Instead of killing tumor cells, this strategy is aimed at preventing toxic side effects of modern chemotherapy, for example, by making normal cells resistant to chemotherapeutic toxicity. This approach tries to solve the problem that the cytotoxicity of chemotherapy cannot usually discriminate

between proliferating normal and cancer cells. Proliferating normal cells like hematopoietic precursor cells are especially affected, as evidenced by the fact that bone marrow suppression is still dose-limiting in most high-dose courses of chemotherapy. To overcome this limitation, different experimental approaches have been developed. One strategy to make hematopoietic precursor cells resistant to chemotherapy is the direct gene transfer of drug resistance genes like transporters that extrude drugs across the plasma membrane. These include the multiple drug resistance gene 1 (MDR1), the multiple drug resistance proteins (MRPs), or enzymes that render drugs resistant to alkylating agents such as glutathione-S-transferase and *O*⁶-alkylguanine DNA alkyltransferase or resistant to antimetabolites such as dihydrofolate reductase (DGFR) (Licht and Peschel 2002). The MDR1 gene encodes for the P-glycoprotein, a cell membrane multidrug transporter that effluxes a broad spectrum of hydrophobic and amphipathic compounds, including several chemotherapeutic drugs currently used in clinical studies (Gottesman et al. 1995). *Ex vivo* transfer and expression of the MDR1 gene in hematopoietic progenitor cells has been shown to increase the resistance of hematopoietic precursor cells to chemotherapy in rodent models (Mickisch et al. 1992; Podda et al. 1992; Sorrentino et al. 1992; Licht et al. 1995; Sorrentino et al. 1995). In the first several clinical trials, low level expression of the transferred gene was reported only occasionally. More recently, however, prompt hematopoietic recovery and long term *in vivo* vector expression was seen (Moscow et al. 1999; Abonour et al. 2000). We may see further clinical improvements if efficient transduction is achieved (especially of very immature cells) and drug selection strategies are further optimized. The encouraging report of *in vivo* correction of X-linked severe combined immunodeficiency (SCID) (Cavazzana-Calvo et al. 2000; Hacein-Bey-Abina 2002) with at least 17 out of 20 patients now benefiting from this life-saving gene therapy also indicates that transduction of human hematopoietic stem cells is now feasible (Cavazzana-Calvo and Fischer 2007). Clinical benefit may result, in particular, in situations where corrected cells have an *in vivo* selective advantage.

36.2.7 MARKER GENES

Six percent of all clinical gene therapy protocols use marker genes for several purposes (Rosenberg et al. 2000). Marker trials have confirmed the assumption that contamination of reinfused bone marrow with tumor cells causes tumor recurrence after autologous bone marrow transplantation (Rill et al. 1994). In other studies, hematopoietic stem cells or T-cells were marked and traced over a longer duration, providing important insights into their long-term survival.

36.3 VECTORS FOR CANCER GENE THERAPY

36.3.1 VIRUS-BASED GENE TRANSFER VECTORS

In this section, the various gene transfer vectors (e.g., adenovirus- and retrovirus-based vectors) will be discussed with respect to

their specific relevance for efficacy and toxicity in cancer gene therapy. For the general biology, development and design of the vectors, the reader is referred to the corresponding chapters in this textbook, which focus on particular vectors.

One of the most widely used vectors for *in vivo* application in cancer gene therapy is the replication-deficient recombinant adenovirus. First-generation adenoviral vectors (Ad vector) can be generated to the highest titers (up to 10^{12} /plaque forming [i.e., infectious] units/mL) among viral vectors (Wilson 1996). Moreover, they easily infect cells of epithelial origin including cancer cells, most likely because these cells express the appropriate receptors, the coxsackie adenovirus receptor (Bergelson et al. 1997) and integrins (Wickham et al. 1993) for binding and internalization, respectively. Since Ad vectors infect dividing and nondividing cells, dormant tumor cells, which can make up a considerable fraction of the tumor mass, can also be killed. These properties have made first-generation adenoviruses one of the vectors of choice for clinical studies targeting cancer. Of the 1280 clinical gene therapy protocols initiated to date, 326 (24.9%) use Ad vectors, the majority of those for cancer treatment. Commonly, serotype C adenoviruses are used but the discovery of CD46 as the cellular receptor for serotype B adenoviruses has made these vectors promising alternatives (Gaggar et al. 2003). Ad vector-mediated gene transfer can be accompanied by toxic side effects on normal tissue mainly due to residual adenoviral gene expression in occasionally transduced normal cells (Nevins 1981; Spergel and Chen-Kiang 1991; Yang et al. 1994; Lieber et al. 1997; Amalfitano et al. 1998; Brand et al. 1999). This toxicity can be reduced using Ad vectors of the second generation where adenoviral genes such as the E4 region or the E2a gene are deleted (Wang et al. 1995; Bramson et al. 1996; Gao et al. 1996; Wang and Finer 1996; Wilson 1996; Yeh et al. 1996) or helper-dependent (i.e., minimal or gutless) adenoviral vectors (HD-Ads), which are completely devoid of all viral genes (Haecker et al. 1996; Parks et al. 1996; Parks and Graham 1997). The side effects of first-generation Ad-vectors such as toxicity and immunity can be turned into a desired adjuvant situation for cancer therapy as demonstrated by the group of Rosenberg (Chen et al. 1996). However, in cancer gene therapy where vector toxicity to the tumor cells at the first glance may be desirable, this toxicity may be of disadvantage in some situations. For instance, leakage of intratumorally injected vectors carrying a prodrug-converting enzyme (suicide gene strategy) into the host organ has been shown to produce severe side effects (Brand et al. 1997). Regional and systemic application of vectors with the aim of targeting metastases will inevitably transduce normal tissue. Other anticancer strategies are even explicitly based on transduction of normal tissue for its use as a bioreactor as in the antiproteolytic impregnation concept, antiangiogenic, and some immunological approaches. Therefore, cancer gene therapy (like gene therapy of other diseases) will depend enormously on safer vectors. In addition to increased safety (Morsy et al. 1998), HD-Ads have some other advantages over first-generation vectors including an extremely high packaging capacity, which allows for a better adaptation to the tumor

cell's particularities, as well as the potential for long-term gene expression (e.g., Schiedner et al. 1998), apparently higher gene expression (Maione et al. 2000), and better retained tumor-specific gene expression (Shi et al. 2002). The two main disadvantages of HD-Ads have been contamination with helper virus and difficulties in obtaining high titer preparations. Helper contamination has been significantly improved and titers of up to 2×10^{11} bfu (blue forming units) are possible with modern techniques. HD-Ads have been tested in several preclinical models including cancer models (Rodicker et al. 2001) but no clinical trials have been conducted so far.

Another very popular vehicle for gene transfer, accounting for more than one-third of all trials and half of all patients treated, is retrovirus-based vectors. Most of these are derived from murine leukemia virus (MLV). Retroviral vectors were the first vectors for which all the viral genes were provided by vector producer cells (VPCs). The retroviruses themselves contain only the LTRs, the packaging signal, and the transgene. In the field of cancer therapy, these vectors have dominated trials utilizing *ex vivo* transfer of markers, drug resistance, and immunomodulatory genes. For *in vivo* gene transfer, the VPCs themselves were often directly applied into the tumors due to the initially low achievable titers of 10^6 /mL in the retroviral supernatant with the rationale that these VPCs will deliver retroviruses until they are eliminated by the immune system (Culver et al. 1992). As for adenoviral vectors, many animal studies were carried out, including *in vivo* gene transfer of retroVPCs or retroviral vectors into established tumors, and complete remissions of microscopic tumors have been reported (Culver et al. 1992). Current packaging cell lines give titers of greater than 10^7 infectious particles per mL (Cosset et al. 1995). Moreover, the use of different envelope proteins, such as the G protein from vesicular-stomatitis virus, has improved titers following concentration to greater than 10^9 /mL (Cosset et al. 1995), although these titers are still far below what is achievable with adenoviruses. Especially from a safety standpoint, their property of only infecting dividing cells may prevent toxicity to nondividing normal tissue. On the other hand, these vectors leave out dormant cancer cells, which may decrease their antitumor efficacy.

In contrast to MLV-based vectors, lentiviral retroviruses based on pseudotyped HIV-1 are able to infect nondividing cells (Blomer et al. 1996; Naldini et al. 1996a,b; Robbins et al. 1998), although there is some debate about whether hematopoietic stem cells should preferentially not be in G0 (Sutton et al. 1999) and whether hepatocytes are much more efficiently transduced *in vivo* if proliferating (Park et al. 2000; Follenzi et al. 2002; VandenDriessche et al. 2002). Lentiviral vectors may therefore be of interest for cancer gene therapeutic approaches, which rely on long-term transduction of noncancerous tissue for cancer therapy. Mainly due to (perhaps overestimated) safety concerns with respect to the generation of wild-type virus, only nine clinical trials have been initiated yet. However, the use for example, of apathogenic animal lentiviruses (Stitz et al. 2001; Kuate et al. 2002) may soon circumvent this concern.

Based on their tropism for neuronal tissues, HSVs are in principle highly suitable for neurological cancer therapy. In general, they can infect dividing and nondividing cells. Similar to adenoviruses, cytotoxic genes must be deleted from the viral genome and genes must be provided from helper viruses or cell lines in order to prevent unwanted toxicity if normal tissue is transduced. Successful attempts in this direction have been made (Fink et al. 1995; Marconi et al. 1996; Wu et al. 1996; Zhu et al. 1996; Fink and Glorioso 1997a,b). HSV has already been used in 43 clinical trials and the intratumoral injection mode at least did not cause severe toxicity (see Section 36.4.4 on Glioblastoma).

