucleotides to the nucleus, PEI has been shown to translocate to the nucleus whether complexed with DNA or in the free form [68] and fluorescence microscopy studies of dendrimer–antisense complexes (Oregon green conjugated poly(amidoamine)_{G5} and carboxytetramethylrhodamine labeled antisense oligonucleotide) suggest that dendrimers have the ability to accumulate to some extent in the nucleus [69]. Also it appears that separation of the nucleotide from the dendrimer is not a prerequisite for activity as poly(amidoamine)_{G5} dendrimer antisense oligonucleotide complexes are active in the nucleus (the nucleus is the site of action of the oligonucleotide in question) although a large proportion of antisense oligonucleotide in the nucleus seemed to be still complexed [69].

Common strategies to encourage nuclear localization include exploiting the nucleocytoplasmic transport machinery by modifying the plasmid DNA with specific sequences so that it can be recognized by cellular factors as a nuclear import substrate [70,71]. A common example of such modification is to attach a DNA nuclear localization signal, for example, the simian virus 40 (SV40) enhancer domain to the plasmid construct, aiding the recognition of these plasmid DNA constructs by transcription factors, with subsequent nuclear import of the resultant complex [72]. The use of an SV40 enhancer sequence improves nuclear delivery *in vivo* and in turn gene transfer [70].

Furthermore, oligopeptide sequences known as nuclear localization signals (NLS), which direct transport to the nucleus, may be linked to plasmid DNA using electrostatic attractions or covalent bonds [73–76]. The site for covalent attachment of NLS to plasmid DNA has to be chosen with care, and the golden rule in this matter is to prevent binding of the NLS to the expression cassette in order to ensure that the transcription ability of the transgene is preserved [77]. These NLS are mainly composed of positively charged oligopeptides made up of sequences of lysine or arginine residues.

14.5 OVERCOMING THE BIOLOGICAL BARRIERS TO GENE DELIVERY

As can be appreciated from the foregoing account, some of the biological barriers faced by naked nucleotides may be overcome by the use of polyplexes and dendriplexes, although new barriers to targeted gene transfer may be introduced by the use of cationic complexing agents. In order to overcome the biological barriers detailed above, a gene therapy vector would include a poly(cationic) sequence for DNA condensation, a stealth type coating to evade detection by the macrophages of the reticuloendothelial system—preferably one that may be shed at the site of cell entry—a colloidal stabilizing entity to prevent colloidal instability in the blood and accumulation in lung capillaries, ligands facilitating cell-specific entry or the site-specific uncovering of a cationic surface to facilitate cell entry, an endosomolytic component which could also be a polycation, and finally nuclear localization signals. Although the ideal system described above does not exist at present, various polymers have been evaluated for their ability to protect and deliver genes across the barriers outlined above and these individual polymers are treated below.

Herman Staudinger's realization that macromolecules consisted not, as previously thought, of aggregates but were in fact long, chain like molecules, started a long journey of discovery which has since led to a wide array of new polymeric materials that have affected every aspect of our lives. Polymeric gene delivery systems are usually positively charged at physiological pH (cationic) [8] and the most commonly used molecules are shown in Figure 14.3. Cationic polymers, by virtue of their possession of protonable groups at physiological pH (amine groups) are able to undergo electrostatic interactions with DNA, the latter of which is anionic at physiological pH [8]. DNA is compacted within the electrostatic complex, a process termed DNA condensation and the

colloidal particles which result from this process are known as polyplexes (Figure 14.5). It is these polyplexes that enable the transport of DNA across the various biological barriers to its nuclear destination. In the delivery of siRNA however, a polyplex is not used, but rather a polymer, siRNA conjugate [49]. There is also some evidence that the noncationic poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) triblock copolymers facilitate gene transfection on direct injection into muscle tissue [78], and despite the fact that cationic polymers are widely used in preclinical studies, the few polymeric gene therapy clinical trials on record have involved the use of poly(vinyl pyrrolidone) [79] and poly(lactic acid)–co–glycolic acid [80], both of which are noncationic at physiological pH.

14.6 POLY(L-LYSINE)

The first cationic polymer-based gene delivery vehicle was poly-L-lysine, the use of which was first reported in 1987 [81]. In this pioneering effort, poly(L-lysine) was conjugated to asialoorosomucoid for targeted gene delivery to liver hepatocytes [81]. On its own, poly(L-lysine), although able to efficiently bind DNA, is not an effective gene transfer agent [82] with adenovirus particles [83], histidyl residues [84], or lysomotropic agents such as chloroquine [85] being required for gene transfer to be observed. Additionally poly(L-lysine)-based polyplexes are associated with their own intrinsic cytotoxicity and although this characteristic may be alleviated somewhat by converting the polymer to an amphiphile [82,86], or by glycosylation [87], unnecessary cytotoxicity associated with an intrinsic poor activity makes this polymer an unlikely first choice material. Recently, L-lysine–L-histidine copolymers have been found to deliver genes, with the L-lysine moieties effecting DNA binding and the L-histidine moieties effecting endosomal escape of the polyplex [88].

A great deal of the early knowledge gained by working on poly(L-lysine) served to elucidate the problems confronting nonviral gene delivery and paved way for the development of the more efficient systems that followed. This first generation polymer can be said to have provided researchers in the field with a valuable learning experience although it is unlikely to feature as a gene delivery system in a marketed product.

14.7 POLY(ETHYLENIMINE)

PEI (Figure 14.3) is one of the most efficient cationic polymer gene transfer systems available, although it has not yet been approved for clinical use. PEI's *in vivo* gene transfer ability has been proven on both local (intravitreal [89], intratracheal [90], and intratumoral [38]) and systemic [91] administration. PEI exists in a number of molecular weight formats (0.42–800 kDa) and transfection efficiency is highest at a molecular weight of between 12 and 70 kDa [92,93] and the most commonly used PEI molecular weight is 22–25 kDa [90,91]. Both linear and branched formats of the polymer exist (Figure 14.1) and the linear molecule is a more efficient gene

transfer agent than the branched material [90,91,94], although the reason for this is unclear at present. Despite the fact that PEI is a successful gene transfer agent for experimental animal studies, there have been reports of unacceptable toxicity with the use of this polymer [26,57,90,95] and even nontoxic doses are associated with the upregulation of numerous genes associated with adverse events [96] in contrast to the use of nontoxic doses of chitosan. Toxicity is undoubtedly modulated by reducing the quantity of protonable amine groups per molecule either through the attachment of poly(ethylene oxide) chains to PEI [97,98] or by the methylation of secondary and tertiary amines to give quaternary ammonium groups [98]. However, an improved biocompatibility with these two methods usually comes at the expense of a reduction in activity. Branched PEI (MW ~25 kDa), unlike linear poly(ethylenimine) (MW ~22 kDa), also induces proinflammatory markers of tissue damage (the chemokine receptors CCR5 and CCR3) [99]. It thus appears as if the linear material enjoys a superior biocompatibility profile. Recently low-molecular weight (MW < 2 kDa) cross-linked PEI, incorporating biodegradable cross-links between individual 2 kDa fragments, was shown to result in improved biocompatibility without the loss of gene transfer activity [100], with the high-molecular weight cross-linked material facilitating gene transfer into the cell and the degraded low-molecular weight fragments resulting thereafter being less toxic, due to their low-molecular weight.

Every third atom of the PEI molecule is a nitrogen atom, resulting in a densely charged backbone composed of 25% primary amines, 50% secondary amines, and 25% tertiary amines. These amine groups are important for DNA binding and enabling the therapeutic transgene escape from the endosome on uptake into the cell [58]. The proton sponge hypothesis (Section 14.4) has been put forward to explain the mechanism by which PEI enables escape of the exogenous gene from the endosome subsequent to cellular uptake.

Gene therapeutics may be administered locally or systemically but one of the problems associated with the systemic (intravenous) administration of cationic lipids and cationic polymers such as PEI is the fact that gene transfection occurs predominantly in the lung endothelium [91]. Apart from poly(propylenimine) dendrimers [101], for example, which transfect the liver in mouse models, very few nonviral systems have been found not to predominantly transfect the lung. This passive targeting to the lung is thought to be the result of aggregation of the polyplexes in the blood and their entrapment within the lung capillaries (Section 14.3) [26]. While transfection of the lung endothelial cells may occasionally be welcome, it is sometimes necessary to achieve gene expression in other areas such as tumors located at sites remote from the lung or the site of injection. To reduce the likelihood of passive lung targeting, poly(ethylene oxide) has been grafted on to PEI [97,102]. Conjugation of poly(ethylene oxide) units to PEI reduces the surface charge of the polyplexes and prevents their aggregation and localization within the lung capillaries [26,103,104]. However while poly(ethylene oxide) chains improve the colloidal stability of these particulate formulations by providing a steric hindrance to particle aggregation

[26,97], this strategy is often accompanied by diminished polyplex gene transfer activity, largely due to poor cellular uptake of the poly(ethylene oxide)-covered polyplex [97,103]. In order to counteract these cellular uptake problems, it is thus necessary to apply a ligand at the distal end of the poly(ethylene oxide) groups, which facilitates receptor-mediated uptake.

A variety of other PEI derivatives have been employed in an effort to improve the gene transfer ability of PEI polyplexes. One such modification which has proved successful is the attachment of the nuclear localization signal D-mellitin to PEI [105]. Other modifications, including the use of amphiphilic PEIs [98,106–108] or the conjugation of poly(ethylene oxide) to PEI [98,109], have met with limited success, with improvements in toxicity sometimes being observed but with no simultaneous improvements in gene transfer efficiency.

In summary, it can be concluded that PEI is an efficient gene transfer polymer, however it appears that the cytotoxicity of this molecule has so far yet to be ameliorated to the extent that it may be considered as a suitable excipient candidate in the clinical development of gene therapeutics. Although PEI, by virtue of its tumorostatic activity, when injected intravenously [6], may serve as a lead for the development of anti-cancer gene medicines. However, what the field requires for noncancer gene therapeutics is gene carrier PEI derivatives that are orders of magnitude less cytotoxic than the current crop of PEI polymers, but which also maintain the *in vivo* gene transfer activity of the current molecules. One promising approach is the use of low-molecular weight PEI fragments cross-linked with biodegradable cross-links [100].

14.8 CHITOSAN

Chitosan (Figure 14.1) is a carbohydrate polymer, derived from chitin; the latter a by-product of the shell fish industry and was first reported as a gene delivery agent in the mid-1990s [110,111]. Chitosan is composed of *N*-acetyl-D-glucosamine and D-glucosamine monomers linked by $\beta(1,4)$ glycosidic bonds. The presence of amino groups in chitosan gives chitosan the ability to condense DNA. Chitosan is attractive as a gene delivery tool because of its good biocompatibility profile when compared to cationic liposomes [112–115], polyamine polymers [116], and polyamine dendrimers [114]. Chitosan is not as amine dense as PEI or poly(L-lysine) (Figure 14.3) and this property could be responsible for its good biocompatibility and also possibly for its relatively poor gene transfer ability [113,115,117–119]. Chitosan's favorable biocompatibility has prompted researchers to find ways to optimize gene transfer with this agent. Controlling molecular weight appears to be the key and an optimum gene transfer activity lies between a degree of polymerization of 7 and 635 [119–121]. Additionally, increasing the charge density by incorporating a permanent positive charge in the molecule in the form of a trimethyl quaternary ammonium group appears to offer some marginal benefit [115] and the incorporation of targeting groups such as galactose improves targeting to hepatocytes [111,113]. Urocanic acid groups have aided gene transfer, the latter possibly by aiding endosomal escape [116]. However chitosan, while being able to achieve

gene transfer to some extent, appears to lack the required level of efficiency that would be needed to allow it to be developed for the clinical delivery of genes.

14.9 OTHER GENE DELIVERY POLYMERS

The cationic polymers discussed above have to date served as key players in the gene delivery field. Other polyamino acids with protonable nitrogen atoms, necessary for DNA binding, have also been studied, such as poly(L-histidine) [122] and poly(L-ornithine) [86] derivatives. In addition various other polymers have been studied as gene transfer systems. Among these are a group of biodegradable polymers, e.g., poly(α -(4-aminobutyl)-L-glycolic acid) [123–125], and poly(β -amino esters) [126], designed to degrade subsequent to having performed their delivery function. The poly(β -amino esters) are possible candidates for microparticle genetic vaccines as the intradermal administration of poly(β -amino ester)-based microparticles encapsulating a gene encoding for an octapeptide epitope which stimulates polyclonal CD8 T cell responses in mice, results in an antigen specific, immune-mediated tumor growth delay [127]. The use of biodegradable gene carriers is aimed at minimizing the cytotoxicity associated with the accumulation of such agents within the cell and hence is aimed at improving the biocompatibility of the gene transfer agent. Other polymers that have been developed are thermo-sensitive amine polymers designed to form a gel *in situ* on administration and thus provide a depot system capable of sustained DNA delivery [128]. There is also some evidence that the noncationic poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock copolymers improve the gene transfection seen on direct injection of genes into muscle tissue [78], and both polyvinyl pyrrolidone [79] and poly(lactic acid-co-glycolic acid) [80] have been used in clinical studies.

14.10 DENDRIMERS

Dendrimers (from the Greek “dendron”: tree, and “meros”: part) are highly ordered, branched monodisperse macromolecules [129] (Figure 14.4). Such dendritic structures first emerged in a new class of polymers named “cascade molecules,” initially reported by Vögtle and his group at the end of the 1970s [130]. Further development by Tomalia's group [131], and Newkome's group [132,133] gave rise to larger dendritic structures. These hyper-branched molecules were called “dendrimers” or “arborols” (from the Latin “arbor” for tree). For a historical view see review [134]. Their unique molecular architecture means that dendrimers have a number of distinctive properties which differentiate them from other polymers; specifically they are not the result of statistical polymerization events but are built up in a stepwise fashion from a core group (a convergent method of synthesis: Figure 14.4) or by the addition of dendrimer arms to a core group (a divergent method of synthesis). The controlled synthetic approach means that dendrimers tend to be monodisperse with a well-defined size and structure. Dendrimers used in gene delivery are given in Figure 14.4.

Dendrimers used for gene delivery contain amine functional groups and are usually protonated at physiological pH (cationic); such amine groups, which when protonated may be electrostatically bound to DNA phosphate groups to give dendriplexes (Figure 14.6) [12,34,101,135–137]. This electrostatic interaction protects DNA from degradation [34,35].