A fourth type of vector, which has become very interesting for gene therapy in general during the last years, is adeno-associated virus (AAV)-based vectors. These helper virus (e.g., adenovirus)-dependent vectors induce only a minor cellular immune response and have the potential to integrate into the host genome. Therefore, they are very promising candidate vectors when long-term expression is required (for instance, for the protection of hematopoietic precursor cells during high-dose chemotherapy). With respect to clinical trials, AAV are fairly advanced. Forty-eight trials have already been initiated, most of them, however, for noncancerous disease. For the general biology of AAV-based gene transfer vectors, please refer to *Gene and Cell Therapy* (chapter 6).

The poxviruses fowlpox virus and vaccinia virus infect a wide variety of cells types. In addition, they are safe and have a high packaging capacity (Scheifflinger et al. 1992). Due to their high intrinsic immunogenicity, they have mainly been used as an adjuvant and transfer vehicle for immunogene therapy of cancer. An impressive number of 125 clinical studies using pox virus have been initiated.

In addition, several other viruses have been used for the transfer of genes into cancer cells. They usually have some interesting features but also bring certain disadvantages, which have so far prevented widespread use. EBV viruses have a natural tropism for B-cells, but the potential development of wild-type transforming viruses by homologous recombination raises a safety concern. Baculoviruses are insect viruses and cannot replicate in human cells but they have been shown to efficiently infect a variety of human cell lines (Hofmann et al. 1995; Sandig et al. 1996). However, the human complement system rapidly inactivates these vectors such that extensive modification of the cell surface is required (Sandig et al. 1996; Hofmann and Strauss 1998; Huser et al. 2001) to improve gene transfer *in vivo*. Alpha viruses like sindbis virus (Xiong et al. 1989) and Semliki-forest-virus (Berglund et al. 1993) can efficiently multiply their RNA genome in target cells, allowing for very high transgene expression. Further improvements in their packaging systems could make these vectors very interesting agents for the future, especially for gene delivery to the brain, antitumor therapy by induction of apoptosis, or intratumoral replication and immunogene transfer (Lundstrom 2001).

Autonomous parvoviral vectors (Maxwell et al. 1996) such as HI, MVM, and L1II can only replicate during the S-phase of the host cell and have been used as replication-competent

viruses for cancer gene therapy *in vitro* or in preclinical settings. Other viruses which have been evaluated for gene therapy include NDV, reovirus, poliovirus, and vesicular stomatitis virus (Wildner 2001).

Chimeric vectors, which are constructed by the use of two or more viruses, may have the advantages and disadvantages of both vectors. To date, several types of hybrid vectors have been published including first-generation adenovirus/AAV (Herz and Gerard 1993; Fisher et al. 1996; Liu et al. 1999), HD-Ad/AAV (Goncalves et al. 2002; Shayakhmetov et al. 2002) HD-Ad/transposon (Yant et al. 2002), HD-Ad/retrotransposon (Soifer et al. 2001) and first-generation adenovirus/retrovirus (Feng et al. 1997; Caplen et al. 1999; Roberts et al. 2002). These chimeras were evaluated mainly to combine the high efficacy of gene transfer with the long duration of gene expression; to facilitate AAV production; and to overcome the limited cloning capacity of AAV. HSV/AAV (Johnston et al. 1997; Heister et al. 2002) chimeras or baculovirus/AAV chimeras (Palombo et al. 1998) were constructed to combine cell specificity with stable gene expression.

With respect to long-term safety of viral vectors, occasional reports of possible oncogenicity have been described in animals for AAV (Donsante et al. 2001). Due to the development of therapy-associated leukemias, most likely due to insertional oncogenesis, safety concerns are higher for MLV-derived retroviruses (Li et al. 2002). Three cases of leukemia occurred in a trial for SCID that was very successful to that point (Hacein-Bey-Abina et al. 2003). A careful case-by-case risk-benefit analysis is clearly required (Buchholz and Cichutek 2006). Oncogenicity has not been a major concern for adenoviruses, which, however, can integrate at a low rate as well (Hillgenberg et al. 2001; Mitani and Kubo 2002).

Gene silencing as a reason for limited duration of gene expression despite vector integration has been described extensively for retrovirus and also for AAV (Chen et al. 1997) but inclusion of matrix attachment regions (MAR) or scaffold attachment regions (SAR) can improve the problem (Agarwal et al. 1998).

In summary, it seems that with respect to viral vectors it is possible to exploit nature's evolutionary achievements to our benefit and even to deviate markedly from nature's path without deleterious consequences. It is sometimes quite mysterious that even dramatic modifications of viral genomes still give viable and effective vectors. Since it seems that there is a workaround for nearly every problem, as long as time and money are provided, one can be confident that the vector problem, still the main issue in gene therapy, can be solved as long as the target diseases justify the effort and alternative ways of treatment are not provided.

36.3.2 NONVIRUS-BASED GENE TRANSFER VECTORS

In general, nonviral vector systems have some advantages over viral systems. They are less toxic, less immunogenic, and easier to prepare. On the other hand, they have a much lower

efficacy of gene transfer, particularly *in vivo*, and a more limited duration of gene expression than several viral vectors. Roughly 30% of clinical trials have utilized nonviral vectors. Two-thirds of these used naked DNA plasmids and one-third cationic liposomes, which are probably the most important nonviral vectors to date. Attempts to increase efficacy of gene transfer with cationic lipids and polymers will have to target three major barriers: stability during and after the manufacturing process, extracellular barriers, and intracellular barriers. An important step in improving extracellular stability of positively charged liposomes and polymers (which have a tendency to aggregate and precipitate) was the inclusion of hydrophilic polymers like polyethylene glycol (PEG). This provides steric stabilization. PEGylation seems also to reduce interactions of cationic particles with blood components such as albumine, which present major extracellular barriers to nonviral gene transfer. Modifications to decrease unwanted preferential uptake of liposomes by the reticulo endothelial system include the addition of sialic acid to make "stealth" liposomes (Lasic et al. 1991). The most challenging and perhaps most rewarding task will be the elucidation of intracellular barriers to nonviral gene delivery. Cationic DNA complexes bind to the negatively charged cell membrane and are taken up by endocytosis. As for viral vectors, targeting by addition of ligands for cellular receptors has been used to circumvent extracellular barriers. For example, transferrin is a common ligand used to target tumor cells (Kircheis et al. 2001; Mao et al. 2001). Endocytosed DNA is largely retained in the endosomal compartment and it is important that endosomal release is completed before lysosomal degradation initiates. Fusogenic lipids like Dioleoylphosphatidylethanolamine (DOPE), fusogenic peptides from viral vectors (Wagner 1999), or substances with high buffering capacity (which in addition can swell like polyethylenimine [PEI]) have been used to release DNA from endosomes. After vesicle escape, the nucleic acid must traffic to the nucleus. DNA is not very stable in the cytoplasm, which may be due to the presence of cytoplasmic nucleases. It is therefore particularly important to define the optimal time point to release DNA from protection by the endosome or from coverage from vector after endosomal release. Recently, nuclease inhibitors have shown to improve naked DNA-mediated gene transfer (Walther et al. 2005). Once the vector arrives at the nucleus, another hurdle has to be overcome since nuclear entry of DNAs larger than 250bp is hardly possible. A promising attempt to circumvent this problem is the inclusion of nuclear localization signals (NLS, Kaneda et al. 1989; Dean 1997).

Naked DNA is most interesting for immunological approaches in which efficacy of gene transfer is not the most crucial criterion. Interestingly, skeletal muscle cells are fairly susceptible to transfection with directly injected plasmid DNA. However, in mice, systemic application of naked DNA has led to astonishing high rates of gene transfer in mice if administered systemically in extremely high volumes and with generation of high pressure in target organs (Budker et al. 1996, 1998). Transient membrane defects are probably the mechanism how naked DNA enters the cells by this hydrodynamic method (Zhang et al. 2004).

In addition to liposomes and naked DNA, cationic polymers (e.g., linear PEI, LPEI) have gained attention during recent years although no clinical trials yet exist. Other modalities include electroporation (limited spatial distribution *in vivo*), ultrasound-facilitated gene transfer, and particle bombardment (Yang et al. 1990; Burkholder et al. 1993; Cheng et al. 1993; Gao et al. 2007). In this latter technique, 1–3 μm small gold or tungsten particles are covered with plasmid DNA accelerated in an electrical field and fired onto the target tissue. Due to a depth of penetration of up to 50 cell layers, this approach has been applied for vaccination into uninvolved skin of melanoma patients (Cassaday et al. 2007).

36.3.3 TRANSGENE

A gene therapeutic expression cassette consists of the regulatory elements, the transgene, and the poly A signal. The transgene is usually a wild-type cDNA but other structures are possible. Among these are mutated transgenes, such as dominant negative oncogenes to inhibit oncogenes, or mutated cDNAs, which lead to other defects favorable for cancer gene therapy. The availability of high-capacity vectors like HD-Ad or HSV has allowed the inclusion of full-length genes including introns and other features, which may eventually be as interesting for cancer gene therapy as they already are for the treatment of monogenetic disease. Finally, recent developments of small double-stranded DNA oligonucleotides, which apparently can interfere with RNA, may dramatically influence cancer gene therapy. These oligonucleotides have already been included in viral vectors and antitumor efficacy has been reported after *ex vivo* gene transfer (Brummelkamp et al. 2002).

36.3.4 CANCER-SPECIFIC GENE EXPRESSION (TRANSCRIPTIONAL TARGETING)

If one wants to exploit differences between tumor and normal tissue for tumor therapy, tumor-specific gene expression is a particularly rewarding area. Transcriptional targeting restricts gene expression to the target tissue even if undesired tissues have been transduced as well, thereby providing a significant improvement in safety. Tumor-specific promoters are only active in those target tissues naturally expressing their respective tumor-specific endogenous genes. If one engineers an expression cassette in which any therapeutic gene is placed behind that tumor-specific promoter, it will, due to its promiscuous nature, express this transgene in a tumor-specific fashion as well. A huge variety of tumor-specific promoters have been examined during the last years for their use in gene therapy. This is basically because every tumor type has its own more or less tumor-specific genes. Tumor-specific gene expression can obviously only be as specific as the degree of differential gene expression of the respective endogenous gene. Therefore, it has certain limitations. In other words, residual gene expression in undesired tissues is frequently observed. Among the promoters used are tissue-specific promoters, which will also be active in the corresponding normal tissues, and proliferation-specific promoters, which will be

active in proliferating nonmalignant tissue. In addition, the expression levels are often only gradually higher in the tumor than in the normal tissue. One must carefully examine how these gradual differences translate into the therapeutic situation.

Tumor-specific promoters are particularly interesting in the situation of metastatic cancer where the tissue-specific promoter allows transgene expression in the metastatic tumor cell but not in the surrounding normal tissue, even if it is transduced by the vector. For instance, the carcinoembryonic antigen (CEA), which is physiologically expressed predominantly in colon tissue but not in liver tissue, allows transgene expression predominantly in colon cancer cells metastatic to the liver. Toxicity to the liver seen with the ubiquitous CMV promoter that expresses a suicide gene (Brand et al. 1997; van der Eb et al. 1998) can be prevented if the CEA promoter is used instead (Brand et al. 1998). Other examples of such a promoter strategy include the alpha-feto-protein (AFP) promoter for hepatocellular carcinoma (HCC); the promoters of *erbB2*, an oncogene often found in breast tumors; the PSA; or the promoter of the tyrosinase gene, which has specificity for melanoma.

However, the maintenance of tissue specificity can be a problem after inclusion into a vector. For adenoviral vectors, loss as well as maintenance of tissue specificity has been reported (Chen et al. 1995; Connelly et al. 1996; Imler et al. 1996; Sandig et al. 1996; Siders et al. 1996; Tanaka et al. 1997; Brand et al. 1998). In this context, the orientation of the expression cassette can play an important role. For instance, the transcriptional activity of the E1A enhancer, which is not deleted in E1-deficient first-generation adenoviruses can induce loss of tissue specificity. This type of promoter interference can even stem from regions located downstream from the expression cassette (Steinwaerder and Lieber 2000). This can even occur if the expression cassette is inserted in the reverse orientation to the main adenoviral reading frame (own observations). To circumvent this problem, an insulator element derived from the chicken gamma-globin locus (HS-4) was employed to shield an inducible promoter from viral enhancers. Induction ratios could be improved up to 40-fold as compared to vectors with an uninsulated promoter (Steinwaerder and Lieber 2000). In a similar approach, transcriptional terminators have been implemented to restrict read-through of the E1A enhancer (Buvoli et al. 2002). Finally, insertion of a specific promoter at a site distant from the E1A enhancer (e.g., close to the right ITR) has retained higher specificity and lower background (Rubinchik et al. 2001).

In contrast to first-generation adenovirus, HD-Ads seem to allow full maintenance of promoter specificity. This has recently been demonstrated for the PSA and the tyrosinase promoters (Shi et al. 2002).

Also in contrast to first-generation adenovirus, insertion of expression cassettes in reverse orientation into retroviral vectors normally maintains tissue specificity. Orientation in frame, however, puts the transgene under the influence of the strong retroviral LTR with subsequent loss of specificity (Wu et al. 1996). Alternatively, self-inactivating (SIN) vectors,

which do not possess any promoter on the 3' or 5' end of their genome after integration into the host cell genome (Yu et al. 1986), can be used. The LTR can also be replaced by the tissue-specific promoter. The problems of tissue-specific expression seen in adenovirus or retrovirus vectors do not seem to occur in AAV vectors (Su et al. 1996; Zhou et al. 1996). This is probably because the flanking ITRs possess no regulative activity. Recently, maintenance of tissue-specific expression was reported for the PSA promoter in a lentiviral vector (Wu et al. 2001).

A major problem with tumor-specific promoters, whose specificity may be satisfying, can be insufficient promoter strength. An ingenious strategy to compensate for the weakness of tumor-specific promoters has been made possible through the introduction of the CRE lox system into the concept of transcriptional targeting. On one of the constructs, the tumor-specific promoter regulates the expression of the CRE recombinase. This enzyme then recognizes loxP sites (on a second construct), which flank a spacer region separating a strong viral promoter and a therapeutic transgene. Cleavage of the loxP sites excises the spacer, thereby inducing transcription of the transgene. Expression of the transgene with this system is supposed to be higher than with simple tumor-specific expression because the stability of the CRE enzyme will amplify the tumor-specific effect. The utility of this system has been proven using the AFP promoter *in vitro* (Sakai et al. 2001) and the CEA promoter *in vivo* (Kijima et al. 1999). Other strategies to compensate for promoter weakness have used transcriptional transactivators under tissue-specific control, which then have activated a minimal promoter for transgene expression (Koch et al. 2001; Qiao et al. 2002; Zhang et al. 2002). So far, all these systems have used two types of adenoviruses for either promoter/transgene construct. However, incorporation of both expression cassettes on one vector should be possible.

As in other fields of gene therapy, the packaging size of the vector to be used for gene transfer is one of the most important limitations for the construction of cancer-specific expression cassettes. So far, vectorologists have mainly worked with the intron-free cDNA coding for the transgene. Recently, the availability of vectors with substantially increased packaging capacity, such as HD adenoviruses, has allowed the inclusion of whole minigenes into a viral vector (Mitani et al. 1995; Fisher et al. 1996; Kochanek et al. 1996; Parks et al. 1996). This provides the necessary space for longer and potentially even more specific regulatory elements.

In contrast to constitutive promoters, tumor specificity in patients who are resistant to chemotherapy could be mediated by therapy-inducible promoters. In this respect, the examination of gene regulation mechanisms in cancer cells like the multidrug resistance gene (MDR1), the X-irradiation-induced tissue-type plasminogen activator (t-PA), the early growth response gene (Egr-1), the human heat shock protein HSP 70, or the glucose-regulated protein (GRP78) led to the discovery of a class of promoter sequences that are involved in such stress responses. These promoters carry responsive elements that are inducible either by radiotherapy, cytostatic drugs, or

hyperthermia (all conventional treatment modalities). It has already been shown that the expression of therapeutic genes could be enhanced and the efficacy increased if placed under the control of therapy-inducible promoters (Joki et al. 1995). The combination of therapeutic genes under the control of therapy-inducible promoters used with conventional cancer treatment methods could enhance overall treatment efficacy and also retain specificity.

36.3.5 TARGETED VECTORS (TRANSDUCTIONAL TARGETING)

Currently, the predominantly used viral vectors for gene transfer can infect a broad variety of target cells and tissues. Although this is of interest for cell type-independent gene expression, it is a disadvantage when tissue-specific gene expression is required as in cancer gene therapy. Therefore, the surface of the vector needs to be modified to infect the cancer cell in a more specific manner (retargeting).

Several approaches have been developed to redirect the tropism of adenoviral vectors in favor of cancer cells. The efficacy of binding to the surface of a given target cell by an adenovirus depends on the presence of specific receptors like the coxsackie and adenovirus receptor (CAR) and to a lesser extent the alpha2 domain of MHC class I on the cell surface, which interact with the adenoviral fiber knob protein (Wickham et al. 1993; Bergelson et al. 1997; Hong et al. 1997; Tomko et al. 1997). After binding, the adenovirus is internalized through clathrin-coated pits. This process is mediated through an interaction between RGD motifs on adenoviral penton base protein loops and integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$. Two major strategies have been used to redirect adenoviral infection: conjugate-based strategies and genetic targeting strategies. Conjugate-based strategies include bispecific recombinant proteins, peptides, or chemical conjugates to redirect adenoviral infection. Examples include bispecific conjugates consisting of the Fab fragment of a neutralizing antiknob monoclonal antibody covalently linked to folate (Douglas et al. 1996; Wickham et al. 1996; Goldman et al. 1997); polymer-mediated ligand coupling to adenoviral capsid, or avidin bridging between biotinylated adenovirus; and biotinylated potential ligands for cellular receptors. Increases of 100-fold and more in infectability have been described in several *in vitro* studies as compared to wild-type adenovirus. The best results reported so far for *in vivo* systemic vascular delivery of two-component targeted vectors were obtained using adenovirus with bispecific antibodies. These blocked the CAR-binding domain and redirected the vector either to FGF receptors on tumor cells, which led to substantially increased survival using the HSV tk/GCV approach (Gu et al. 1999) or to angiotensin-converting enzyme on pulmonary capillary epithelium, which enhanced gene transfer to the lung at least 20-fold. The same group has recently initiated the first clinical study using retargeted adenoviruses for the treatment of cancer with a suicide gene approach (Barnett et al. 2002).