Poly(amidoamine) and poly(propylenimine) dendrimers bind DNA at a 1:1 stoichiometry of primary amine to phosphate, but it is only at higher ratios that more stable and efficient complexes are being formed [12,136]. These dendriplexes are heterogenous [135] and with some systems, e.g., poly(amidoamine)_{G7}-DNA complexes (where the subscript G7 refers to the generation, i.e., generation 7, see Figure 14.4), more than 90% of transfection activity lies in just 10%–20% of complexes (found in the low density aqueous soluble fraction). It is apparent that the formation of dendriplex nanoparticles needs to be finely tuned to optimize transfection efficiency.

Poly(amidoamine) and poly(propylenimine) dendrimers efficiently deliver nucleic acids into cells, ranging from small oligonucleotides to plasmids and artificial chromosomes [6,12,69,138–144]. The higher generation poly(amidoamine) dendrimers (e.g., generation 5–generation 10) efficiently transfect cells and are more efficient gene carriers than the lower generation materials [145,146]. For these higher generation dendrimers a near exponential increase in efficiency with generation has been observed [145]. On the other hand toxicity has been shown to be directly related to molecular weight [147,148]. For example, the higher generation poly(amidoamine) dendrimers lead to the formation of transient holes (G7) or the enlargement of existing holes (G5) [45] and a tendency to cause hemolysis and changes in erythrocyte morphology have been linked to the presence of surface primary amine groups [148]. Thus a balance needs to be struck between the transfection enhancements seen with the higher generation poly(amidoamine) dendrimers and the related toxic effects. Degradation of these higher generation dendrimers to reduce the branch density in individual molecules increases the activity of the higher generation poly(amidoamine) dendrimers considerably, enhancing activity by almost 50-fold [146].

The ability of the poly(propylenimine) dendrimers to bind DNA is generation dependent as is their cytotoxicity [12]. Optimum activity without attendant compromising cytotoxicity was found in the lower generation poly(propylenimine) dendrimers, specifically poly(propylenimine)_{G3} (DAB-AM16) [12]. Dendrimer cytotoxicity is reduced by the formation of dendriplexes or the conversion of dendrimer primary and tertiary amines to their quaternary ammonium functions [12]. Additionally the quaternary ammonium dendriplexes were still transfection competent, with transfection occurring mainly in the liver [12]. From the foregoing, reducing primary amine density appears to be generally linked to improvements in biocompatibility. Attempts to bring the higher generation (above generation 3) poly(propylenimine) dendrimers into the gene therapy arena have focused on ameliorating their cytotoxicity and the fourth generation dendrimers have thus been

modified by amidation of the terminal primary amines followed by the conversion of the internal tertiary amines into quaternary ammonium groups [149] and in other instances by the addition of guanidine groups to the terminal primary amines [150].

When higher generation poly(amidoamine) dendriplexes [200 μg DNA complexed with 650 μg poly(amidoamine)_{G9}] are injected intravenously, gene expression occurs mainly in the lung parenchyma but not in other organs [151]. Lower generation dendrimer conjugate [poly(amidoamine)_{G3}- α -cyclodextrin] dendriplexes, however, transfect primarily the spleen [152], while the lower generation poly(propylenimine) (generation 2 and generation 3) dendriplexes [50 μg DNA complexed with 250 μg poly(propylenimine)_{G3}] transfect primarily the liver [101].

14.11 SYSTEMIC TARGETING

Genetic therapies often require to be targeted to specific organs, tissues, and cell types. Targeting is either achieved by exploiting the use of targeting ligands or by exploiting a poorly understood propensity for dendriplexes and polyplexes to target specific tissues.

14.11.1 LIVER TARGETING

Liver targeting of gene therapeutics may facilitate the gene therapy of hepatic carcinomas such as hepatocellular carcinoma. Passive targeting to the liver has been achieved using poly(propylenimine)_{G3} dendriplexes formulated at a nitrogen-phosphate ratio of 16 (N:P ratio = 16) [101]. This passive liver targeting is unusual with polymer and dendrimer gene delivery systems, which typically transfect the lung [91,151] on intravenous administration, as do cationic lipoplexes (cationic liposome–DNA electrostatic complexes) [153]. The poly(propylenimine)_{G3} system appears to avoid the lung due to a hypothesized mechanism involving diminished aggregation within the blood, the diminished aggregation itself a result of the lower molecular weight of poly(propylenimine)_{G3} (MW = 1.684 kDa) when compared to PEI polymers (MW ~ 25 kDa) or transfection-competent poly(amidoamine) dendrimers (MW > 28 kDa). However, while gene transfection is found in the liver with these low-molecular weight poly(propylenimine) dendrimers, it is not clear if poly(propylenimine)_{G3} dendrimers target hepatocytes or whether these dendriplexes target other liver cell types.

Targeting gene expression to hepatocytes has been achieved by conjugating either asialoorosomucoid [81] or galactose [154–156] to gene delivery polymers or dendrimers. The galactose moiety has been used in elegant experiments to target siRNAs to hepatocytes [49]. Rozema's group [49] have demonstrated that delivery of siRNA may be achieved by using a polyvinyl ether conjugated siRNA in which conjugation is achieved via an intracellularly cleavable disulphide bond. This polymer–siRNA conjugate is then further linked to both poly(ethylene oxide) units—to prevent nonspecific extracellular interactions and *N*-acetyl galactosamine to achieve hepatocyte

targeting (Figure 14.8). The polymer-siRNA conjugate effectively silenced the apolipoprotein B gene, which is involved in cholesterol transport and serum cholesterol levels were also decreased [49]. Unfortunately silencing of the apolipoprotein B gene was accompanied by a fatty liver in experimental animals and hence apolipoprotein B gene silencing in this manner will still require additional effort before it becomes a legitimate therapeutic target. Competing technologies employing lipid modified poly(amidoamine) dendrimers, termed interfering nanoparticles [157] or lipid particles termed stable nucleic acid lipid particles, [158] also lead to apolipoprotein B silencing and reduced blood cholesterol levels.

14.11.2 LUNG TARGETING

On intravenous injection of PEI polyplexes, gene transfection occurs predominantly in the lung endothelium [91], due to a hypothesized mechanism involving aggregation of the polyplexes in the blood and their entrapment within the lung capillaries [26]. For the treatment of lung cancers such as nonsmall cell lung cancer, the commonest form of lung cancer and cystic fibrosis, it will be optimal to transfect the cells lining the airways as opposed to the cells lining the lung capillaries. However, evidence that inhaled therapies may be useful is not yet apparent.

14.11.3 TUMOR TARGETING

Cancer gene therapy is currently limited by the difficulty of efficiently delivering therapeutic genes to remote tumors and metastases by systemic administration [5,40]. However, poly(propyleneimine)_{G3} dendriplexes on intravenous administration induce tumor gene expression [6]. When murine xenografts were treated by intravenous injection of poly(propyleneimine)_{G3} dendriplexes containing a tumor necrosis factor (TNF- α) expression plasmid under control of a tumor-specific promoter, regression of established tumors was observed in 100% of the animals (Figure 14.9). The treatment (5 injections over 10 days) also led to an excellent long-term response (80% complete and 20% partial response at 17 weeks). The antitumor activity is the result of a combination of the effects of the tumor-specific expression of TNF- α and an intrinsic anti-proliferative effect of the dendrimer [6]. This novel anti-proliferative effect was also observed with other cationic polymers. The lack of apparent toxicity and significant weight loss compared to untreated controls suggests that the treatment is relatively well tolerated [6]. Furthermore, the administration of poly(propyleneimine)_{G3} dendriplexes containing genes expressing either p53, a minimal p53-derived apoptotic peptide, or a small hairpin RNA (shRNA) sequence that targets the P73 apoptosis inhibitor, iASPP, results in tumor regression, independent of p53 status [143]. The gene expressing the shRNA sequence leads to downregulation of iASPP and consequently activation of the p73 apoptosis pathway [143]. These studies conducted by Bell and coworkers were the first to validate p73 as a target in cancer therapy. It is

possible that the good tumor gene expression seen with the poly(propyleneimine)_{G3} dendriplexes could be linked to the ability of these dendriplexes to avoid the lung (Section 14.11.1). Others have observed that low-molecular weight (MW ~ 4kDa) oligoethylenimine pseudodendrimers also direct gene expression away from the lung tissue and to tumor tissue on intravenous administration, when compared to linear (MW ~ 25 kDa) PEI [159].

Exploiting receptor-mediated uptake is another method of targeting gene therapeutics to tumors and as such both folate [160] and transferrin [51,161] ligands have been used for tumor targeting. PEI-TNF- α polyplexes are able to achieve tumor regression, on systemic administration through a combination of gene transfer [162] and an intrinsic anti-proliferative activity of the carrier PEI (Figure 14.9) [6]. Tumor targeting with PEI polyplexes was achieved by using poly(ethylene oxide) groups to prevent nonspecific interactions and a transferrin ligand to facilitate receptor-mediated uptake into tumor cells [162].

14.12 LOCAL DELIVERY OF GENES TO SPECIFIC ORGANS OR TISSUES

Due to the problems surrounding systemic gene therapy, as detailed above, a number of local delivery strategies have been attempted. In actual fact the world's first licensed gene therapeutic (Gendicine) [163] was licensed for intratumoral delivery in the treatment of head and neck cancer and the intratumoral delivery of genes, although not practical in all cases, does yield favorable results. For example, the intratumoral delivery of a poly(amidoamine) suicide gene (HSV-tk) dendriplex [100 μ g HSV-tk and 300 μ g poly(amidoamine) dendrimer] led to a pronounced growth delay [164]. This plasmid which expresses an enzyme which activates the prodrug ganciclovir contained Epstein-Barr virus (Epstein-Barr virus nuclear antigen gene, EBNA1/OriP) sequences with the ability to replicate and persist in the nucleus of the transfected cells. The animals received up to four weekly cycles (single injection of complex followed by 100mg kg⁻¹ per day of the prodrug Ganciclovir for 6 days) [164]. Plasmids containing the EBNA/OriP system increase gene expression eightfold when compared to normal plasmids and when the EBNA1/OriP system is used in conjunction with a vector expressing *Fas* ligand; the injection of 10 μ g plasmid complexed with the dendrimer (Superfect) at a ratio of 10:1 (w/w) also led to a pronounced tumor growth delay [165]. A growth delay was also demonstrated after intratumoral injection of plasmids coding for the anti-angiogenic peptide angiostatin or the tissue inhibitor of metalloproteinase-2 genes in special dendrimer/plasmid/oligonucleotide complexes [166].

With the aim of developing treatments against blindness caused by neovascularization, oligonucleotide delivery to the back of the eye has been successfully attempted by the intravitreal injection of complexes with antisense oligonucleotides and a lipid L-lysine dendrimer [167]. The oligonucleotide therapy inhibits neovascularization of the choroidea by downregulation of VEGF over a period of up to 2 months.

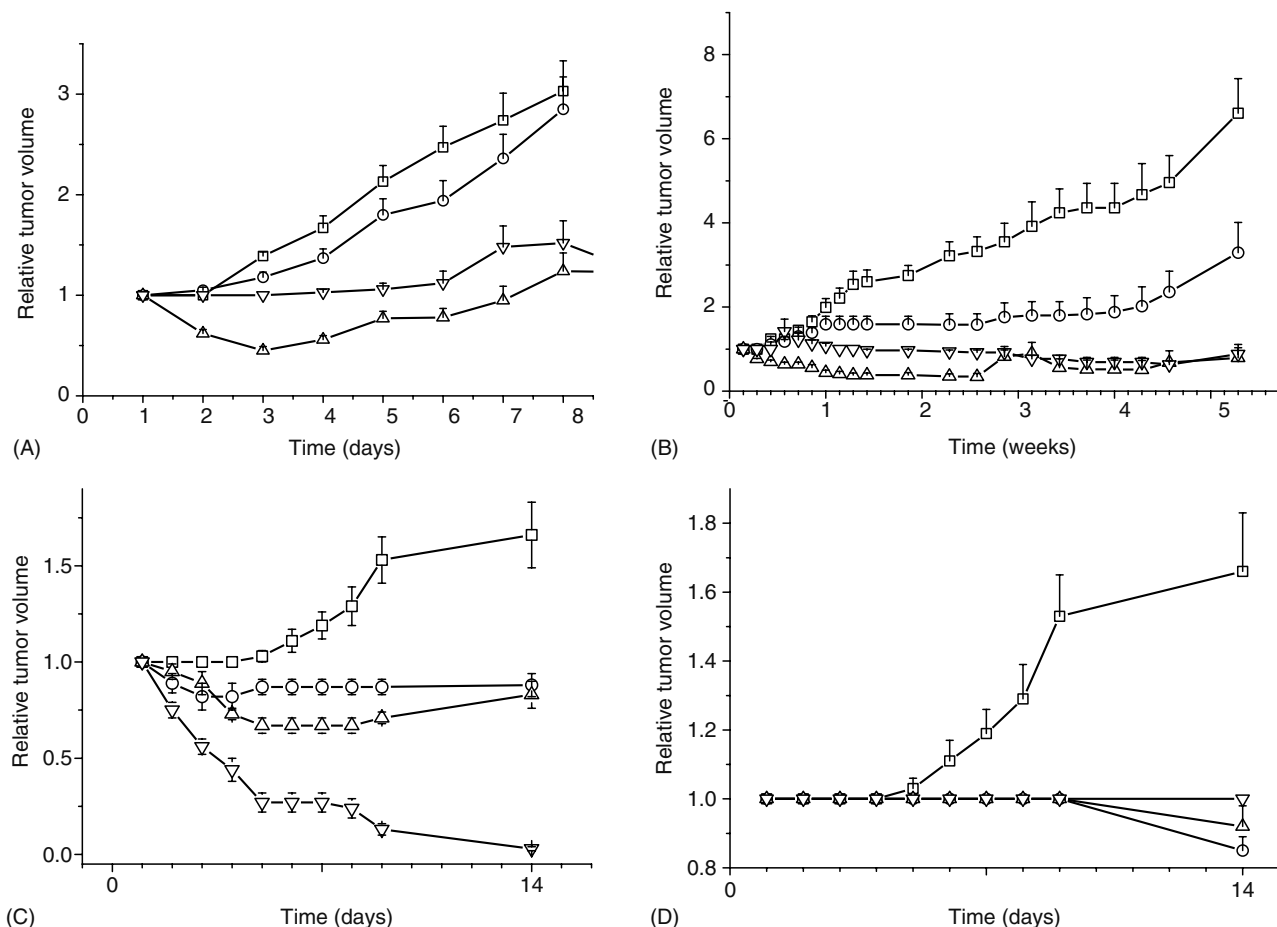

FIGURE 14.9 Experimental systemic tumor gene therapy with cationic polymers. (A) Therapeutic effects of the systemic mTNF- α gene therapy (5 injections given every second day) against established LS174T colorectal adenocarcinoma (ATCC CCL-188). (B) C33a (ATCC HTB31) cervix carcinoma xenografts. DNA-dendrimer nanoparticles (Δ) are superior to the administration of naked mTNF- α DNA (O) and dendrimer alone [poly(propylenimine)G3, ∇] and lead to tumor regression and prolonged tumor growth retardation when compared to tumors in untreated animals (\square). (C) Various cationic polymers are used to treat established A431 xenografts either complexed with mTNF- α expression plasmid or (D) as polymers alone. Poly(propylenimine)G3 dendrimers (Δ), linear PEI (O), and fractured poly(amidoamine) dendrimer (∇) and respective complexes were given by single tail-vein injection (treatment day = day 0). (Adapted from Dufes, C. et al., *Cancer Res.*, 65, 8079, 2005.)