Conjugate-based approaches have two main advantages: the wide range of cellular receptors, which can be targeted

and the fact that there is no need to make structural changes to the adenovirus itself. The disadvantages of the system include the larger size and irregular shape of the particles, as well as regulatory issues such as the need to obtain approval of all components of a two- or three-component system.

These problems can be circumvented by genetic targeting approaches, which genetically modify fiber, penton base, and hexon capsid proteins. By far the most extensively studied alterations have been done on fiber knob, including fiber knob pseudotyping, genetic incorporation of targeting ligands into the fiber protein, and genetic fiber replacement strategies. Fortunately, two sites in the fiber protein have been identified where ligands can be inserted safely without disrupting fiber knob trimerization. These are the C-terminal end of the fiber tail, which projects from the surface of the virion, and the so-called HI loop within the fiber knob. Incorporation of targeting ligands led to increased infectability of target cells *in vitro* of up to three orders of magnitude (Amalfitano and Parks 2002; Nicklin and Baker 2002). Even large reporter enzyme genes for imaging can be inserted into the C-terminus of protein IX (Li et al. 2005, 2006). The advantage of entire replacement of fiber over just incorporating ligands is the possibility of achieving real retargeting because only then can initial affinity of adenovirus to CAR be abrogated. To date, attempts have been successfully made to abrogate infection of CAR positive cells, but infectability of retargeted adenoviruses in general was lowered 20-fold (van Beusechem et al. 2000; Magnusson et al. 2001). A pseudotyped adenoviral vector has recently been utilized for targeting replication competent adenovirus to liver metastases and an increase of the transduction rate from 0% to 8% was observed (Shayakhmetov et al. 2002).

A combination of conjugate-based strategies and genetic targeting has recently been described. Efficient and selective gene transfer into human brain tumor spheroids has been achieved using antibody-targeted vectors; native tropism to both CAR and integrin were abolished (van Beusechem et al. 2002).

A variety of retargeting attempts have recently been undertaken for AAV. The primary attachment receptor for AAV is heparan sulfate proteoglycan (Summerford and Samulski 1998), and coreceptors are fibroblast growth factor receptor-1 (Qing et al. 1999) and $\alpha_v\beta_5$ integrins (Summerford et al. 1999). These receptors are widely expressed in the human body. Retargeting is therefore feasible especially as AAV is an integrating vector. In addition, it seems that despite efficient internalization, nuclear trafficking of AAV may be inefficient. Retargeting to new receptors could allow for new and more efficient ways of trafficking. As for adenoviruses, genetic and nongenetic approaches have been used to retarget AAV. The former strategy has been more popular by far, however. *In vivo* gene transfer has been performed with AAV-2 pseudotyped with AAV-5 capsid or AAV-8 capsid; this produced higher levels of transduction than wild-type AAV-2 in injected skeletal mouse muscle or liver, respectively (Gao et al. 2002).

A lot of effort has recently been put into genetic incorporation of targeting ligands into the AAV capsid. In contrast to

adenovirus, the structure of the AAV capsid has not yet been elucidated. This will eventually enable pinpointing of the capsid epitopes, which mediate cell surface receptor binding and enable specific site-directed mutagenesis for ablation of wild-type AAV-2 tropism. Despite this drawback, by modeling the AAV capsid on the known structure of canine parvovirus, several studies have already demonstrated that genetic incorporation of peptide epitopes into the AAV capsid can modify tropism.

The first genetically targeted HD-Ad has been published (Biermann et al. 2001). The wild types of commonly used retroviruses such as ecotropic MLV strains do not recognize a receptor on human cells. They have therefore been pseudotyped with natural viral fusion proteins such as the amphotropic MLV env protein or the vesicular stomatitis virus (VSV)-G glycoproteins (Yee et al. 1994). These pseudotyped retroviruses now infect a variety of human cells. This is not always desirable, as in the case of adenovirus and AAV. Therefore, retargeting of these vectors to specific cell types has been attempted. In addition, studies have shown that several cell types including hematopoietic stem cells are still insufficiently infected by pseudotyped vectors. Some specificity is achieved just by using other viruses for pseudotyping (such as gibbon ape leukemia virus [GaLV] [von Kalle et al. 1994], human foamy virus [HFV] [Lindemann et al. 1997], simian immunodeficiency virus [Indraccolo et al. 1998], and HIV-1 [Mammano et al. 1997]).

More was expected from direct targeting approaches such as inclusion of a wide variety of ligands into the MLV glycoproteins. Efficient retargeting was achieved in several cases. Unfortunately, upon binding most of the chimeras were unable to trigger the highly complicated fusion events of viral envelope and target cell membrane necessary for efficient viral transduction. The most straightforward approach to circumvent this problem was the creation of tethering or escorting ligands. These were again cloned into the MLV env glycoproteins, but at a site which does not abrogate wild-type receptor interaction and disturb fusion. This type of retargeting has already proven successful for preclinical cancer therapy. Systemic application of an ECM-targeted retrovirus allowed enhanced transduction of tumor tissue and significantly prolonged survival of mice as compared to a nontargeted vector (Gordon et al. 2001). During these studies, an observation was made that was paradoxical at first glance: some receptor ligands conferred excellent binding to target cells but due to lysosomal sequestration, no gene transfer was achieved (Cosset et al. 1995; Fielding et al. 1998; Russell and Cosset 1999). This phenomenon, which has been called inverse targeting, can cause the selective transduction of EGF-receptor negative tissue if the vector has been engineered to contain EGF and if the EGF-receptor negative tissue is principally infectable by the wild-type vector (as has been demonstrated by inverse targeting of lentiviral vectors to the spleen) (Peng et al. 2001). This type of inverse targeting can be reversed into true targeting by inclusion of a protease cleavage site inserted between the EGF domain and the amphotropic receptor. In this case, EGF serves as a tethering molecule but extracellular proteases

present on the target cells cleave it off and efficient infection occurs. This approach has proven to discriminate between (matrix metallo) protease rich and poor in EGF receptor-positive tumors in nude mice (Peng et al. 1999).

Another innovative way to achieve retargeting without losing fusion uses proteins of nonretroviral enveloped viruses instead of the natural receptors. These proteins are able to trigger membrane fusion. MLV vectors coated with the influenza virus hemagglutinin (HA) glycoprotein, including a cell surface-specific ligand, could be selectively targeted to and incorporated into cells expressing the expected target cell surface molecules (Hatzioannou et al. 1999). Finally, similarly to adenovirus and AAV, bifunctional bridge proteins have been examined for targeting with success *in vitro* (Boerger et al. 1999).

The benefit of combining transcriptional targeting and tropism-modified targeting was recently demonstrated using the endothelial cell-specific FLT-1 promoter and an anti-ACE antibody. This combination achieved an impressive 300,000-fold improvement in adenoviral transduction of the lung (Reynolds et al. 2001).

36.4 CLINICAL TARGETS FOR CANCER GENE THERAPY

36.4.1 BLADDER CANCER

Superficial transitional cell cancer (TCC) of the bladder is the fifth most common solid malignancy in the United States (Greenlee et al. 2000). Seventy to eighty percent of patients with bladder cancer present with these low-grade, noninvasive tumors confined to mucosa. Although most superficial cancers can be managed with periodic transurethral resection, this is not an ideal situation because recurrence is the rule (Dalbagni and Herr 2000). Even with close surveillance and follow-up, at least 50% will eventually require a cystectomy. Intravesical chemotherapy or installation of Bacille Calmette-Guérin can prolong the disease, but still 30% of patients will die of recurrent metastatic bladder cancer within 15 years (Dalbagni and Herr 2000).

Intravesical gene therapy is a promising new approach for the treatment of refractory superficial bladder cancer. Several approaches have proven preclinical efficacy, including transfer of immunomodulatory genes such as IL-2 (Horiguchi et al. 2000), IFN- γ (Hashimura et al. 1997), and IFN- α 2b (Adam et al. 2007); installation of tumor cells transfected with GM-CSF, IL-2, or HLA B7-1; HSV tk/HSV tk-based suicide approaches (Jin et al. 1995; Sandig et al. 1997); oncolytic herpes virus, which was interestingly efficient against metastases if injected systemically (Gallardo et al. 1996) and transfer of p16 (Fujiwara et al. 1994), pRb (Spitz et al. 1996), or p53 (Melero et al. 1997).

A clinical trial of installation of empty vaccinia virus did not lead to any systemic toxicity but recruitment of lymphocytes and induction of a brisk local inflammatory response were seen (Gomella et al. 2001). Intravesical installation (but not intratumoral injection) of Adeno-p53 led to transgene

expression and induction of the p53 target gene p21 in patients with bladder cancer awaiting total bladder resection. No dose-limiting toxicity was observed at doses of up to 7.5×10^{13} particles (Kuball et al. 2002). The superficial nature of TCC and the unique opportunity of intravesical vector installation make this disease particularly suited for cancer gene therapy at the current state of development.

36.4.2 BREAST CANCER

One of the most important target malignancies for cancer gene therapy is breast cancer. Breast cancer will affect one in every nine women in the United States and a similar incidence is seen in Europe (Harris et al. 1993). Conventional treatments such as surgery, radiotherapy, and adjuvant systemic therapy allow disease-free survival for many years. However, the loco regional recurrence rate and the rate of disseminated disease are high, and even 10%–40% of patients without obvious axillary lymph node involvement at the time of surgery relapse (Miller et al. 1993). In these cases, curability by conventional methods is very unlikely.

Based on the unsatisfying outcome of classical strategies to improve cancer treatment, several gene transfer approaches are under experimental and clinical investigation. These include immunological approaches or the transfer of tumor suppressor genes or prodrug-activating enzymes.

Several immunological strategies are based on the use of tumor-specific antigens to improve recognition of breast cancer cells by the effector cells of the immune system. In this respect, several tumor-specific antigens are under experimental investigation to set up a specific vaccination strategy for patients with breast cancer. Candidate antigens are mucin 1 (MUC-1), MAGE-1, CEA, and members of the erbB gene family of cell surface receptors (Ruppert et al. 1997). A recombinant vaccinia virus expressing MUC1 and IL-2 has been used in a phase I/II study in nine patients with advanced breast cancer (Scholl et al. 2000); one patient had a concomitant decrease in CEA serum levels and remained clinically stable for 10 weeks.

Among the first immunological approaches for breast cancer patients was a phase I study of immunotherapy of cutaneous metastasis using allogenic (A2, HLA-B13) and xenogenic (HLA- H-2K (k)) MHC–DNA liposome complexes (Hui et al. 1997). Several partial and complete responses of the injected tumorous nodules were observed.

Intratumoral adenovirus-mediated gene transfer of the 4-1BB costimulatory molecule-ligand (ADV/4-1BBL) to liver metastases in a syngeneic animal model of breast cancer induced a dramatic regression of pre-established tumor (Martinet et al. 2002). Excellent tumor regressions were also observed with a combination of IL-2- and IL-12-expressing adenoviruses in a mouse model of mammary adenocarcinoma; 63% of animals underwent complete regression of both treated and untreated tumors (Addison et al. 1998). Direct *in vivo* IFN- β gene delivery into established tumors generated high local concentrations of IFN- β , inhibited tumor growth, and in many cases caused complete tumor regression. Because the mice

were immune-deficient, it is likely that the antitumor effect was exerted primarily through direct interferon-mediated inhibition of tumor cell proliferation and survival (Qin et al. 1998).

Gene transfer strategies for breast cancer patients can also be used to improve classical strategies in breast cancer therapy like chemotherapy. In this field, purging techniques in high-dose chemotherapy are under intensive experimental investigation. Before initiation of high-dose chemotherapy for women with breast cancer, autologous stem cell transplants are collected from the patient and are given back after the therapeutic protocol is completed. Because these preparations can still be contaminated by tumor cells, different strategies aim at purging these stem cell transplants from contamination. However, magnetic purging techniques are expensive and not very efficient while pharmacological purging is very effective but toxic not only to the tumor (Hildebrandt et al. 1997). Therefore, to limit the toxicity of pharmacological purging of contaminating cancer cells, either hematopoietic precursor cells of the autologous stem cell transplants need to be made resistant to chemotherapy, or contaminating tumor cells need to be made more sensitive to chemotherapy. Thus, one genetic approach tries to infect only hematopoietic cells and make them resistant to chemotherapy through transfer of a multidrug resistant gene (Frey et al. 1998). An example of the other strategy of making contaminating tumor cells more sensitive to chemotherapy is adenovirus-mediated gene transfer of a prodrug-activating enzyme like HSV-tk or CD (Chen et al. 1995; Yee et al. 1996; Garcia-Sanchez et al. 1998). This approach exploits the fact that breast cancer cells, which contaminate autologous stem cell transplants, express more adenovirus-internalizing integrins than hematopoietic precursor cells (Seth et al. 1996; Wroblewski et al. 1996; Li 1997). Preclinical studies have already demonstrated that the concept of adenovirus-mediated gene transfer into contaminating breast cancer cells of autologous stem cells is a real alternative strategy for direct clinical application (Wolff et al. 1998; Lillo et al. 2002). Purging of hematopoietic stem cells from breast cancer cells has also been successfully performed with conditionally replication-competent HSV (Wu et al. 2001) and a complete lack of toxicity has been shown for a p53 adenovirus (Hirai et al. 2001). Bone marrow cells themselves are the target of retroviral transfer of MDR genes. Recent clinical trials showed a selective enrichment of these cells by subsequent chemotherapy and the maintenance of transduced cells for more than 1 year has been reported (Takahashi et al. 2006).

Another strategy, which has been adapted for gene therapy of breast cancer, is the use of antioncogene and tumor suppressor genes. *In vivo* administration of BRCA1 led to tumor growth retardation comparable to that obtained with p53 or p21 (Randrianarison et al. 2001).

Hydrodynamic-based gene delivery of a secreted form of the TNF-related apoptosis-inducing ligand, TRAIL, led to the regression of a human breast tumor established in SCID mice (Wu et al. 2001).

Adenovirus-mediated transfer of the cDNA of the proapoptotic bcl-x_s into breast cancer cells led to a significant

reduction of tumor growth after the transduced cells were transplanted into immunodeficient mice (Clarke et al. 1995; Ealovega et al. 1996). As described in the literature on colorectal cancer, breast cancer also develops by a succession of genetic alterations (Mars 1990; Cho and Vogelstein 1992; Parsons et al. 1993; Cox et al. 1994; Devilee and Cornelisse 1994). Although the degree of genetic heterogeneity is particularly high in breast cancer, these multiple genetic changes may interfere with just a few critical cell cycle regulatory pathways and therefore represent suitable targets for corrective gene therapy (Lukas et al. 1995). Successful *in vitro* approaches include oligonucleotide-mediated transfer of antisense myc (McManaway et al. 1990; Watson et al. 1991), ErbB-2 (Bertram et al. 1994; Casalini et al. 1997), cyclin D1 (Zhou et al. 1995), and TGF alpha (Kenney et al. 1993); the transfer of genes for intracellular antibodies, which prevent growth factor receptors to reach the cell surface, as reported for ErbB-2 (Wright et al. 1997); and other transgenes such as PKA, EGFR, TGF-beta, IGFIR, P12, MDM2, BRCA, Bcl-2, ER, VEGF, MDR, ferritin, transferrin receptor, IRE, C-fos, HSP27, C-myc, C-raf, and metallothionin genes (Head et al. 2002). Some of these have already been tested *in vivo*. For example, excellent inhibition of breast tumor growth *in vivo* was shown by retroviral transfer of antisense C-FOS (Arteaga and Holt 1996).

The best existing *in vivo* data so far has been seen with adenoviral transfer of the tumor suppressor p53, which argues for the fruitfulness of combining a highly efficient gene transfer vehicle with a nearly universal apoptosis inducer (Nielsen et al. 1997). In addition, good efficacy of tumor growth reduction was achieved using liposomes for the transfer of a p53 cDNA (Xu et al. 1997). The importance of the p53 status for the efficacy of chemotherapeutic drugs is a matter of intense debate. Whereas in the majority of studies, the loss of p53 has been associated with decreased sensitivity to chemotherapy, the opposite was reported for the chemotherapeutic drug taxol (Wahl et al. 1996). An interesting approach to counteract the MDM2-protein, which is often elevated in wtp53 positive tumors, was conducted by generating a recombinant adenovirus expressing a p53 variant (i.e., deleted for the amino acid sequence necessary for MDM2 binding). Apoptotic activity of rAd-p53-expressing the mutated p53 with that of a recombinant adenovirus expressing wild-type p53 in cell lines that differed in endogenous p53 status caused higher levels of apoptosis in p53 wild-type tumor lines compared with wild-type p53 treatment, showed apoptotic activity similar to that seen with wild-type p53 treatment in p53-altered tumor lines, and showed greater antitumor activity in an established p53 wild-type (hepatocellular) tumor compared with treatment with wild-type p53 (Atencio et al. 2001). With a similarly mutated adenovirus, tumor regressions were also observed in a sarcoma model (Bougeret et al. 2000). In combination with chemotherapy, coapplication of docorubicin did show an overadditive effect (Lebedeva et al. 2001) whereas cyclophosphamide did not (Nielsen 2000).

Stable preclinical tumor regressions were also achieved by intratumoral injection of an adenovirus harboring the adenoviral E1A gene under the control of the tumor-specific

MUC1 promoter with and without an additional TNF- α transgene expression cassette (Kurihara et al. 2000). In a clinical trial, an E1A gene complexed with DCC-E1A cationic liposome was injected once a week into the thoracic or peritoneal cavity of 18 patients with advanced cancer of the breast ($n = 6$) or ovary ($n = 12$) and led to HER-2/neu downregulation, increased apoptosis, and reduced proliferation (Hortobagyi et al. 2001).

Injection of a plasmid harboring the CD gene under the control of the tumor-specific erbB-2 promoter in 12 patients with breast cancer showed the safety of the approach; expression of the transgene was seen in 90% of cases although no antitumor efficacy was reported (Pandha et al. 1999). Retroviral transfer of the suicide gene P450 led to partial responses and stable disease in patients with cutaneous metastases upon application of cyclophosphamid (Braybrooke et al. 2005).