Gene therapy targeted at the central nervous system (CNS) is attractive for the treatment of cognitive decline or pain. However, delivery to the CNS has only been achieved using local delivery strategies. Low-molecular weight (MW ~ 600Da) PEIs have been linked via an activated β -cyclodextrin to produce a gene transfer polymer, which on injection into the spinal cord produced transfection levels similar to that produced by high-molecular weight (MW ~ 25 kDa) PEIs [168]. Additionally, the PEI- β -cyclodextrin conjugates are less cytotoxic, when compared to high-molecular weight (MW ~ 25 kDa)-branched PEI [168]. Gene therapy of the CNS has also been revealed as a mechanism to control neuropathic pain [169], as the intrathecal administration of PEI polyplexes consisting of a plasmid encoding for interleukin 10 (IL-10) leads to prolonged pain control.

Gene therapy of cardiovascular tissue could be useful in cardiac transplantation and evidence of gene delivery to cardiac tissue has been presented. Using direct injection in a murine

cardiac transplant model poly(amidoamine)_{G5} dendriplexes demonstrated more widespread and prolonged expression compared to the naked plasmid and when combined with a viral IL-10 gene were able to prolong graft survival [170]. The efficiency of the procedure was improved at a higher nitrogen to phosphate charge ratio of 20:1 [171], and in combination with electroporation [171].

14.13 CLINICAL TRIALS

Out of the 1340 gene therapy trials currently on public record, 55% utilize viral vectors [17] and to date no clinical studies utilizing polymers have been reported in the peer reviewed literature. However, the National Institutes of Health do record three clinical trial registrations involving the use of polyvinyl pyrrolidone gene medicines [79]. Polyvinyl pyrrolidone has been used to deliver recombinant human insulin-like growth factor-I genes by direct injection into muscles to treat peripheral

neuropathy and muscle weakness and has been used to deliver both human interferon α (hIFN- α) and human interleukin-12 (hIL-12) formulations intratumorally into squamous cell carcinomas of the head and neck [79]. Additionally polyvinyl pyrrolidone has been used to deliver hIFN- α and hIL-12 intratumorally to metastatic melanoma patients with unresectable carcinomas [79]. The results of these trials have not been publicized. There are also reports of the use of poly(lactic acid)-co-glycolic acid gene medicines being used for DNA vaccination studies [80], although once again results are not available in the public domain. Despite evidence showing cationic polymers to be superior gene transfer agents than polymers possessing a neutral or anionic charge at physiological pH, clinical investigators have adopted a cautious approach and have opted for excipients that are generally regarded as safe [172], such as polyvinyl pyrrolidone and poly(lactic acid-co-glycolic acid), both of which are nonamine polymers, and hence not cationic at physiological pH.

14.14 CONCLUSION

A number of polymers and dendrimers, by virtue of possessing a cationic charge at physiological pH, have been found to be suitable candidates for the carriage of genes across the various biological barriers outlined above. While the lower generation poly(propyleneimine) dendrimers, and the 25 kDa PEIs and polyvinyl ether polymers have demonstrated the ability to bring about a therapeutic response in preclinical models, the search for efficient and safe gene delivery systems is far from over. Researchers have achieved a modicum of success with these first generation agents, and it is likely that some of these agents will move into clinical development. It is feasible that a licensed nonviral gene therapeutic will emerge from the cationic polymer or cationic dendrimer class of agents, however, what has been learnt from these early studies on polymeric and dendrimer systems will continue to assist in the development of more efficient agents no matter from where such agents originate. An ideal gene delivery system has to be able to shuttle the gene safely to the nuclei of its target tissue with the gene enjoying travel that has limited encounters with degradative influences. We know that certain cationic dendrimers or polymers can fulfill these requirements, and providing the cytotoxicity of the carriers are either appropriately channeled to facilitate tumor cell kill or otherwise curtailed, it is likely that the first class of synthetic gene delivery agent that completes the clinical development journey may be a cationic dendrimer or polymer with targeting ability.

15.1 INTRODUCTION

Natural mechanisms enable the active transport of macromolecules into cells, such as receptor-mediated endocytosis, macropinocytosis, phagocytosis, and other mechanisms used also by various viruses and microorganisms to infect cells. These natural pathways can be used in a new, artificial setting as means of a transfer route to deliver nucleic acid into cells. A series of intra- and extracellular barriers have to be overcome

before a delivered gene can exert the required effect. In addition, the host organism has developed defense mechanism to protect the genome against the uptake of exogenous nucleic acids. For example, many processes including the immune response can counteract viral infection processes, which present a significant problem for the development of viral gene vectors. For this reason, nonviral vectors have been developed with useful characteristics such as reduced immunogenicity,

and pharmaceutical advantages (simple synthesis and large-scale production). However, they show far lower transfection efficiency compared to viral vectors.

More effective nonviral delivery systems are needed. These can succeed in therapy only if properly directed towards the target site, i.e., the diseased tissue, for example, a tumor. Thus, targeting is one of the major bottlenecks in gene therapy. Once the target cell is reached, intracellular uptake and release of the therapeutic nucleic acid in bioactive form is the second major delivery task. This chapter reviews the development of polymer-based nonviral transfer systems (polyplexes) which exploit receptor-mediated delivery to target and transfer therapeutic nucleic acids into cells.

The first receptor-targeted polyplexes and their *in vivo* use were described already 20 years ago [1,2]. Their further development and current concepts on types of therapeutic nucleic acids, polymer conjugates, polyplex formation, and targeting across extracellular and intracellular barriers are reviewed. Recent designs of bioresponsive polyplexes that during the delivery process change their characteristics to fit best for the various delivery steps, and current therapeutic polyplex concepts are also discussed.

15.2 DEVELOPMENT OF POLYPLEXES

15.2.1 NUCLEIC ACIDS FOR GENE THERAPY

Nucleic acids with therapeutic potential include plasmid DNA (pDNA) or synthetic nucleic acids such as antisense oligonucleotides, ribozymes, small interfering RNA (siRNA), other double-stranded nucleic acids like decoy DNA [3] or double-stranded RNA, polyinosine–cytosine (polyIC) [4], and RNA aptamers [5]. The various types of nucleic acids achieve different effects at the molecular genetic level. Thus, pDNA vectors are mainly used for intranuclear delivery to replace or to substitute a specific genetic function in the target cell resulting in a *gain of gene function*. The transcriptional/translational machinery amplifies the effector molecules to therapeutically relevant levels, which act directly in the producer cell or can be transported to other cells. In contrary, *loss of gene function* is often mediated by intracytoplasmic delivery of synthetic antisense oligonucleotides or siRNA reducing the expression of endogenous genes in a sequence-specific manner [6]. In the siRNA approach the catalytic nature of the formed RNA-induced silencing complex (RISC) in degrading the target mRNA leads to knockdown of the target gene; this effect, however, is limited to the transfected cells. The different molecular and biophysical properties (size, stability) and delivery requirements for pDNA (requires nuclear uptake, optionally persistent expression) and siRNA (cytoplasmic delivery, transient) also influence the therapeutic strategies.

15.2.2 NUCLEIC ACID CARRIER MOLECULES

The efficacy of gene therapy depends on several factors. Direct delivery of “naked” nucleic acids, i.e., in the absence

of a carrier, can be only rarely applied with reasonable efficiency, such as in case of naked pDNA in intramuscular vaccination or hydrodynamic delivery [7,8]. In systemic applications, problems like undesired interactions with blood components, degradation, and complement activation occur. For safe and efficient transfer into the cells, nucleic acids need to be stabilized. This can be achieved by using carrier molecules that condense and compact the negatively charged nucleic acids into particles of virus-like dimensions. The carriers can be cationic polymers or lipids which lead to non-covalent complex formation into “lipoplexes” or “polyplexes” [9]. This chapter focuses on polyplexes, i.e., polymer-based systems.

Polyplexes are formed by nucleic acids and polycationic polymers like polylysine (PLL), polyethylenimine (PEI), or polyamidoamine (PAMAM) dendrimers [10–12]. Gene transfer efficiency strongly varies between the different formulations. Within commonly used polymers, PEI and PAMAM dendrimers are the most effective polycations with excellent and consistent transfection efficiency on several cell lines. The buffering capacity of these polymers offers the opportunity to escape from the endosome (proton sponge effect) [13]. Drawbacks of PEI and PAMAM dendrimers are significant toxicity and lack of degradability. PLL, in contrast, is biodegradable but ineffective in transfection efficiency unless endosomal disruptive agents are included. A series of other nucleic acid-binding polycations have also been used: for example, polyarginine [14], protamine [15], nuclear high-mobility group proteins [16], histones [17], and biodegradable polymers as described below.

The cationic residues within the polyplex can enhance binding to the cell and may also mediate the transfer of nucleic acid to the cytoplasm by disruption of the vesicular membranes. Thus, condensing the nucleic acid is essential for efficient transfer into cells; however, not every polymer that binds and condenses nucleic acid results in efficient gene transfer.

In addition, the polymeric carrier should also protect nucleic acids from degradation by serum nucleases and shield them from undesired interactions with the physiological environment due to neutralizing the negative charges. In reality, the carrier is unable to carry out all the tasks meaning that in some cases its primary role is to bind and protect nucleic acids from the environment.

Furthermore the polymeric carrier has to meet different requirements depending on the type of nucleic acid. In case of siRNA a release of siRNA from the carrier molecule is necessary in the cytoplasm to allow forming the RISC complex. In case of pDNA, nuclear entry, vector unpacking, and transcription are the necessary steps. Any of these steps might be rate limiting depending on the nature of the carrier. Carrier molecules should interact with the genetic material in a nondamaging reversible manner which in most cases is provided by noncovalent electrostatic interaction. In few cases, also reversible covalent attachment has been exploited, for example, covalent linkage of siRNA with cholesterol which was found to greatly enhance activity of siRNA [18].

15.2.3 NEW CATIONIC POLYMERIC CARRIERS

Commonly used nucleic acid carriers like PEI are limited by inherent toxicity and moderate efficiency. Thus, novel biodegradable carriers with improved efficiency, less toxicity, and a better biocompatibility are required [19–24]. Polycationic carriers with high-molecular weight (HMW) often show acute- and long-term toxicity. In contrast, low-molecular weight (LMW) polymers often show reduced toxicity but also low transfection efficiency and *in vivo* stability. Bioreversible cross-linking of LMW polymers into larger molecules, either by reducible disulfides or hydrolyzable linkages, is one encouraging strategy. Several approaches were performed in cross-linking LMW-PEI via ester- or amid-linkages to receive a strongly enhanced gene transfer efficiency *in vitro* and *in vivo* [19,22,25]. Most importantly, these polymers were less toxic than standard PEI. Moreover, ester linkages were also used for synthesis of biodegradable copolymers of PLL and polyethylene glycol (PEG) [26].

Several strategies for biodegradable carriers are based on reductive cleavage of disulfide bonds [27]. Read et al. synthesized reducible polycations based on short histidine and oligolysine residues enhancing gene transfer efficiency *in vitro* for pDNA, mRNA, and siRNA [28]. Intracellular cleavage of disulfide bonds leads to release of the pDNA, and histidine residues mediate endosomal escape. The reducible polycations showed promising transfection efficiency; toxicity was not observed under conditions where PLL was strongly toxic. In combination with PEG, disulfide cross-linked polymers were also applied to facilitate gene transfer *in vivo* [29].

Davis and colleagues designed novel cationic β -cyclodextrin-based polymers (β CDPs) [30], whereby the incorporation of cyclodextrin in the amidine-containing polymers reduced toxicity of the polymer by up to three orders of magnitude. Modification of β CDPs with PEG and transferrin (Tf) was used successfully for *in vivo* tumor targeting of RNA-cleaving DNA enzymes [31]. Adamantane-PEG-Tf conjugates fuse with the polyplex by forming adamantane-cyclodextrin inclusion complexes. Also cyclodextrins were used for grafting PEI which enables coating of polyplexes with adamantane-PEG conjugates [32].

It has to be emphasized that successful pDNA formulations are not always suitable for siRNA delivery. Leng et al. [33] demonstrated that a branched carrier consisting of lysine and histidine residues designed for pDNA was not able to mediate siRNA delivery. Compositions of various related carriers (with different degree of branching, length of terminal arms, changed histidine-lysine-sequences) generated a suitable carrier for siRNA with minimal toxicity and luciferase knockdown activity. Hassani et al. tested different formulations to deliver siRNA into the mouse brain *in vivo* [34]. They found out that linear PEI, a powerful pDNA delivery agent, was not suitable for efficient siRNA delivery at concentrations where cationic lipid formulations were effective. Aigner et al. showed that PEI is able to deliver siRNA into distant subcutaneous tumors [35]. Fractionation of standard PEI

generated a low-molecular weight fraction with superior transfection efficiency in pDNA and siRNA delivery [36].