Injection of adenovirus-harboring dominant negative mutants of estrogen receptors into pre-established T47D tumors in nude mice induced tumor regressions (Lee et al. 2001).

Finally, *in vivo* studies of reovirus breast cancer therapy revealed that viral administration could cause tumor regression in an MDA-MB-435S mammary fat pad model in SCID mice. Reovirus could also effect regression of tumors remote from the injection site in an MDA-MB-468 bilateral tumor model, raising the possibility of systemic therapy of breast cancer by the oncolytic agent (Norman et al. 2002).

In summary, although metastatic breast cancer poses high demands on current cancer gene therapists, nearly all therapeutic principles have been evaluated in animals and some are already in clinical evaluation.

36.4.3 COLORECTAL CANCER

Colorectal cancer is the third most frequently occurring cancer in the United States (Parker et al. 1997). Surgical removal of the primary tumor is the established first-line therapy. This strategy can be a curative approach if all cancer cells are eliminated. However, already at a very early stage of tumor development, colorectal cancer metastasizes to the liver. In 60% of all cases, the only manifestation of distant metastasis (Kemeny and Seiter 1993) occurs in this organ. Consequently, liver metastasis of colorectal cancer is one of the very few indications where treatment of metastasis can lead to a significant improvement of the prognosis of the disease.

Single liver metastasis of colorectal cancer represents a promising target for intratumoral or regional gene therapy. Studies in experimental animals demonstrated significant tumor reduction by gene transfer of the tumor suppressor gene p53 (Harris et al. 1996). However, neither a clinical trial applying p53 adenovirus into the hepatic artery (Venook 1998; Chung-Faye et al. 2000) nor intratumoral injections (Habib et al. 1995) have revealed any clinical response. The suicide approach by gene transfer of prodrug-activating enzymes like cytosine deaminase, HSV-tk, or nitroreductase followed by systemic application of the corresponding prodrugs 5-fluorocytosine, GCV, or CB1954 has led to good results in animal experiments (Kemeny et al. 1993; Hirschowitz et al. 1995; Djeha et al. 2001).

A single dose of adenovirus transferring the HSV-tk gene, followed by a 10-day intraperitoneal GCV treatment, led to a reduced tumor growth of more than 90% and a significant reduction of the tumor volume (O'Malley et al. 1997; Schrewe et al. 1990). This experimental approach was extended by the combination of adenovirus vectors carrying the transgene of different cytokines with the adenovirus encoding for HSV-tk. The results so far have suggested that the HSV-tk/GCV effect can be increased by simultaneous cytokine gene expression (O'Malley et al. 1997). However, in an orthotopic model of colon carcinoma metastatic to the liver, the HSV-tk strategy was compromised by severe hepatic toxicity and the death of several animals (Brand et al. 1997). Similar toxicity was seen if the vector was applied intraportally for the treatment of HCC in mice or rats (van der Eb et al. 1998). In contrast, no toxicity was observed with retroviral vectors (Caruso et al. 1996) (own findings). The liver toxicity observed using adenovirus vectors could be abrogated if the CMV promoter was replaced by the colon-specific CEA promoter in these vectors (Brand et al. 1998). The generation of tumor cell-specific transgene expression in colorectal liver metastases by adenovirus vectors can also be accomplished by modification of the adenoviral fiber protein by inclusion of the CEA-receptor (Curiel et al. 1992). Recently, the results of an Adeno-HSV tk/GCV phase I trial with intratumoral injection of an RSV.HSV tk-adenovirus were reported. Ultrasound-guided percutaneous injection of up to 10^{13} adenoviral vector particles only caused mild hepatic toxicity upon GCV treatment; this may indicate that extensive leakage into the liver tissue was prevented. No clinical benefit was observed (Sung et al. 2001).

A clinical phase I trial with conditionally oncolytic replication-competent E1B55K deleted adenovirus was performed (Habib et al. 2001). It was possible to safely deliver virus by direct intratumoral, intraarterial, and intravenous injection up to a dose of 3×10^{11} infectious particles. In a phase II trial for patients with colorectal liver metastases, virus was administered intraarterially together with the chemotherapeutic 5-FU. After 3 months, stable disease was demonstrated in six of seven patients (Habib et al. 2001). More recently, the combination of RCA with chemotherapy again showed overadditive effects when 25% of patients with colorectal liver metastases displayed marginal to partial response (Reid et al. 2002). The sole application of Onyx-15 RCA into the hepatic artery of patients with colorectal liver metastases, which had failed 5-FU therapy, lead to increased survival in a phase II study (Reid et al. 2005). Among other potential oncolytic viruses HSV showed promising effects in animal models (Bennett et al. 2002) and is now used in a clinical trial for patients with gastrointestinal cancer metastatic to the liver.

Antiangiogenic and antiproteolytic strategies have been implemented but are still in the preclinical phase. A prevention of colorectal liver metastasis of up to 95% was achieved when Ad-TIMP-2 or Ad-TIMP-1 were injected into the tail vein of mice; this leads to a preferential transduction and quasi-impregnation of the liver with the antitumor gene (Brand et al. 2000; Elezkurtaj et al. 2004). Good preclinical results

have been obtained with the proangiogenic endostatin gene as well, which was transferred in models for primary and metastatic liver cancer either alone or in combination with chemotherapy (for review, see Hernandez-Alcoceba et al. 2006).

Multiple liver metastases are also targets for immunological gene therapy strategies. In this respect, the CEA is one of the most promising candidates under investigation. In two clinical studies of recombinant vaccinia virus-CEA immunization, T-cell responses were demonstrated (Conry et al. 1995; Tsang et al. 1995). In a recently published clinical trial of a dual expression plasmid encoding CEA and hepatitis B surface antigen (HBsAg) in 17 patients with metastatic colorectal carcinoma, four patients developed lymphoproliferative responses to CEA after vaccination although no objective clinical responses to the DNA vaccine were observed (Conry et al. 2002). A combination of CEA and costimulatory molecules has revealed a CEA-specific immune response and some positive clinical results (for review, see Mohr et al. 2007) such that subsequent trials are active at Duke and Georgetown Universities. In addition, significant tumor growth inhibition of xenografts from colon tumor cells in established animal models has also been accomplished using different approaches. These include vaccinia virus-mediated transfer of B7-1 and IL-12 (Rao et al. 1996); adenovirus-mediated transfer of IL-12 (Caruso et al. 1996); liposomal transfer of MHC class I molecules (Plautz et al. 1993); or the transfer of fibroblasts, which had been transduced *in vitro* with IL-2 (Fakhrai et al. 1995) (this last result has led to the initiation of a clinical phase I study) (Sobol et al. 1995). The results of these experimental studies indicate that the dormant or suppressed immunogenicity of colon tumor cells can be evoked by several immunomodulatory mechanisms. Moreover, the good antitumor efficacy achieved even with vector systems, which traditionally suffer from low gene transfer efficacy, suggests that a certain level of gene transfer may be sufficient to induce an immune response.

In summary, colorectal liver metastases are unique. Their cure could mean a cure for the patient. Therefore, they have served as the model disease for gene therapy of metastatic disease. Initial, encouraging clinical results have been obtained.

36.4.4 GLIOBLASTOMA

Glioblastoma is the most common primary brain tumor. Despite advances in diagnosis and treatment, the median survival time is still only 1 year from the time of diagnosis (Mahaley et al. 1989). This tumor rarely metastasizes to distant organs, suggesting that improvements in local treatment could be of great benefit. Therefore, glioblastoma has been one of the model diseases for gene therapy with suicide genes. Reviews on this topic are provided by Rainov et al. (2001) and Lam and Breakefield (2001). The first preclinical studies for cancer gene therapy were performed using retrovirus-mediated transfer of the HSV-tk gene into established intracranial glioblastomas in Fisher rats (Culver et al. 1992). Based on these early promising results, other vector systems have been tested for the HSV-tk/GCV approach including adenoviruses,

liposomes, AAV, or HSV. All these vectors have been successfully used in animal studies where it was frequently possible to observe complete remissions with long-term survival (Table 36.1). Consequently, several clinical phase I, II, and III trials were initiated making the gene therapy of glioblastoma by the HSV-tk/GSV approach the most advanced system for cancer gene therapy. The suicide gene approach has been combined with surgery. As much malignant tissue as possible is removed, leaving the local infiltrating parts for multiple vector injections. This strategy has to leave out the large isles of healthy tissue within the tumor network, which is a characteristic of this tumor. This is the reason why complete resections can be rarely performed. As demonstrated by results from a multicenter phase II trial in Germany, there is no clear-cut clinical outcome so far. In a 1 year follow-up report of 10 patients with recurrent glioblastoma multiforme, where retroviral vector packaging cells were administered into the tumor followed by application of GCV, 4 of the 10 patients died because of tumor progression. Of the other six patients, one presented a complete remission at 12 months, and five had progressive disease but with a significant increase in quality

of life (Weber et al. 1997). Other reports demonstrated responses in the CT scan; a clear enhancement was visible in the areas where the retroviral VPCs carrying the transgene had been injected (Ram et al. 1997). However, clinical responses were rare and not marked. Unfortunately, the first phase III trial with HSV tk retroVPCs did not have any treatment benefit (Rainov et al. 2001). Some responders were observed in trials using adenoviral vectors but therapy was accompanied by severe neurological symptoms (Alavi et al. 1998; Trask et al. 2000). As discussed in the context of colorectal liver metastases, toxicity can in principle be abrogated by tissue-specific expression of the transgene, e.g., by the nestin (Kurihara et al. 2000) or myelin basic protein (Shinoura et al. 2000) promoter or targeted vectors (Rainov et al. 2001). Several phase I trials with conditionally replication-competent HSVs have been performed to date. Toxicities related to the vector were not reported and occasionally exciting antitumor efficacy was seen (Markert et al. 2000; Rampling et al. 2000; Papanastassiou et al. 2002; Harrow et al. 2004). Conditionally replication-competent adenovirus (e.g., Onyx-015) has been evaluated in clinical trials as well (Chiocca et al. 2004) and most recent

clinical data indicates that the injection of the virus is well tolerated and occasional regressions can occur.

Besides the strategy of using prodrug-converting enzymes, gene transfer of the tumor suppressor gene p53 has also been commonly tested in experimental models with success either alone (Badie et al. 1995; Cirielli et al. 1999) or in combination with radiotherapy and chemotherapy (Trepel et al. 1998; Biroccio et al. 1999; Broaddus et al. 1999). Among the cell cycle inhibitory proteins, p16 is very often inactivated in glioblastoma. Adenovirus-mediated gene transfer of p16 generated significant tumor growth reduction in p16-negative glioblastomas (Fueyo et al. 1996). For the transcription factor E2F-1, it could be demonstrated that adenovirus-mediated overexpression resulted in a tumor growth reduction in p53 wild-type expressing glioblastoma cells (Fueyo et al. 1998). Other apoptosis-inducing genes (caspases [Shinoura et al. 2000; Jacobson et al. 2000], TNF- α [Walczak et al. 1999; Niranjana et al. 2000]) or antioncogenes (ras, Shu et al. 1999 meningioma) have been successfully evaluated in animal models. In addition to the use of molecules regulating cell cycle and apoptosis, several immunomodulatory genes have been tested to treat experimental glioblastoma tumors either alone and in combination (Sampson et al. 1997; Glick et al. 1999; DiMeco et al. 2000; Herrlinger et al. 2000). Growth inhibition was seen in most cases, which indicates that although the brain is an immunoprivileged site, this barrier could effectively be surmounted at least in some tumors. A clinical trial using interferon- β (Eck et al. 2001) has been initiated. In several preclinical trials the combination of gene/viral therapy with chemotherapy has shown overadditive effects (for review, see Lesniak (2006)).

In summary, although the HSV tk suicide gene trials probably represented one of the earliest sobering results in gene therapy, the disease is certainly a very good candidate for gene therapy. This is especially so if targeted vectors will distinguish between normal brain tissue and the deeply infiltrating and surgically inaccessible tumor branches of glioblastoma multiforme.

36.4.5 HEAD AND NECK CANCER

Each year, in the United States, approximately 40,000 individuals are diagnosed with carcinoma of the head and neck (HNSCC) and upper aerodigestive tract (Society 1993). More than two-thirds of the individuals with HNSCC present with stage II or IV of the disease (Dimery and Hong 1993) and 50–60% of these patients ultimately develop local recurrence despite optimal local therapy. These patients may therefore obtain significant benefit from local or regional gene therapeutic approaches.

A high percentage of these tumors are negative for p53 and several clinical trials with percutaneous or endobronchial p53 gene transfer are under way or already closed. Several clinical studies have used adenoviral vectors, while one trial used retroviruses. In summary, no major toxicity was observed. Indications of antitumor efficacy included increased survival times compared to historical controls in four of 15 patients with recurrent disease; dose-related improvements in time-to-disease

progression in a large phase II trial; and partial response or at least stable disease in two-thirds of patients in a trial with 52 patients who had previously failed conventional treatment. Consequently, one p53 adenoviral vector (INGN 201) is now in phase III testing. Most strikingly, the first gene therapeutic cancer medicine to obtain regulatory approval (2003, China) is such an p53 adenovirus (Guo and Xin 2006). Since approval, thousands of patients have been treated with this virus and reports on large-scale efficacy are eagerly awaited.

Despite these findings of clinical efficacy, improvements of the strategy are necessary, mainly because of the requirement of highly efficient gene transfer. Based on the bulky mass of head and neck cancer, it is unlikely that the large tumor burdens, which remain even after radical surgery, can be sufficiently transduced even by the highly efficacious replication-deficient adenoviral vectors. Therefore, and because of the good accessibility, head and neck cancer has become the model disease for therapy with selectively replication-competent adenoviruses. The underlying concept of the use of replication-competent recombinant adenoviruses is based on the capability of adenovirus to induce cell lysis by its progeny inside of an infected target cell (Horwitz 1996; Shenk 1996). To limit the cytotoxicity only to tumor cells and not to normal cells, researchers exploited the fact that about 50% of tumors carry a mutation in the tumor suppressor gene p53. A recombinant replication-competent adenovirus was constructed, which should specifically replicate only in p53 negative tumor cells (Bischoff et al. 1996). For further explanation of this concept, please see the Section 36.2.4. Although the concept underlying the mode of action of the vector is not yet completely understood, several clinical trials have been performed. The published data, mainly with the vector ONYX-015, are among the most encouraging in clinical cancer gene therapy. With respect to toxicity, results suggest that the intratumoral injection of ONYX-15 limits proliferation of the vector to malignant tissue; it is well tolerated except for transient low-grade fever and injection site pain. Three clinical trials have been formally published so far (Ganly et al. 2000; Khuri et al. 2000; Nemunaitis et al. 2001): A phase I trial, a phase II trial for intratumoral injection of ONYX-15 alone, and one trial for the combination of virus and cisplatin. Five of 36 patients in the phase II trial showed partial or even complete ($n = 3$) responses (Nemunaitis et al. 2001). In the combinatorial approach, 63% as compared to 30%–40% in the historical controls showed partial or complete responses (Khuri et al. 2000). Replication-competent NDVs have led to a complete response in one patient of squamous cell carcinoma of the tonsils (Pecora et al. 2002).

Besides these dominant strategies for HNSCC, immune modulatory approaches have already been tested clinically. Partial responses have been observed in four out of nine patients with advanced HNSCC upon intratumoral injection of HLA-B7 plasmid (Allovecin-7) (Wickham et al. 1993). Among several approaches showing promising preclinical efficacy, including transfer of suicide genes, Bcl-2, superoxid dismutase (SOD), and EGF-receptor, transfer of adenovirus E1A in a liposomal formulation has been tested clinically.

It showed only minimal toxicity and modest clinical efficacy with one out of 24 patients with recurrent, unresectable HNSCC having a complete response; two patients having a minor response; and seven patients having stable disease (Villaret et al. 2002).

With respect to immunogene therapy, liposomal-mediated gene transfer of HLA-B7 costimulatory molecules has led to stable disease and some partial responses in phase I and phase II trials for HNSCC patients (Gleich et al. 2001).

Head and neck cancer is probably the tumor type with the best clinical results in cancer gene therapy obtained so far. This may be due to the good accessibility for intratumoral approaches; the low tendency for metastazation, with the opportunity for long time follow-ups and (perhaps) a favorable immunologic and intracellular molecular situation. These first successes have encouraged many researchers to believe that less favorable starting points in other cancer types can be overcome, leading to clinical efficacy.

36.4.6 HEMATOLOGIC AND LYMPHATIC MALIGNANCIES

These malignancies are the domain of chemotherapy. Due to the development of advanced protocols, the initial rate of remission and the rate of long-term survivors have dramatically increased. In all stages, the primary therapeutic intention is curative. The usual treatment regime consists of several cycles of intensive or high-dose chemotherapy up to a full eradication of the patient's bone marrow followed by autologous or allogeneic bone marrow transplantation. Due to the good susceptibility of leukemic and lymphatic cells for chemotherapy, conventional treatment usually leaves only minimal residual disease. This residual tumor load can, however, lead to relapses in up to 80% of patients with leukemia (Braun et al. 1997) and has usually a bad prognosis. Gene therapy could try to prevent this situation.

Several immunologic approaches have been tried. Preclinical *in vivo* gene transfer of TNF-alpha was used for T-cell lymphoma (Gillio et al. 1996) and myeloma (Cao et al. 1998), B7 for several lymphomas (Chen et al. 1994; Martin-Fontecha et al. 1996) and GM-CSF for T-cell leukemia (Hsieh et al. 1997). Transfer of IL-2 into lymphomas has been clinically examined (Hersh et al. 1996).

Human primary hematologic malignant cells are unfortunately highly resistant to transduction by most available vectors. Only recently, modifications of vectors and *ex vivo* transduction protocols have allowed increased gene transfer at least into cultured allogeneic vaccine lines with adenovirus, HSV, liposomes, and retroviral vectors. Another problem is the considerable phenotypic heterogeneity of the cancer, which can cause an incomplete representation of potential antigens of the whole malignant cell population in the population selected for gene transfer and vaccination.

Despite these problems, a considerable number of cancer gene therapy trials using *ex vivo* cytokine-transduced vaccines have been conducted. Among several cytokines, IL-4 and GM-CSF protected best against tumor challenge, and GM-CSF-transduced cells could also inhibit further progression of preestablished lymphatic tumors (Levitsky et al. 1996) in a

mouse model. Most clinical trials used IL-2, but in others IL-4, 7, 12, IFN- γ , and GM-CSF vaccines were applied.