15.3 CELLULAR TARGETING AND ENDOCYTOSIS

15.3.1 ENDOCYTOSIS OF POLYPLEXES

Endocytosis is the major pathway of entry into cells. However, various endocytic pathways [37,38] operate in eukaryotic cells, i.e., clathrin-dependent and -independent pathways, the latter including phagocytosis, macropinocytosis, and caveolae-mediated internalization. Understanding cellular uptake and intracellular processing of nonviral gene delivery systems is a key aspect in developing more efficient vectors. In one study small particles (<200 nm) were found to internalize via clathrin-mediated endocytosis, whereas large particles (>500 nm) internalized via caveolae-mediated endocytosis [39]. In many cell types, positively charged polyplexes like pDNA/PEI polyplexes internalize through adhesion to negatively charged transmembrane heparan sulfate-proteoglycans (HSPG) [40,41]. Clathrin-dependent receptor-mediated endocytosis (coated pit endocytosis) involves the binding of a ligand to a specific cell surface receptor, resulting in the clustering of the ligand/receptor complexes in clathrin coated pits, invagination into the cell and taking off of the coated pits from the cell surface membrane to form intracellular coated vesicles, and maturation (uncoating, fusion of vesicles) into endosomes. Within these endosomes, ligands and receptors are sorted to their appropriate intracellular destination (e.g., lysosome, Golgi apparatus, nucleus, or cell surface membrane). The clathrin-independent endocytosis [42] resulting in uncoated pits includes phagocytosis, pinocytosis, and potocytosis. Phagocytosis is a mechanism of internalizing large particles and microorganisms (>0.5 μ m). This mode of internalization is initiated by receptors on the phagocyte recognizing the particle either directly or indirectly via opsonization. Internalization is primarily mediated via pseudopod action rather than pits (invaginations) on the cell surface. The wrapped particle, initially situated in the early phagosome, is eventually destroyed along the endocytosed pathway. Thus, cell capability to recognize particles via receptors and to form pseudopods seems to be a major characteristic mediating phagocytic internalization. Potocytosis and transcytosis may use caveolae as routes for internalization [38,43]. Many receptors contain motifs in their cytoplasmic domains that act as recognition sequences for initiating enhanced intracellular uptake process of macromolecules. With ligand interaction, the rate of receptor internalization is increased.

Gersdorff et al. [44] evaluated the impact of clathrin- and caveolae/lipid-raft-dependent endocytosis on cell entry and transfection efficiency of PEI polyplexes. Interestingly, the productive endocytotic pathway was varying in different cell types. For example, in COS-7 cells the clathrin-dependent pathway was the main contributor to the transfection process, whereas in HeLa cells the lipid-raft-dependent pathway was more relevant, consistent with other literature [45].

15.3.2 LIGAND CONJUGATES FOR TARGETING POLYPLEXES

Gene transfer vehicles have to accomplish several major delivery tasks, especially transferring the nucleic acid from the site of administration to the surface of the target cells, and facilitating the internalization into the cells. Incorporation of receptor ligands has been considered to promote these tasks, i.e., targeting and enhanced cellular internalization of the nucleic acid (Figure 15.1). For *in vivo* application, both processes are substantial for successful gene therapy.

Targeting ligands can be proteins like Tf, asialoglycoproteins, epidermal growth factor, or they can be small natural/synthetic molecules, e.g., folic acid, peptides, or sugar derivatives. Examples of ligands that have been used as conjugates with polycationic carriers for targeted gene transfer are shown in Table 15.1 and Refs. [2,15,46–83]. In the selection of a ligand several aspects have to be considered. Some ligands are very tissue-specific (e.g., asialoglycoproteins/hepatocytes), whereas others are not (e.g., Tf/iron supply to many cell types). Some ligands are internalized very efficiently (e.g., Tf, anti-CD3 antibody bound to the T-cell receptor associated surface molecule CD3), whereas some others may be internalized either very slowly or not at all. Some ligands may carry charges and interact with other proteins and surfaces (e.g., FGF with blood), others not or may even act as a shield (e.g., serum protein Tf). Thus, the proper choice of ligand for efficient gene transfer is important. Ligands have been successfully incorporated into polyplexes by conjugation to polycations such as PLL, PEI, protamines, and histones, or also intercalating DNA-binding compounds (Table 15.1).

One commonly used ligand is the serum glycoprotein Tf for targeted gene delivery. The Tf-receptor required for iron uptake into cells is over-expressed in tumor cells due to the higher demand of iron for their growth. Tf as a protein ligand combines both a shielding function of the vectors and a

FIGURE 15.1 Assembly of polyplexes. Gene transfer particles are composed of nucleic acid, ligand–polycation conjugates and additional elements, e.g., shielding agents. Surface characteristics of polyplexes (charge density, degree of coating with ligand/shielding agents) can influence cell binding. Unspecific interactions can be reduced by shielding with PEG. Cell targeting is mediated by ligand–receptor interaction. Examples of targeting ligand/receptor systems can be found in Table 15.1.

targeting function towards the tumor site [84,85]. It was shown that incorporation of Tf or anti-Tf receptor single-chain antibody Fv (anti-Tf scFv) fragments into polyplexes and lipopolyplexes resulted in enhanced gene transfer efficiencies *in vitro* and *in vivo* [86–94]. Conjugation of PEG to pDNA/PEI polyplexes or lipopolyplexes containing Tf or anti-Tf scFv fragments as targeting ligand further improved applications for *in vivo*.

After systemic administration of Tf–PEG-conjugated vectors gene expression was mainly found at the tumor site [92,93,95]. Tail vein injection of Tf-conjugated pDNA/PEI polyplexes into tumor-bearing mice resulted in 100-fold higher luciferase reporter gene expression in the distant tumors in comparison with the other organs [88,92] and maintains over 3 days upon single injection. Systemic application of Tf polyplexes of pDNA encoding TNF- α into tumor-bearing mice induced tumor necrosis and inhibition of tumor growth in several mouse tumor models [89,95].

A cationic cyclodextrin carrier containing Tf as targeting ligand and PEG for shielding was developed for systemic siRNA delivery [96]. Repeated systemic delivery of siRNA against the Ewing's sarcoma-specific chromosomal translocation t (11:22) inhibited growth of metastatic Ewing's sarcoma in a murine model.

EGF is another largely investigated ligand for tumor targeting [4,19,97–99]. The EGF-receptor (EGFR) is upregulated in several tumors including epithelial tumors, glioblastoma, and hepatocellular carcinoma. Conjugation of EGF to PEGylated PEI polyplexes resulted in strong enhancement of gene expression *in vitro* [98]. Also upon systemic application in hepatocellular carcinoma-bearing mice, a 10-fold enhanced gene expression was found at the tumor site [47]. Shir et al. recently described therapeutic effects of EGF-targeted polyplexes containing poly IC observing the complete regression of established EGFR over-expressing glioblastomas in nude mice [4].

Another tumor target is the folate receptor which shows a narrow expression on healthy tissue whereas it is upregulated in numerous cancer types [100]. Efforts in the development of folate receptor-targeted vectors by using folate itself as a targeting ligand show promising tumor-specific gene transfer [101].

Similar to tumor cells, also tumor vascular endothelial cells over-express certain surface markers that are only upregulated in neoangiogenic tumor blood vessels or exist at very low levels on normal blood vessels. Such surface receptors include, for example, the integrins like $\alpha v \beta 3$ and $\alpha v \beta 5$. Several approaches to target gene transfer carriers towards the integrins use synthetic peptides with the RGD sequence [102–104]. RGD-targeted PEI polyplexes have shown enhanced gene transfer efficiency compared to PEI. Thereby the receptor-mediated gene transfer depends on the degree of RGD substitution of targeted PEI conjugates [105]. Coupling RGD via a PEG spacer to PEI, targeting was partially reduced, possibly because of hiding the RGD sequence inside the PEG curtain [104,105]. Suh et al. demonstrated the influence of optimal composition of RGD–PEG–PEI conjugates on transfection efficiency showing that a growing degree of PEG–RGD incorporated onto PEI leads to decreased transfection efficiency

TABLE 15.1
Ligands Used in Receptor-Targeted Polyplexes

Receptor	Ligand	Polycation Used
Airway cells	Surfactant proteins A and B	PLL
Arterial wall	Artery wall-binding peptide	PEG-PLL
ASGP-R	Asialoglycoproteins	PLL, oligolysine, bisacridine, polyornithine, PEI
Carbohydrates	Synthetic galactosylated ligands	PLL
CD3	Lectins	PLL, PEI
CD5	Anti-CD3	PLL
CD13	Anti-CD5	PEI
CD44	NGR	PPI
CD117	Hyaluronic acid fragments	PLL
EGF receptor	Steel factor	PLL, PEI, PLL plus gal4 domain
	Anti-CD117	
	EGF, EGF peptide	
	Anti-EGF	
	TGF- α	
ErbB2	Anti-ErbB2	PLL plus gal4 domain
Fc receptor	IgG	PLL
FGF2 receptor	Basic FGF	PLL
Folate receptor	Folate	PLL, PEI
Hepatocyte basolateral surface	Malarial circumsporozoite protein	PLL
Her2	Anti-HER2	PLL, PEI
Insulin receptor	Insulin	Cation-modified albumin, PLL
Integrin	RGD peptide	Oligolysine, PEG-PEI
LDL receptor family (hepatocytes)	Receptor-associated protein	PLL, poly(D)lysine
Mannose receptor (macrophages)	Synthetic ligands, mannosylated	PLL
Nerve growth factor (NGF) receptor TrkA	NGF-served synthetic peptide	Oligolysine
Neuroblastoma	Antibody ChCE7	PEG-PEI
Ovarian carcinoma cell surface antigen OA3	Antibody OV-TL16 Fab' fragment	
PECAM (lung endothelium)	Anti-PECAM antibody	PEI
Poly-immunoglobulin receptor	Antisecretory component Fab' fragment	PLL
Serpin-enzyme receptor	Peptide ligand	PLL
Surface immunoglobulin	Anti-IgG, Anti-idiotypic	PLL
Thrombomodulin	Antithrombomodulin	PLL
Tn carbohydrate	Anti-Tn	PLL
Transferrin receptor	Transferrin Anti-TfR scFv	PLL, protamine, ethidium dimer, PEI, PEG-PEI

Note: PEG, polyethylene glycol; PEI, polyethylenimine; PLL, polylysine; PPI, polypropylenimine.

[104]. Recently, RGD-PEG-PEI conjugates have been successfully tested for systemic antiangiogenic siRNA therapy [106]. Repeated intravenous administration into neuroblastoma-bearing mice resulted in sequence-specific inhibition of tumor growth.

As a further ligand for targeting angiogenic blood vessels, the NGR peptide (=Asn-Gly-Arg motif) has been investigated [107]. NGR shows highest affinity for aminopeptidase N (APN, also known as CD13) which plays an important role in tumor invasion [108]. Moffatt et al. recently reported promising *in vivo* results using a CD13 targeted PEG-PEI polyplex resulting in enhanced gene expression at the tumor site [56]. In these polyplexes CNGRC (the cyclic form of a pentapeptide containing the NGR motif) conjugated with PEG is attached

to PEI via noncovalent phenyldiboric acid/salicylhydroxamic acid bridges. *In vivo* application for p53 gene transfer polyplexes showed encouraging therapeutic effects, i.e., significant regression of non-small-cell lung carcinoma. Moreover, this vector targeted tumor tissue and tumor-associated endothelial cells but not normal cells [109].

Other possibilities, e.g., using antibodies to target specific cells, have been investigated successfully. Anti-CD3 antibody, coupled to pDNA polyplexes, has been shown to be very efficient in targeting T cells via binding the CD3 T-cell receptor complex [110]. Also attachment of modified MIP-1 beta to the surface of pDNA-liposome complexes targeting CCR5 displayed on the surface of helper T cells and macrophages increased gene expression in circulating lymphocytes

approximately sixfold [111]. Malignant B cells have been successfully targeted by anti-idiotypic antibodies [112].

The majority of approaches attaches ligands to polyplexes by conjugation to polycations. An alternative mode to incorporate ligands into polyplexes employs nucleic acid-binding domains derived from transcription factors to attach a protein component to pDNA [113]. For example, pDNA containing GAL4 recognition motifs can interact with GAL4 containing carrier molecules. Cell-specific ligands can be combined with the GAL4 domain to form a chimeric fusion protein to allow gene delivery to specific cells, e.g., GAL4/invasin fusion protein has been shown to transfect target cells in an invasin receptor-dependent manner [114]. However, for complex formation, and hence condensation, an additional condensing agent such as PLL is required.

15.4 INTRACELLULAR TRAFFICKING AND BARRIERS

Once the nucleic acid has been internalized into the target cell, several intracellular barriers (Figure 15.2) have to be overcome for successful gene expression. To tackle the

intracellular barriers, a polyplex needs to escape from the endosome, survive the cytoplasmic environment, traffic the cytoplasmic environment targeting the nucleus with subsequent nuclear entry, and be disassembled in the nucleus so it can be recognized by the cell's transcription machinery.

Overcoming these intracellular barriers can be achieved by certain carrier molecules [115] and cell-targeting ligands, although exploiting other factors, e.g., additional endosomal releasing mechanisms and nuclear localization signals, might strongly improve the capacity of a polyplex to overcome intracellular barriers.

15.4.1 ENDOSOMAL RELEASE

The first major intracellular barrier that greatly compromises the efficiency of efficient gene transfer is the entrapment and degradation of the polyplex within intracellular vesicles after taking off of the coated pits from the plasma membrane (Figure 15.2). Entrapment and degradation can be seen as two separate barriers, because overcoming vesicular degradation would only result in accumulation of the transferred gene in the vesicles limiting further transport to

FIGURE 15.2 Intracellular release and trafficking of polyplexes. Polyplexes have to be stabilized and shielded to avoid unspecific interactions in the blood circulation. Incorporation of PEG into the polyplex is one approach to mediate these characteristics. After binding to the cell surface either by specific ligand–target–receptor interaction or unspecific interaction of positively charged polyplexes to negatively charged transmembrane heparan sulfate–proteoglycans (HSPG), polyplexes are internalized into endosomal vesicles. The acidic environment triggers cleavage of bioreversibly linked PEG from the polyplex enhancing release from the vesicle to the cytosol. Polyplexes entrapped in endocytic vesicles can be effectively transported into the perinuclear region. In the initial phase during endocytosis into vesicles, polyplexes are colocalized with the actin cytoskeleton, followed by rapid intracellular migration along microtubules. The nucleus is separated from the cytoplasm by the nuclear envelope, that is stretched by nuclear pore complexes (NPC) mediating active transport of macromolecules from the cytoplasm to the nucleus.

the nucleus. Thus, after cellular internalization, the transferred gene needs to overcome enzymatic degradation during vesicular fusion into lysosomes, and afterwards it needs to be released from the vesicles to traffic the cytoplasm and target the nucleus.

Several strategies have been developed to ensure the protection and release of polyplexes from intracellular vesicles involving incorporation of vesicular destructive elements to polyplexes, which perturb the integrity of vesicle membranes allowing the contents to get into the cytoplasm in a nondamaging manner. Application of endosomal-releasing elements to the transfection agents has shown to enhance gene transfer. Lysosomotropic agents, membrane active peptides and proteins, and also photosensitizing compounds possess properties that disrupt vesicular membranes promoting the release of polyplexes.

15.4.1.1 Lysosomotropic and Membrane-Disruptive Agents

Lysosomotropic agents are weak-base amines that can specifically inhibit lysosomal function [116,117], e.g., ammonium chloride and the weakly basic alkylamines such as methylamine, propyl amine, or chloroquine. These agents are termed lysosomotropic because they accumulate in the endosomes which is partly due to the initially low lysosomal pH, and partly because of continuous perfusion of protons into the endosome.

In some cell lines, e.g., erythroid cell line K562, gene expression is strongly enhanced by adding chloroquine to the transfection medium [48]. Chloroquine seems to accumulate in the endosomal compartment acting osmotically, vacuolarizing, and eventually disrupting the vesicle. In this case, the transferred gene is protected and released from intracellular vesicles. Bafilomycin or monensin, two other agents that also prevent endosomal acidification but do not accumulate, show no enhanced transfection efficiency. Regarding chloroquine, its effectiveness in enhancing gene transfer is also dependent on cell type, which ensures vesicular accumulation of the lysosomotropic agent. For example, the K562 cells have a defect in their vesicular pump system, determining the enhanced accumulation of chloroquine in endocytic vesicles in comparison to other cells [118]. The use of chloroquine is limited due to toxic properties; analogs are being generated for better performance [119].

Many biological processes such as entry of viruses, bacteria, and toxins into cells, or the activities of antimicrobial peptides are examples how efficiently nature can modulate membrane barriers and promote endosomal escape. The membrane reorganization process is the result of specific actions of certain membrane disruptive elements (peptides and proteins).

In most cases, the membrane active area in such elements are peptide domains with amphipathic sequences. Under appropriate conditions the amphipathic sequences can interact with lipid membranes, perturbing them, which can be specifically used to influence gene transfer investigating various

endosomolytic agents [120]. Membrane active peptides can be derived from viral peptide sequences such as the N-terminus of influenza virus hemagglutinin subunit HA-2 [121,122] or the N-terminus of rhinovirus VP-1, from other natural sources such as melittin from bee venom [123,124], or they may be designed synthetically from the derived peptides by molecular modeling, for example GALA, KALA, EGLA, or JTS1 [125–130] or other artificial sequences [131,132].

The peptides can be incorporated into polyplexes by covalently linking to the polycation. Another possibility to achieve attachment is simple noncovalent ionic interaction between positively charged polyplexes and the negatively charged residues of membrane destabilizing elements. Membrane destabilizing peptides have shown to enhance receptor-mediated gene transfer up to 1000-fold.

Also natural nonviral endosome-destabilizing agents including listeriolysin O [133] were incorporated into polyplexes. Melittin conjugates [123,124,134] have shown to enhance gene transfer efficiency, however toxicity limits their application. Melittin shows pronounced lytic activity also at neutral pH which is responsible for toxic side effects. To overcome this limitation, Rozema et al. modified the lysines of melittin with a dimethylmaleic anhydride derivative masking the lytic activity at neutral pH. Upon endosomal acidification, the masking groups are removed and the lytic activity of melittin is restored [135]. Meyer et al. coupled melittin modified with dimethylmaleic anhydride covalently to PLL resulting in enhancement of gene transfer efficiency and also reducing the toxicity of both melittin and PLL [136]. Other approaches to pH-dependent lytic activity include acidic melittin analogs [137] or the incorporation of melittin into bioreducible copolymers [134].

15.4.1.2 Photochemical Membrane Disruption

Endosomal escape is a major drawback for efficient gene delivery. To overcome this a method called photochemical internalization (PCI) [138,139] was developed. Cells are treated with photosensitizing compounds, such as tetra (4-sulfonatophenyl) porphine or aluminium phthalocyanine, that locate in the membranes of endosomes. These amphiphilic photosensitizers become activated upon illumination and induce formation of reactive oxygen species, destroying endosomal membrane structures which lead to release of polyplexes into the cytoplasm. PCI enhances gene transfer of viral and nonviral carrier like adenovirus, lipoplexes, and polyplexes with or without receptor targeting [99,140–142]. Glucosylated PEI with increased solubility and transfection efficiency in comparison to unmodified PEI was used for polyplex formation injected directly into the tumors. Luciferase reporter gene expression after photosensitization was increased up to 100-fold in comparison to nonirradiated tumors.

Kataoka et al. developed a system assembling the photosensitizer and the gene carrier in one ternary complex [143]. pDNA was complexed with cationic peptides and afterwards anionic photosensitizers, a dendrimeric phthalocyanine, were

attached to the polyplex. These ternary polyplexes achieved *in vitro* more than 100-fold increase of luciferase reporter gene expression in comparison to transfections without PCI; *in vivo* gene expression was detectable only at the laser irradiated site.

In vitro, PCI already showed encouraging results in improving gene delivery of polyplexes [144,145]. For lipopolyplexes the PCI effect was variable and depends on the type of liposomes used [141]. Moreover, receptor-mediated gene delivery in combination with PCI worked very well combining targeting and endosomal release facilities. Kloeckner et al. showed a 2- to 600-fold enhanced transfection efficiency of EGF-targeted polyplexes *in vitro* compared to transfections without PCI [99]. Ndoye et al. recently showed promising therapeutic effects in an HNSCC model *in vivo* with PEI-mediated p53 gene transfer combined with PCI [146].

15.4.1.3 Cationic Proton Sponge Polymers

In contrast to nucleic acid-binding polycations such as PLL, there are other polycations like PEI or PAMAM dendrimers that possess intrinsic endosomolytic activity [147], thus not requiring the presence of additional endosomolytic agents. Most of these agents have buffering capacity below physiological pH. This buffering capacity is due to residues of these agents being not protonated at physiological pH, making them efficient "proton sponges." Upon acidification in the intracellular vesicle further protonation of the polymers occurs which triggers chloride influx, resulting in osmotic endosome swelling, and thus, destabilization and rupture of the intracellular vesicle membrane, resulting in the escape of the included polyplex [148,149]. Intracellular trafficking studies measuring intravesicular pH using a pH-sensitive dye confirmed that PEI polyplexes can buffer the endocytic vesicles while PLL polyplexes do not [150].

Histidinylated PLL was also found to have enhanced transfection properties, presumably mediated by a related vesicular escape mechanism [151]. It can be noted that several polymers effective in gene transfer are proton sponges; however, not every cationic proton sponge is an effective gene transfer agent [152].

15.4.2 CYTOPLASMIC TRAFFICKING, NUCLEAR ENTRY, VECTOR UNPACKING

Besides receptor-mediated endocytosis and release from endosome the delivery systems encounter several tasks such as, cytosolic transport towards the nucleus, release of pDNA/siRNA, and nuclear import. To date the order of these processes is unclear, whether cytoplasmic trafficking proceeds before or also after endosomal escape, whether unpacking occurs before or after nuclear entry. Different scenarios have been observed, however, it remains unclear which of the observed routes are the productive ones. Investigators have attempted to incorporate nuclear localization signals into polyplexes for improved nuclear targeting, without convincing success. In contrast to pDNA-based therapeutics, nuclear

transport is irrelevant for siRNA, where targets are primarily localized in the cytoplasm.

15.4.2.1 Cytoplasmic Trafficking

Free cytosolic pDNA or also pDNA polyplexes are too large to freely diffuse within the cytosol [153]. Polyplexes entrapped in endocytic vesicles, however, can be effectively transported into the perinuclear region. Single particle tracking studies using PEI polyplexes in living cells [154] found colocalization of polyplexes with the actin cytoskeleton in the initial phase during endocytosis into vesicles, followed by rapid intracellular migration along microtubules. In a subsequent study [155], EGF-targeted polyplexes were analyzed in respect to internalization into EGF-receptor expressing cells. Uptake kinetics and internalization dynamics of EGF-targeted polyplexes were faster and more efficient internalization (within 5 min in average) compared with untargeted PEI polyplexes (more than 30 min). Transport phase I was characterized by very slow, actin cytoskeleton-mediated movement of the particles at the cell surface and during internalization. Within the cell during phase II, endosomal particles displayed increased velocities with normal and confined diffusion (due to cytoskeleton-restricted movement) in the cytoplasm. Phase III was characterized by very fast active transport of polyplexes within vesicles along the microtubules [154,155].

15.4.2.2 Nuclear Entry

The nucleus is separated from the cytoplasm by the nuclear envelope, which consists of two chemically distinct membranes, the inner and outer membrane (continuous to the endoplasmic reticulum), and in between the perinuclear cisterna space. NPCs stretch the nuclear envelope, and active transport of macromolecules from the cytoplasm to the nucleus occurs through these complexes.

There are several distinct nuclear import signals which guide the import of proteins into the nucleus. These signals are part of the primary sequence of the protein destined to be targeted into the nucleus. The best characterized ones are the SV40 LTA "classical" NLS (nuclear localization signal) and M9 (an import signal of hnRNP A1 protein) import signals. The utilization of such NLS signals for polyplex delivery has been attempted, however, no convincing break-through has been achieved [156].

The nuclear envelope represents an obvious barrier for polyplex-mediated gene transfer. How polyplexes find their way to the nucleus, whether it occurs before or after polyplex dissociation is not fully understood. Rudolph et al. analyzed the dissociation of pDNA from polyplexes after cellular uptake and describe the interaction of gene vectors with t-RNA mediating the dissociation [157].

In dividing cells pDNA may passively enter the nucleus during cell division when the nuclear membrane is broken down [158]. Although rupture of the nuclear envelope is not a necessity for some PEI polyplexes to penetrate the nucleus [115,159], transfection efficiency of polyplexes in general is critically dependent on cell division [160]. However, many

cell types are nondividing with the nuclear membrane staying intact, thus nuclear entry and trafficking may represent an additional intracellular barrier for successful *in vivo* gene transfer.

15.4.2.3 Vector Unpacking

The cell nucleus is saturated containing large amounts of DNA, RNA, and proteins. In addition, nuclear processes, e.g., replication, transcription, translation, and DNA repair processes, are constantly active in specific compartments, resulting in a nuclear jam [161,162].

Within all these cellular components and nuclear processes, the polyplex needs to become exposed enabling the nuclear expression machinery to recognize and express it. Early disassembly and release of the nucleic acid from the carrier molecule in the cytoplasm may prevent efficient transfer to the nucleus, hence obliterate expression. Polyplexes most likely disassemble in the nucleus which is a characteristic desirable for successful gene transfer and expression [115].

The release of pDNA complexed with polycations, including linear and branched polyethylenimine (LPEI, BPEI) and PLL, was analyzed with confocal microscopy using fluorescence resonance energy transfer (FRET) between a pair of donor-acceptor fluorescent dyes (fluorescein and Cy3) tagged on a single pDNA molecule. pDNA complexed with LPEI underwent a more rapid unpacking after endosomal release in comparison to pDNA complexed with BPEI. These intracellular characteristics showed a clear correlation to their gene transfer efficiency. The pDNA/LPEI polyplexes revealed a considerably higher and faster gene expression compared with pDNA/BPEI polyplexes. In the pDNA/PLL polyplexes, neither endosome escape nor pDNA disassembly was observed [163].

Another study describes a quantitative comparison of the cellular uptake and subsequent intracellular distribution (e.g., endosome, cytosol, and nucleus) of exogenous pDNA transfected by viral and nonviral vectors *in vitro*. As a model, adenovirus (Ad) and Lipofectamine Plus (LFN) were used for comparison since they are highly potent and widely used viral and nonviral vectors, respectively. The findings indicate that LFN requires three orders of magnitude more intranuclear gene copies to exhibit a gene expression comparable to that of the Ad. This suggests that the difference in transfection efficiency principally arises from differences in nuclear transcription efficiency and not from a difference in intracellular trafficking between Ad and LFN [164].

15.4.3 PERSISTENCE OF GENE EXPRESSION

Several factors threaten the persistence of transferred pDNA within the nucleus: (1) degradation by intranuclear nucleases, (2) pDNA loss, mainly during cell division, although pDNA may also be rapidly lost even when cells are not dividing, (3) loss of transfected cell, because of apoptotic, inflammatory, or immune response, (4) silencing of the introduced gene by transcriptional shut-off, (5) possibly inefficient intranuclear trafficking.

pDNA loss can be prevented by including specific sequences to the transferred gene that ensure either integration of the pDNA into host chromosome, or extrachromosomal replication with equal segregation to daughter cells. These persistence ensuring sequences can be derived from certain viruses or from chromosomes.

Retroviruses and adeno-associated virus (AAV) stably insert their genome into host genome. The integration mechanisms have been characterized (retrovirus: LTR sequences, integrase protein; AAV: ITR sequences, rep protein) and may be exploited by incorporation of the corresponding nucleic acid and protein elements into a virus like particle (polyplex).

The sleeping beauty (SB) transposon system has been recently evaluated providing encouraging results [165,166]. SB transposase catalyses the excision of a transposon from a donor molecule and its integration into a cellular chromosome.

The phase integrase C31 (phiC31) system represents another novel technology for gene therapy. The phiC31 integrase can integrate introduced pDNA into preferred locations in unmodified mammalian genomes, resulting in robust, long-term expression of the integrated transgene [167].

Other viruses such as herpes virus, e.g., EBV, can persist in infected cells without integrating their genome into the host. This persistence is partially due to replication property of viral pDNA via cis-acting origin of replication which is activated by the trans-acting gene product of the viral EBNA-1 and additional nuclear retention mechanisms. The viral persistence mechanisms can be utilized in designing extrachromosomal replicating pDNA constructs (episomal vectors) by integrating the appropriate sequence elements, recognizable in mammalian cells, into the pDNA construct being transferred (e.g., EBV Ori P, EBNA-1). pDNA constructs containing these sequences have the ability to replicate once per cell cycle with nuclear retention without interfering with the host chromosomes. An alternative to using viral origin of replication, human genomic sequences may be used to mediate pDNA construct replication [168].

The inhibition of gene expression by RNA interference hosts a high potential for application in therapy of human diseases. However, while exogenous applications of siRNA efficiently inhibit gene expression, these effects are only transient in mammalian cells. Lipp et al. designed a short hairpin RNA-expression cassette to target the bcr-abl oncogene that was then introduced into the nonviral plasmid vector pEPI-1 [169,170] which replicates episomally in the absence of selection. Forty-two days after transfection of the bcr-abl-positive cell line K562 the bcr-abl-dependent growth rate was found to be drastically reduced in K562 cells. Western analysis revealed a more than 90% reduction in the expression of the fusion protein bcr-abl while the expression of the bcr protein remained unaffected. This and further studies demonstrate that the vector system pEPI-1 can be used for efficient long-term gene expression including specific gene suppression by using a short hairpin RNA transcription unit.

15.5 EXTRACELLULAR BARRIERS TO GENE DELIVERY

Upon *in vivo* application polyplexes face both intracellular and extracellular barriers. A schematic diagram of the potential intracellular and extracellular fate of a polyplex is shown in Figure 15.3. Strategies have to be developed in designing polyplexes that are able to survive blood or other biological fluids, and to escape extracellular physical barriers in order to reach the target cells. The specific strategies must consider the physicochemical properties of polyplexes, e.g., size, shape/flexibility, overall charge, charge density, and nonelectrostatic interactions at the surface. Besides considering these physical properties, one could imagine to use active endogenous cellular transport mechanisms such as transcytosis [171].

In systemic administration, i.e., intravenously application of the vector, the circulatory pathway/environment and various nontarget cells and organs, encountered by the polyplex, are major challenges [172]. Local administration methods such as direct injection of the vectors into the target region or topical administration are not confronted with the circulation problems, but, nevertheless, still confronted with barriers such as extracellular matrix or inflammatory and immune responses.

15.5.1 PHYSICAL RESTRICTIONS OF TRANSFECTION PARTICLES

Size seems to be a general critical factor for drug targeting [173]. Because of size restriction, several hundred nanometer

large polyplexes are not able to penetrate endothelial and epithelial barriers [174], or extravasate from the vascular to the interstitial space (Figure 15.4). Particle size is also an important factor when considering organ clearance and intraorgan distribution. For example, particles that are too large to pass through the vascular endothelium to the liver parenchyma are engulfed and degraded by liver Kupffer cells, i.e., phagocytic cells located next to the vascular epithelial cells.

The structure of condensed nucleic acid polyplexes has been analyzed in several reports, e.g., [15,175–178]. Polyplexes have been characterized by electron microscopy and atomic force microscopy (shape, size), laser light scattering (size), their electrophoretic mobility (reflects charge and size of complexes), zeta potential measurements (charge), circular dichroism (conformation of pDNA), or centrifugation techniques (molecular weight and condensation). The results give some insight on generating small polyplexes. In addition, the compact polyplexes are more stable against enzymatic or mechanical degradation, which takes place during nucleic acid transport to the target cells/tissue.

However, preparation of effective polyplexes for *in vivo* delivery of nucleic acids remains a major hurdle. The extent of nucleic acid condensation depends on a number of variables including the ratio of positively charged nucleic acid-binding element (cationic carrier) to negatively charged nucleic acid. Also the size and modification of the nucleic acid-binding element, size and sequence of the nucleic acid, and even the procedure of complex formation [49] are strongly influencing the *in vitro* and *in vivo* gene transfer efficiency. The net charge

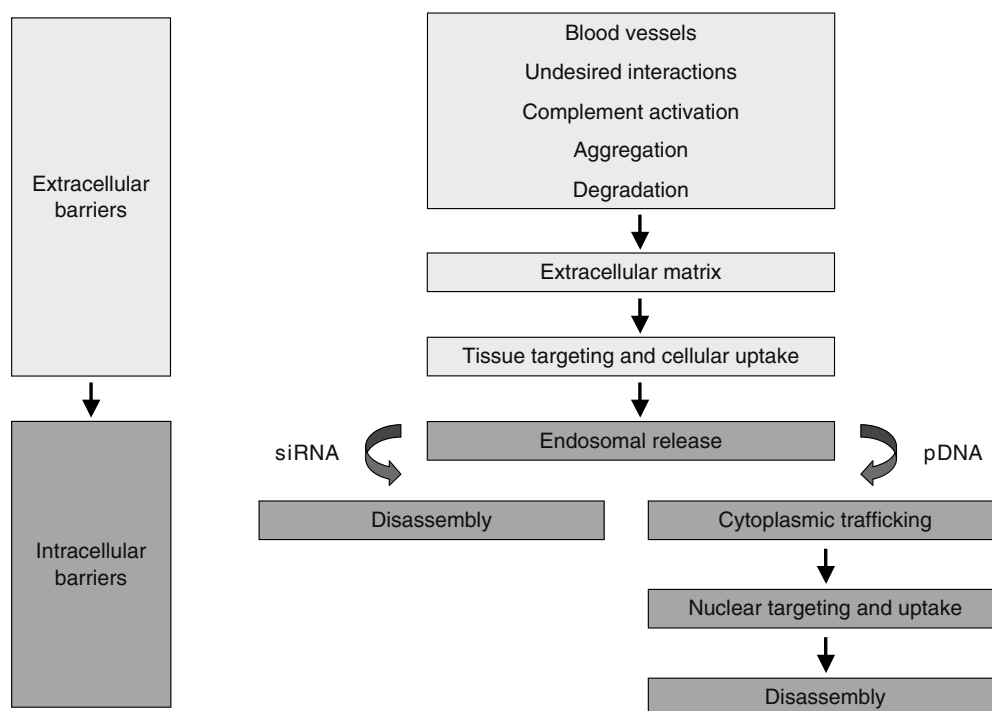

FIGURE 15.3 Extracellular and intracellular barriers to gene delivery.

FIGURE 15.4 Vascular barriers to gene delivery. Route of polyplexes across the vascular barrier into the interstitial space, avoiding interactions with the extracellular matrix in order to reach the target cells/tissue.

of the nucleic acid/cationic carrier complex affects its solubility. Polyplexes with either an excess of nucleic acid or positively charged carrier are stabilized in solution by the negative or positive charges. At molar charge ratios (positive charges of carrier nitrogens to negative charges of nucleic acid phosphates) close to electroneutrality, often aggregation of polyplexes is observed unless the carrier contains hydrophilic domains such as PEG for stabilization. The procedure of complex formation still has to be improved in generating homogeneous and stable polyplexes capable of overcoming the physical barriers.

For example, Wagner et al. described one approach for polyplex formation [15]. Flash mixing of dilute compounds in physiological phosphate-free buffer results in formation of kinetically controlled polyplexes. At ratios of electroneutrality or higher, donut- and rod-like particles of 80–120 nm in diameter are formed for PLL polyplexes. Polyplexes containing Tf-conjugated PLL have increased solubility compared to unmodified PLL. For this type of polyplex formation a strong influence of parameters such as pDNA concentration or charge ratio, and ionic strength of solution was observed. Mixing pDNA/PEI polyplexes at N/P (PEI nitrogen: DNA phosphate) molar ratios below 6/1 in 150 mM saline results in rapid aggregation, which can be avoided by complex formation at low ionic strength (e.g., glucose balanced buffer) generating particles with an average diameter of approximately 40–50 nm [178]. It was also found that incorporation of hydrophilic PEG residues into polyplexes stabilize and prevent their aggregation [179].

Furthermore, purification of pDNA/PEI polyplexes from free PEI demonstrated low cellular and systemic toxicity, whereas also high transfection efficiency was achieved at high pDNA concentrations. Size exclusion chromatography (SEC) or electrophoresis was used to purify the pDNA/PEI polyplexes, which did not change their size and zeta-potential [180,181].

15.5.2 UNDESIRE INTERACTIONS WITH PLASMA, DEGRADATIVE ENZYMES, MATRIX, AND NONTARGET TISSUE

Polyplexes, when administered *in vivo*, are surrounded by a variety of compounds present in blood plasma. Salts, lipids, carbohydrates, proteins, or enzymes contribute to changes in the physicochemical properties of the polyplex. Some of these factors (opsonins) may coat the polyplex, causing aggregation, dissociation, or degradation of the polyplex. This may influence the composition of the polyplex as well as the bioavailability. Thus, the polyplexes, even when reaching the target cells/tissue, may no longer exhibit the physical properties necessary for efficient gene transfer into cells.

Previous studies have demonstrated the inactivation of pDNA/PLL polyplexes by blood components [182], whereby one of the factors was identified as the complement system [183]. Upon incubation of polyplexes with human plasma, specific proteins (IgM, fibrinogen, fibronectin, and complement C3) bind to the complexes. By coating pDNA/PEI polyplexes with PEG through covalent coupling to PEI, interaction with blood components was found to be strongly reduced [179].

Once the polyplex has traveled across the vascular barrier into the interstitial space, it has to avoid interactions with the extracellular matrix in order to reach the target cells/tissue (Figure 15.4). The extracellular matrix comprises different combinations of collagens, proteoglycans, hyaluronic acid, fibronectin, and other glycoproteins. These components could act as barriers by binding the polyplexes, e.g., hyaluronic acid binds cations very effectively. This implies that polyplexes resulting in a net positive charge could also interact with the extracellular matrix like binding, dissociation, or aggregation. Thus, optimizing the polyplexes bearing an overall low charge ratio close to neutrality is a possibility to avoid such interactions.

15.5.3 INFLAMMATORY AND IMMUNOLOGICAL RESPONSES

As a result of introducing foreign molecules into the body, individual immune cells are stimulated to produce antibodies (humoral immunity). In addition to this humoral response, specific T cells may also be activated (cellular immunity). These two processes are the specific immune response. There is, however, also the nonspecific immune response, including phagocytosis, inflammation, and other nonspecific host resistance mechanisms such as the complement system [184]. These nonspecific mechanisms are developed immediately against any foreign molecule, even though the host has never encountered. Thus, the nonspecific immune response is a major extracellular barrier for the polyplex.

Inflammatory response is a major problem for any gene delivery system [185]. During an inflammatory response, neutrophil granulocytes and to a lesser extent macrophages migrate out of the capillaries into the surrounding tissue. At the site of inflammation the phagocytes recognize the foreign molecules via receptors on their surface leading to subsequent phagocytosis. Attachment is greatly enhanced and specified upon opsonization of foreign molecules, e.g., by the C3b component of complement. Both neutrophil granulocytes and macrophages have receptors which specifically bind to C3b allowing them to recognize their target.

Positively charged polyplexes have the ability to activate the complement system [183]. The positive charges are responsive to the complement protein C3b. Opsonization of such particles by C3b leads to the initiation of a cascade of events presumably resulting in the clearance of polyplexes by the reticuloendothelial system. Coating the positive charges of the polyplexes with other macromolecules may inhibit interactions with components of the complement system, hence decrease complement activation and clearance of the complexes from the blood circulation [186,187].

15.6 BIORESPONSIVE SYSTEMS: SYNTHETIC VIRUSES

Transport requirements during delivery of nucleic acids can change with time; they differ in the extracellular phase (protection) from the intracellular phase (release and activation). Consistently, the bioresponsiveness of delivery systems is a key issue of prospective developments in nucleic acid delivery [6]. Viruses, the most efficient gene delivery vectors, sense their environment and respond to the biological surrounding in a dynamic manner. Mimicking nature by integrating bioresponsive domains into synthetic carriers (Synthetic viruses) can be advantageous as demonstrated in first experimental approaches.

For example, PEG shielding is beneficial for systemic circulation of polyplexes but could also hinder intracellular release. To overcome this PEG dilemma, Szoka et al. took advantage of differences in the pH of biological compartments.

They prepared several pDNA lipoplexes consisting of a cationic lipid mixture and a pH-sensitive PEG-diorthoester-distearoylglycerol lipid. *In vitro* experiments showed enhanced luciferase reporter gene expression (up to three orders of magnitude) of pH-sensitive lipoplexes compared to the stable shielded ones [188].

A similar strategy was successful in case of polyplexes. Bioresponsive PEGylation with pH-labile hydrazone or acetal linkages were used for *in vitro* and *in vivo* gene transfer [189,190]. PEI polyplexes shielded with these pH-sensitive PEG conjugates lose their PEG shield at low pH, i.e., in endosome. Such polyplexes, when targeted for the Tf or EGF receptor-mediated endocytosis pathway, displayed up to 100-fold higher gene transfer efficiency compared to polyplexes with a stable PEG shield.

A different approach to PEGylate particle-based systems was accomplished by Oishi et al. linking PEG directly to siRNA or antisense oligonucleotides [191,192]. For this purpose they used an acid-labile thiopropionate linker and mixed the grafted oligonucleotide afterwards with PLL to form polyion complex micelles (PIC). Targeted acid-labile PICs showed significant higher inhibition of gene expression *in vitro* compared to the stable PICs in a human hepatoma model.

Besides the pH gradient, changes in the concentration of specific enzymes can also be used as trigger. Harashima et al. designed a cleavable PEG-lipid containing a peptidic substrate for matrix metalloproteinase occurring in the extracellular space of tumor tissues [193]. The cleavable PEG was formulated with pDNA lipoplexes in comparison to standard non-cleavable PEG-lipids mediating an approximately 100-fold enhanced gene expression *in vivo*.

Murthy et al. masked the endosomolytic property of poly(propylacrylic acid) conjugates via acid-degradable acetal linkages [194]. The triggered removal of masking groups by acidification in the endosome was also responsible for restoring the lytic activity of melittin [135]. Chen et al. took advantage of an intracellular reducing environment for reactivation of the lytic activity of melittin [195]. A lysine-modified, disulfide-linked poly-melittin analog was created losing its lytic activity after polyplex formation. Intracellular reduction leads to release of lytic melittin which improves endosomal release and gene transfer efficiency.

Listeriolysin O (LLO) is a natural membrane-disruptive protein from *Listeria monocytogenes*, which contains a single cysteine residue involved in endosomal membrane binding and disruption. Conjugation of LLO by this cysteine via disulfide bond formation to protamine [133] results in the loss of the lytic activity, which is recovered by intracellular reduction. The transfection efficiency was enhanced by three orders of magnitude when the LLO-protamine conjugate was included in pDNA/protamine polyplexes.

The difference in intracellular redox potential has also been used as trigger for intracellular release of the nucleic acid, including pDNA, mRNA, and siRNA, delivered by reducible polyplexes [28].

15.7 THERAPEUTIC APPLICATIONS OF POLYPLEXES

Although gene transfer via receptor-targeted polyplexes is mainly successful *in vitro*, several reports have demonstrated the ability to deliver nucleic acids efficiently to target cells *in vivo*. This has been enabled by using the various methods to overcome the intra- and extracellular barriers, but also to a large extent by shielding of the polyplexes reducing their positive surface charge (zeta potential), hence preventing interactions with blood components. Shielding methods include those with PEG [179], poly-*N*-(2-hydroxypropyl)metacrylamide (pHPMA) [196], poloxamer [197], or targeting ligand density [85].

Numerous pDNA, siRNA, and related nucleic acid formulations have shown very encouraging anticancer effects *in vivo*. The therapeutic effects aimed at are, i.e., interference with neoangiogenesis, reducing tumor cell proliferation, induction of apoptosis, or activation of the immune system.

For disseminated cancer, pDNA and siRNA have to be applied systematically using particle-based systems protecting their content from degradation and transferring it to the cancer tissue, while encountering many barriers on the *in vivo* delivery route. Improved targeting, efficient intracellular delivery, reduced toxicity, and bioresponsiveness are key elements for additional optimization.

15.7.1 TARGETED DELIVERY OF THERAPEUTIC pDNA

15.7.1.1 Targeted Delivery of pDNA To Different Tissues

First encouraging results for *in vivo* gene transfer, via intravenous injection, were obtained by targeting the liver asialoglycoprotein receptor using asialoorosomucoid covalently linked to PLL carrying the CAT marker gene [2,50,198–200]. Gene expression proved to be liver specific as other organs, e.g., kidney, spleen and lungs, did not produce detectable quantities of CAT. Gene expression persistence was improved by applying partial hepatectomy, a procedure for stimulating hepatic regeneration and pDNA synthesis, beginning 12h after surgery resulting in CAT activity up to 11 weeks postsurgery.

Related approaches have been used to target the liver with polyplexes of different sizes. Less than 20nm small galactosylated pDNA/PLL polyplexes encoding human factor IX have been shown to target the hepatic asialoglycoprotein receptor, with up to 140 days of detectable protein in serum of transfected rats, achieved without partial hepatectomy [51]. In another approach, the polymeric immunoglobulin receptor has been targeted by 25 nm pDNA polyplexes bearing antigen-binding fragment of an antibody enabling gene transfer to rat pneumocytes following intravenous administration [52,53].

This type of small PLL polyplexes have been further developed into PEGylated PLL polyplexes. These have been

recently tested in clinical trials in CF patients; transient correction of the CFTR ion channel in nasal epithelium was demonstrated [201].

Polyplexes based on PLL do not demonstrate efficient gene transfer *in vivo*. However, modifications such as addition of endosomal disruptive agents like adenoviruses [54] resulted in efficient gene expression in airway epithelium after intratracheal application [202], and in tumors after intratumoral application [203,204].

The lung has been targeted via systemic tail vein injection of mice by pDNA/LPEI polyplexes [205,206]. High levels of gene expression were observed in the lungs while lower expression in the other organs (including heart, spleen, kidney, and liver). However, systemic gene delivery with positively charged pDNA/PEI polyplexes has strong side effects resulting in lung embolism and severe toxicity [85,207]. The lung can be more specifically targeted by aerosol delivery of PEI polyplexes. Rudolph et al. showed that aerosolized pDNA/PEI polyplexes yielded transfection levels 15-fold higher than a 140-fold higher dose of the same vector applied directly via intratracheal intubation to the lungs of mice [208,209]. The strategy was also successful in sheep as a large animal model for optimizing cystic fibrosis gene therapy. Dose-related toxicity was reduced by aerosol administration compared to direct instillation [210].

15.7.1.2 Targeted pDNA Polyplexes for Cancer Therapy

Receptor-targeted polyplexes can be used to systemically deliver genes into tumors. Intravenous application of standard positively charged pDNA/PEI-Tf polyplexes through the tail vein into tumor-bearing mice resulted in gene expression in the tail and lung; no expression could be observed in the tumor, but serious toxicity [179,204]. However, surface shielding of the Tf-linked polyplexes with PEG via covalent coupling to PEI leads to stabilizing of polyplexes in size and preventing of interactions with plasma proteins and erythrocyte aggregation [179]. Tail vein injecting these PEGylated polyplexes in mice leads to less toxicity and further enhancement of gene expression [179,204]. Similar results were obtained with other Tf polyplexes with electroneutral surface, e.g., shielded optimized adenovirus-linked PLL-Tf polyplexes [204] or PEI-Tf polyplexes with a higher content of Tf as shielding agent [85].

As subcutaneous tumors are not directly supplied by main blood vessels, delivery is dependent on peripheral blood supply. Thus, the polyplexes probably target such distant tumors in a combinatorial passive targeting (i.e., overcoming extracellular barriers, EPR=enhanced permeability and retention effect as described for tumors [211]) and active targeting mechanisms (i.e., specific receptor targeted endocytosis).

Another report demonstrated that intravenous injection of PEGylated EGF-containing pDNA/PEI polyplexes results in a highly specific expression in human hepatocellular carcinoma

(HCC) tumors. Following intravenous injection into human HCC xenograft-bearing SCID mice, luciferase reporter gene expression was predominantly found in the tumor, with levels up to two logs higher than in the liver [47].

TNF- α is a cytokine with immunostimulatory and cytotoxic properties, particularly affecting the tumor vasculature. pDNA encoding TNF- α has been systemically delivered to tumor-bearing mice resulting in expression in tumor cells near to the feeding vessel. Locally produced TNF- α is assumed to be responsible for the obliteration of the tumor vasculature resulting in tumor necrosis [89]. For this purpose Tf-conjugated PEI polyplexes were applied via tail vein, which can additionally contain a PEG shield. Delivery of a luciferase reporter gene resulted in gene transfer into distant subcutaneous neuroblastoma tumors approximately 100-fold higher than in other organs [95,179] and specificity was confirmed by luciferase live imaging in mice [92]. Repeated systemic application of TNF- α polyplexes into tumor-bearing mice induced tumor necrosis and inhibition of tumor growth in four murine tumor models [89,95]. Due to the fact that TNF- α gene expression was largely localized within the tumor, no significant systemic TNF- α related toxicities could be observed. Therapeutic effects were enhanced by the combination of tumor-targeted TNF gene therapy with DOXIL, a liposomal doxorubicin formulation that passively accumulates within tumors [6].

Intravenous TNF- α gene therapy was also effective in treatment of three other established tumor models: epidermoid carcinoma, cervix carcinoma, and colorectal carcinoma [212]. In this study different polyplex formulations were applied based on polypropylenimine dendrimers, and the TNF-alpha gene expression constructs were transcriptionally targeted by telomerase gene promoters. The cationic dendrimer carrier was found to exhibit pDNA-independent, intrinsic antitumor activity, extending from growth retardation to complete tumor regression. These results let one suggest that such combined effects of targeted nucleic acids with polymer-based antitumor activity may be a good basis for efficient gene therapy.

Polyplexes consisting of pDNA and glucosylated PEI have been used for p53 *in vivo* gene transfer in mice bearing head and neck squamous cell carcinoma xenografts. Combining the treatment with PCI technology resulted in enhanced intracellular release of endocytosed polyplexes by photosensitizer and light [142,144], leading to a 20-fold increased and also sustained gene expression. Furthermore weekly treatment repeated for 7 weeks resulted in tumor growth inhibition in all animals [146].

15.7.2 TUMOR-TARGETED DELIVERY OF THERAPEUTIC siRNA

Application of siRNA or siRNA expressing vectors can trigger specific antitumoral effects [213,214]. Cell-type specific antibody-mediated siRNA delivery was achieved with the fusion antibody fragments and the nucleic acid binding polycation protamine [215]. In preliminary experiments, the HIV

envelope protein was used for antibody targeting to an artificial epitope in engineered B16 tumor cells. Intratumoral or intravenous injection of a cocktail of siRNAs for c-myc, MDM2, and VEGF complexed with anti (Env)-protamine reduced the growth of envelope-expressing subcutaneous B16 tumors. An ErbB2 single-chain antibody, protamine fusion delivered siRNAs specifically into ErbB2-expressing cancer cells.

A polymeric cationic cyclodextrin carrier was developed by the incorporation of PEG, for shielding and Tf as targeting ligand, for systemic siRNA delivery [96]. In a murine model of metastatic Ewing's sarcoma, repeated systemic delivery of siRNA against the EWS-FLI1 translocation resulted in significantly reduction of tumor growth. The presence of Tf in the formulation was required for this therapeutic effect.

For antiangiogenic cancer treatment, ideally tumor sites should be in contact with the therapeutic antiangiogenic factors for an extended time period. Specific and extended production of the factors in all tumor sites goes beyond the possibility of pDNA delivery technologies that are currently available. However, the extended localized production of therapeutic factors, which are secreted into the systemic circulation and suppress the tumor neovascularization, has been demonstrated.

Systemic antiangiogenic siRNA therapy has also been attempted using targeted and shielded polyplexes. siRNA targeting VEGF receptor-2 was complexed with RGD peptide-PEG-PEI conjugates. These RGD peptides act as ligands for integrins over-expressed on the tumor neovasculature [106]. Repeated intravenous administration into tumor-bearing mice resulted in siRNA sequence-specific inhibition of tumor growth by more than 90% compared to the control siRNA.

15.7.3 TARGETED DELIVERY OF OTHER THERAPEUTIC NUCLEIC ACIDS

Other therapeutic nucleic acids include antisense oligonucleotides, ribozymes, or aptamers. PEI polyplexes have been applied to stabilize RNA ribozymes against degradation [216]. After intraperitoneal injections in a mouse xenograft model, prolonged blood circulation and intact ribozymes in the distant tumor were obtained. PEI-complexed ribozymes targeted against the pleiotrophin growth factor resulted in intratumoral target gene knock-down and a distinct reduction of tumor growth.

Synthetic antiproliferative poly IC RNA, a strong activator of apoptosis and interferon response, was targeted to glioblastoma by PEI-PEG-EGF polyplexes [4]. Intratumoral delivery of EGF-targeted poly IC induced rapid apoptosis of the target cells and complete regression of intracranial tumors in nude mice, without opposing toxicity on normal brain tissue. To achieve this effect, the incorporation of endosomal releasing agents such as melittin in the polyplexes was required. Expression of several cytokines and "bystander killing" of untransfected tumor cells was found out *in vitro* and *in vivo*. Similarly, delivery of poly IC completely eliminated EGF-receptor over-expressing breast cancer and adenocarcinoma

xenografts. The best effects were obtained with formulations using a novel carrier combining all delivery functions in one polymer conjugate, i.e., melittin-PEI-PEG-EGF.

15.8 CONCLUSION

Since the design of the first targeted polyplexes [1] 20 years ago the field has progressed steadily. Lessons have been learnt on the type of targeting ligands and polymers that can be successfully used. Knowledge on the extracellular and intracellular barriers greatly increased. Polyplexes have been developed into products that have been tested in clinical gene therapy trials *ex vivo* [217] and *in vivo* [201]. Systemic targeting of pDNA and siRNA polyplexes has been demonstrated in several animal models. Understanding the barriers has resulted in the design of the next generation of bioresponsive polyplexes (synthetic viruses) which hopefully will combine the effectiveness of natural viruses with the safety of synthetic pharmaceutical products.

16.1 INTRODUCTION

Electroporation (EP), electrotransfer, or electrokinetic delivery is a technique to introduce nucleic acids and other macromolecules into cells both *in vitro* and *in vivo*, using conditions that induce transient cellular membrane permeabilization. Within the last decade, EP has evolved from an experimental technique derived from *in vitro* applications [1] to a robust preclinical and clinical delivery method; this physical method for *in vivo* non-viral gene therapy is currently used in laboratory animals, large mammals, and human clinical trials [2,3].

EP can be applied to deliver a multitude of macromolecules, from drugs with poor systemic bioavailability, such as bleomycin [4,5] or cisplatin [6], to nucleic acid fragments, oligonucleotides [7], siRNA [8], and plasmids encoding hormones, cytokines, enzymes, or antigens to a wide variety of tissues, such as solid tumors, muscle, in particular skeletal muscle, skin, and liver. Indeed, most EP applications involve delivery of plasmids to different organs and tissues (selected studies are summarized in the following Tables). As with the EP technique itself, plasmids evolved from being a substitute for more-or-less successful viral therapies to attractive candidates for development of clinically relevant products. Advantages of plasmids include simplicity of design, structure, rapid molecular biology manipulation of relevant components, and relative ease of manufacturing under good manufacturing practices (GMP) [9]. The classic disadvantage, low expression level *in vivo*, was resolved by the optimization of EP and other physical methods of delivery adapted to individual applications,

such as the hydrodynamic or ultrasound methods [10]. In this chapter, we focus on the clinical developments of this technique that occurred within the last 3 years.

16.2 MECHANISTIC STUDIES OF ELECTROPORATION

A number of investigators focused on the mechanisms of DNA entry into cells [11], and in particular of DNA behavior and distribution after EP, both at cellular and tissue level, keeping in mind that as a prerequisite to a successful EP, reversible undamaging target cell permeabilization is mandatory [12]. The general mechanistic hypothesis is that during EP transient pores are formed as a function of the transmembrane voltage; during the period of membrane destabilization, macromolecules present in the immediate extracellular medium around target cells can gain access into the intracellular space [13]. It has been hypothesized that when an electromagnetic potential is applied to the cells, firstly, the cell membrane is charging, followed by the creation of pores, and ultimately by the evolution of pore radii. The transmembrane potential, number of pores, and distribution of pore radii were shown to be a function of time and position on the cell surface [14]. Fundamental studies showed that permeabilization of cells occurs only if the local electrical field at the target site reaches a critical value [15,16], typically higher than 200mV. After the EP pulses are completed, a slow resealing occurs in seconds to minutes. Nevertheless, some changes in the membrane properties and decrease in tissue impedance may be measured and remain

present for hours [17,18]. It is thus no surprise that the degree of permeabilization of cells is dependent upon the electric field intensity, specific impedance of the target tissue, length and number of pulses, shape, size, architecture and type of electrodes, buffer formulation, and cell size [19]. The entry of DNA and other macromolecules into cells is still debated. It was hypothesized as either an electrophoretic facilitation during pulses, with DNA molecules reoriented and drawn toward the anode (similarly to *in vitro* EP) [12], or passive diffusion of DNA through the permeabilized membrane defect [16]. As the authors point out, an interesting implication for this latest mechanism would be the ability to transfer neutral particles, such as PEGylated compounds, by EP.

Despite the large variation in EP conditions used for the target tissue or organ [2], the expression achieved in many of these cases represents efficacious levels of gene products, some of which are within the range that is necessary to treat human diseases or to induce a robust immune response. In studies of the electric field-mediated enhancement of gene and drug delivery, different types of electrodes have been used. These include clamp, caliper [20] or four-plated electrodes [21], tweezers [22],

paddles [23], needle arrays [24], electrode-reservoir devices [25], flexible electrode arrays which may be used with endoscopic and laparoscopic devices [26], as well as bathtub-type electrodes for internal organs, such as kidney [27]. While in rodent experiments, external electrodes are prevalent, in large mammals, including humans, the electrode design must be adapted to the application, organ, and animal species.

16.3 TISSUE-SPECIFIC EXPRESSION

16.3.1 SKELETAL MUSCLE

Since the initial report by Aihara and Miyazaki [28], delivering a plasmid encoding for interleukin-5 (IL-5) to mice, *in vivo* EP of the skeletal muscle for vaccines and therapeutic proteins has become widely used. Table 16.1 summarizes some of the recent proof-of-concept literature reports in which EP were used to enhance plasmid delivery to skeletal muscle using reporter plasmids. Although the devices, conditions, methods, and animal models substantially differ, all studies

TABLE 16.1
Electroporation of Macromolecules into Muscle for Proof of Concept Reporter Gene Studies

Plasmid Product or Drug	Muscle Type	Species	Endpoints	References
Luciferase	Muscle and liver	Wistar rats	Controlled EP pulses yield higher luciferase expression	[12]
GFP (green fluorescent protein)	FDB (flexor digitorum brevis), soleus, TA (tibialis anterior), extensor digitorum muscles	C57Bl/6 mice	Testing of a mammalian protein expression system	[60]
Luciferase	Muscle and skin	Mice	Expression is reduced when reporter plasmid is mixed with Ca ²⁺ ions	[61]
SEAP (secreted embryonic alkaline phosphatase), luciferase, mouse IgG, β -gal (β -galactosidase)	Quadriceps and TA muscles	Mice, rats	Optimal EP parameters for long-term expression versus DNA vaccination	[62]
JNK	Muscle	Mice	JNK over-expression affected the phosphorylation state of kinases in skeletal muscle	[63]
GFP, blue fluorescent protein (BFP), β -gal	EDL (extensor digitorum longum)	NMRI mice	Gene expression after co-injection of reporter plasmids	[64]
GFP	Tibialis cranialis (TC) and EDL	C57Bl/6 mice & Wistar rats	Gene expression, muscle performance, and histology of injected muscles	[65]
GFP, luciferase, erythropoietin (EPO)	Tc	C57bl/6 mice	Hemoglobin levels with regulatable promoter	[66]
GFP, luciferase, nNOS	Bladder muscle	Rats	EP conditions for nNOS immunoreactivity and NO release	[67]
SEAP	TA muscle, semimembranosus	Mice, pigs	Serum SEAP levels with various EP conditions	[24]
Luciferase	Muscle	Zebrafish, Indian carp	Promoter strength, EP parameters affect gene expression	[68]
p53	Muscle	C57bl/6 mice	Transfection efficiency of ultrasound versus EP in muscle	[69]
β -gal and myostatin shRNA	TA muscle	Rats	Myostatin mRNA and protein expression and muscle mass	[70]
β -gal, dystrophin, utrophin	Muscle	mdx mice, immune deficient	Transfection efficiency, muscle fiber damage, duration of expression	[31]
Luciferase, GFP, Muscarinic-3 receptor	Bladder	Rats	M3 immunohistochemistry, bladder muscle contractile responses	[71]

TABLE 16.1 (continued)

Electroporation of Macromolecules into Muscle for Proof of Concept Reporter Gene Studies

Plasmid Product or Drug	Muscle Type	Species	Endpoints	References
GFP, luciferase	TA muscle	Balb/c mice, S-D rats	Satellite cell activation, gene expression in muscle cell types	[72]
IL-4, GFP, insulin-like growth factor I (IGF-I)	TA muscle	C57Bl/10 mice	Gene expression, muscle damage following EP, muscle fiber contractility	[73]
β -gal	Muscle	NIH Swiss mice	Effects of intra-arterial versus IM injection, electrode geometry, and DNA vehicle on gene expression	[74]
SEAP or EGFP-expressing Plasmids	TA muscle or gastrocnemius	C57/B16 Mice	Induction of anti-SEAP antibodies, Optimization of EP parameters	[59]
Influenza Hemagglutinin, Neuraminidase and SEAP	Muscle	Pigs	Dependent on target muscle, formulation and current intensity SEAP expression, hemagglutination inhibition titers, histopathology on muscle biopsy samples	

conclude that plasmid injection followed by EP substantially enhances plasmid uptake over injection alone by two to three orders of magnitude, and that the method can be successfully used to deliver nucleic acids for preclinical and clinical applications. As myofibers are postmitotic, multinucleated cells, and muscles are physiologically very well vascularized and accessible for treatment, this organ can be used as a bioreactor for the persistent production and secretion of proteins into the blood stream. Similar to nucleic acid injection alone, the relative level of production would depend on the type of muscle (predominately slow [type I], such as soleus, or the fast

[type II], such as the gastrocnemius–plantaris complex in mice) [29] that impacts transcription [30] as well as fat and fiber content, age and species [24,31].

The applications of intramuscular EP-mediated gene transfer cover a large spectrum of diseases: vaccination (Table 16.2), and therapeutic applications, including autoimmune diseases, including diabetes, malignancies, renal disease, anemia, endocrine dysfunctions (Table 16.3), prevention of drug toxicity, etc. In the case of plasmid encoding non-immunogenic species-specific transgene products, the duration of gene expression, and clinically relevant levels of therapeutic proteins,

FIGURE 16.1 (See color insert following blank page 206.) Graphic representation of the delivery of macromolecules by direct injection followed by electroporation to the skeletal muscle for vaccination purposes. First, (A) the DNA vaccine is administered into skeletal muscle; (B) application of an electric field (electroporation); (C) contact of the expressed antigens with dendritic cells (DC) and subsequent activation; (D) activated DCs presenting antigens to B cells (B) and antigen fragments to T cells (T); (E) activated T-cells presenting antigens to B cells, activation of principal components (PC) for the generation of an immune response to the expressed antigen.

such as erythropoietin or growth hormone releasing hormone, was reported to be at least 9 to 15 months longer in species such as dogs [32], nonhuman primates [18], or cattle [33] compared to rodents [13]. For vaccination applications, strong humoral and cellular responses have been described after nucleic acid delivery by EP in nonhuman primates [34] and other models, sometimes after one single vaccination [35], for both infectious diseases, and genetic immunization [36]. A schematic representation of EP for vaccination purposes is provided in Figure 16.1. Collectively, these studies provide the evidence that adequate levels of secreted proteins can be achieved using plasmids in a simple, safe, and efficient manner, with significant potential for gene transfer and vaccination for large animals and humans.

16.3.2 LIVER

The liver represents a primary target for gene therapeutic treatment of many metabolic diseases, cancers, hepatitis, and other pathologies. Recombinant viral vectors are by far prevalently used to introduce genes into the liver, despite concerns about their safety and potential adverse effects. Another physical delivery technique, the hydrodynamic method, which involves delivery of plasmids or siRNA [37,38] in relatively large volumes, to the hepatic vasculature, gained popularity lately. Electroporation constitutes now an alternative method to deliver transgenes to the liver, mostly for modeling and basic studies concerning EP (Table 16.4), as well as functional identification of regulatory elements in gene sequences [39].

Luciferase, β -gal	Liver	ddy mice	Electroporation of the liver following IV administered naked plasmid DNA resulted in 100-fold higher expression	[122]

The technique is also performed in conjunction with chemotherapy for different malignancies, as electrochemotherapy [40]; interestingly, tumor ablation has been achieved by locally delivering high intensity electric fields. These advances in liver gene delivery may provide powerful tools for basic research or potential clinical application studies.

16.3.3 SKIN

In the last few years, DNA delivery to skin has emerged as a major site for EP-mediated gene transfer applications requiring local or systemic distribution of a transgene product, and in particular for DNA vaccination [41,42] (Table 16.5). The intradermic (ID) space can be limited as a target organ because the volume of formulation that can be delivered is small. A small volume adapted for the ID or subcutaneous injections is translated in comparatively small plasmid doses that can be used in IM injections. Nevertheless, as a frontline of the host's defense against pathogens, skin is well equipped for immune surveillance [43], and nucleic acid doses that can elicit an immune response are much lower than doses needed to ensure a long-term production of a therapeutic protein. Electroporation of skin induces a mild and reversible impairment of the barrier function of the skin, a decrease in skin resistance, and a transient decrease in blood flow. Neither severe inflammation nor necroses are generally observed [44]. Because of surface access, skin EP is relatively painless and can be used for prophylactic vaccination [45,46]. EP has been used to enhance the

transdermal delivery of drugs, such as methotrexate [47]. After direct plasmid injection into skin, transfected cells are typically restricted to the epidermis. However, when EP is applied after the injection, larger numbers of adipocytes, fibroblasts, and dendritic-like cells within the dermal and subdermal tissues, as well as lymph nodes draining electropermeabilized sites, are transfected [48]. While mostly used as a target for vaccination purposes, an example of therapeutic use is the delivery of a keratinocyte growth factor expressing plasmid to the skin was shown to improve wound healing in a mouse model [49]. Gene therapy to enhance wound healing is a rapidly evolving field with several techniques being investigated including EP [50]. Further research is ongoing to improve the delivery of DNA using novel surface electrodes [21] to improve transfection efficiency while decreasing tissue damage. Transdermal drug delivery is another potential application for skin EP, if safety, efficacy, cost-effectiveness can be demonstrated [51].

16.3.4 TUMORS

Electroporation continues to be used as an anticancer treatment, though there are both successes and setbacks in this field [2,52]. Electrochemotherapy or enhanced delivery of chemotherapeutic drugs, especially bleomycin or cisplatin [53], to solid tumors has been used successfully for many years. Melanoma and metastatic melanoma, head and neck squamous cell carcinomas, and basal cell carcinoma are among the most studied tumor

models [54] using electrochemotherapy. Ablation of cancer cells using physical properties of EP has also been demonstrated [55]. Clinical trials using this method for the treatment of solid tumors have been conducted in humans and other species. Recently, investigators focused on plasmid delivery to tumors as a means to increase long-term antitumor immunity [56] successfully, to inhibit angiogenesis or to reduce tumor

volume. Table 16.6 contains reports pertaining to direct EP of the tumor either as a physical disruption method to induce apoptosis or to increase uptake of chemotherapeutic agents in tumor cells. Studies that use EP to improve efficacy of plasmid vectors and other nucleic acids are depicted in Table 16.7. Delivering these compounds using highly effective EP methods may form the basis for future human applications.

16.3.5 OTHERS: EYE, LUNG, CARDIAC MUSCLE, VASCULAR SMOOTH MUSCLE, AND TESTES

Studies examining transfection of various cell types in the eye using EP are summarized in Table 16.8. Recently, electric pulse-mediated plasmid transfer has been used to deliver transgenes to cornea in an effort to ensure long-lasting expression of a desired protein either for treatment of a local disease or for research purposes. Results of these studies demonstrate that EP is an excellent method for delivering genes to multiple cell layers within the cornea with extremely high levels of gene expression and little, if any, inflammatory response or tissue damage. Retinal ganglion cells also have been targeted. After a first demonstration showing retrograde labeling of up to 41% of the total ganglion cells in the electroinjected area, other studies with BDNF gene transferred by *in vivo* EP showed protection of axotomized retinal ganglion cells against apoptosis.

Investigators have also demonstrated the potential application of plasmid EP in many other tissues including the lung, heart, vascular smooth muscle (as previously reviewed by Dean [57]), and testes (Table 16.9).

16.4 SUMMARY AND FUTURE DIRECTIONS

Electroporation has moved from numerous animal experiments to use in on-going human clinical trials, as previously reviewed [2]. Furthermore, the field of EP is rapidly evolving to overcome the early questions of pain associated with the procedure, feasibility, and efficacy of the procedure in humans to deliver chemotherapeutic drugs, DNA vaccines, siRNA, and therapeutic plasmids to multiple organs of the body. Recent developments in the field of EP involve fundamental and pre-clinical studies using devices and techniques that are capable of controlling the pulse pattern, time between the pulses, their length, duration, electric field intensity and spatial distribution,

Rat EPO	Testes	S-D rats	Testicular weight, numbers of spermatids, and sperm	[192]

and various other parameters. The number, shape, nature, and relative placement of electrodes to the target organ are also intensely studied in numerous animal models [58]. Tissue damage that has been previously associated with EP can be minimized by optimization of conditions, and has been shown to be mild to moderate, and transitory at a series of electric field intensities and plasmid quantities [59]. These optimizations are/will be applied into human clinical trials. Only in the last 30 months, more than 300 articles have been published relating to *in vivo* EP and its applications. This progression indicates the acceptance of EP as a potential clinical technique.

Delivering nucleic acids and macromolecules into cells and tissue by physical techniques has been an impediment for years. The preclinical and clinical development of *in vivo* EP represents a quantum leap in this field. Although its exact mechanism remains elusive, this reliable and consistent method entered into human clinical trials in the last year. Preliminary results from these trials, presented at recent international meetings are demonstrating its usefulness and the potential of EP to transform nonviral therapies into a novel medical field.