Vaccinations with the DNA of tumor antigens have also been carried out. Gene therapy provides an advantage here over the use of the respective protein when this is difficult to obtain in the required amount or in the correctly glycosylated form. Encouraging results were obtained in a clinical phase I study of the vaccination of patients with chronic lymphatic leukemia (CLL) with CLL cells adenovirally transduced to overexpress the CD 40 ligand (CD 154); a phase II trial has been initiated (Kipps et al. 2000).

Ex vivo gene transfer into effector cells has also been examined clinically. In a phase I clinical trial, autologous cytokine-induced killer (CIK) cells *ex vivo* transduced with IL-2 were infused in patients with metastatic disease. One out of 10 patients had a complete response of his lymphoma (Schmidt-Wolf et al. 1999).

The generation of chimeric T-cell receptors (TCRs) has been another strategy to generate antitumor immunity for B cell lymphoma. T cells are directed against target cells by grafting an antibody V region of desired specificity onto the TCR and the constant regions. The specificity of this approach *in vitro* has been shown (Gross et al. 1995).

The transfer of donor leukocytes (Mackinnon et al. 1995) or EBV-specific cytotoxic T lymphocytes (Rooney et al. 1995) has been a successful approach for the treatment of B cell lymphoma. A potential problem of this strategy, however, could be graft versus host disease (GvHD). An ingenious way to circumvent this problem is the transduction of the donor T cells with a suicide gene like HSV-tk to be able to kill the donor T cells by GCV if signs of GvHD appear (Verzeletti et al. 1998; Bonini et al. 1997). In a clinical trial, GvHD resolved in two of three patients upon application of GCV. A review of the pros and cons of this strategy can be found in Sadelain and Riviere (2002). Gene marking was used to track the *in vivo* persistence and fate of EBV-specific CTLs in 14 patients with relapsed Hodgkin lymphoma. Infused cells expanded by approximately 1000-fold *in vivo* and five patients were in complete remission at up to 40 months (Larsen and Rasko 2005).

One sustained response in a clinical trial was observed upon the application of TILs engineered to secrete TNF (Brenner 1998). For therapy of multiple myeloma, direct intratumoral gene transfer of the TNF gene was performed preclinically and a substantial gene transfer in nearly 50% of tumors was seen (Wright et al. 1998). Anecdotally, one woman received an injection of an IL-2 adenovirus into an occipital myeloma lesion and gene transfer could be demonstrated although no tumor regression was observed (Stewart et al. 1998). In fact, myeloma cells seem to be among the easiest transducible hematologic cells at least for adenoviruses (Wattel et al. 1996) and AAV (Wendtner et al. 1997).

Lymphomas and leukemias have also been targeted with oligonucleotides against myc (McManaway et al. 1990; Skorski et al. 1995, 1996), bcl-2 (Madrigal et al. 1997), myb (Ratajczak et al. 1992), bcr-abl (Skorski et al. 1995, 1996) and bcr-abl ribozymes (Lange et al. 1993). Transfer efficacy

of antisense oligonucleotides *in vitro* and *in vivo* is highly controversial, but a clinical trial using a bcl-2 antisense oligonucleotide (oblimersen, Genasense; Genta Inc. Berkeley Heights, NJ) demonstrates modest clinical activity in patients with refractory/relapsed CLL (O'Brien et al. 2005).

Therapy-associated side effects like infections and hemorrhages account for 70% of the deaths of adult patients with acute leukemia (Mertelsmann 1998). The transfer of MDR genes into hematopoietic stem cells for chemoprotection holds promise and clinical studies of the transduction of the MDR gene in patients with relapsed and resistant lymphomas are already under way. This approach, however, runs the risk that tumor cells are transduced, making them resistant to chemotherapy. Only the future will show whether this problem can be neglected or circumvented (e.g., by targeted vectors).

In the area of oncolytic viruses, attenuated measles virus, which has a natural tropism for lymphoid tissue, has been examined preclinically. The incorporation of an anti-CD20 fusion peptide into the viral capsid retarded the growth of CD20-positive tumors in mice (Bucheit et al. 2003).

In summary, it comes as no surprise that hematologic malignancies as a systemic disease are the domain of immunologic approaches, which have demonstrated clinical success in several cases.

36.4.7 HEPATOCELLULAR CARCINOMA

Although HCC is of moderate epidemiologic relevance in the Western world, it is the most common cancer in large areas in Asia. HCC often remains localized to the liver, but only a minority of patients is amenable for local therapy such as surgery, liver transplantation, or cryoablation. Standard chemotherapy is largely ineffective. Therefore, HCC is a suitable target for intratumoral application of therapeutic genes. As demonstrated, adenovirus vectors can easily infect and express different types of genes in tumor cells of HCC (Sandig et al. 1997; Brand et al. 1999). In addition, the alpha-fetoprotein (AFP)-promoter is extremely HCC-specific (Ido et al. 1995) for achieving tumor-specific gene expression. Using adenovirus-mediated gene transfer, different experimental approaches were studied demonstrating significant tumor volume reductions by IL-12 (Bui et al. 1997), HSV-tk/GCV (Qian et al. 1997; Sa Cunha et al. 2002), and oncolytic adenovirus (Takahashi et al. 2002); combinatorial expression of p53 and p16 (Sandig et al. 1997) or p21 and GM-CSF using an EGF-receptor targeted adenovirus (Liu et al. 2002).

A pilot clinical study to assess the therapeutic potential of percutaneous intratumoral injection of wild-type p53 (wt-p53) in patients with primary hepatocellular carcinoma was initiated in 1996. Nine patients with primary hepatocellular carcinoma and six patients with colorectal liver metastases received percutaneous injections of a wild-type p53 DNA-liposome complex. In contrast to nonresponders with colorectal metastases, four of nine patients with HCC showed a reduction of tumor volume and a significant decrease in serum AFP levels (Habib 1995; Habib et al.

1996). A phase I trial was recently published, which compared intratumoral injection of ethanol with that of conditionally oncolytic replication-competent E1B55K-deleted adenovirus. In the gene therapy group, one patient showed a partial response and four patients had progressive disease. In the ethanol-treated group, two patients had stable disease and three patients showed disease progression (Habib et al. 2002). When hepatobiliary tumors were treated in a different trial, 50% of patients displayed a transient reduction of tumor markers (Makower et al. 2003). Besides RCAs other oncolytic viruses have been investigated. Excellent results with vesicular stomatitis virus (VSV)-derived vectors have been obtained in HCC-bearing rats and these vectors are currently investigated in the clinic (Shinozaki et al. 2004).

An antiangiogenic gene therapy approach has been pursued with a recently identified antiangiogenic factor, the pigment epithelium-derived factor (PEDF) the transfer of which resulted in antitumor efficacy in a murine HCC model (Matsumoto et al. 2004).

With respect to immunologic approaches transfer of the IL-12 cytokines to HCC gave good preclinical results (Barajas et al. 2001; Waehler et al. 2005). The results of a subsequent clinical phase I trial demonstrate the safety and feasibility of intratumoral injection of a first-generation adenoviral vector expressing IL-12 in primary and metastatic liver cancer patients (Sangro et al. 2004).

36.4.8 LUNG AND PLEURAL CANCER

In the Western world, lung cancer has become the most frequent tumor for males. The main reason for this is smoking; more than 90% of these patients are or were smokers. The prognosis of this cancer is bad. Due to regional or systemic metastases, tumors can be resected in only 25% of the patients. Only one-fourth of these patients will survive 5 years; only 6% of the patients are curable. Because of the tendency for early metastasis, gene therapy approaches aiming at a systemic response such as immunogene therapy are needed. A potent evocation of an immune response has only recently been reported in animal experiments (Esandi et al. 1998). Mesothelioma is a rare type of cancer originating from the pleura.

Because lung cancer metastasizes early, this tumor is a very difficult target for gene therapy. However, the high epidemiologic relevance of lung cancer creates an urgent need to develop alternatives to the standard therapeutic approaches. This is especially true for nonsmall cell lung cancer (NSCLC). Because NSCLC is in most of the cases highly resistant to any kind of chemotherapy and well-documented studies about genetic defects in NSCLC exist, this tumor was from the beginning an attractive target for the use of tumor suppressor genes, e.g., p53. Impressive results were obtained in preclinical studies: Significant tumor growth inhibition in subcutaneous and orthotopic animal models (Fujiwara et al. 1994; Zhang et al. 1994). Therefore, one of the first cancer gene therapy trials was initiated to treat NSCLC by gene transfer of

p53. A retroviral vector containing the wild-type p53 gene under control of a beta-actin promoter was used. Nine patients for whom conventional treatments had failed received direct injections into the tumor. Despite a low efficacy of gene transfer, and lacking evidence for an involvement of T-cell mediated immunity, partial tumor regression was noted in three patients and tumor growth was stabilized in three other patients (Roth et al. 1996). To improve the *in vivo* gene transfer efficacy, adenoviral vectors were used for p53 gene transfer in three additional studies (Schuler et al. 1998; Swisher et al. 1999; Kubba et al. 2000), and in three more studies p53 adenovirus was combined with chemotherapy (Nemunaitis et al. 2000; Weill et al. 2000; Schuler et al. 2001). In several patients in these trials, transient local control was observed. This was clearly attributed to the gene therapy treatment. Several more tumor suppressor genes have now been evaluated on preclinical models including FUS I (tumor suppressor, now in phase I), p16, and pRB (both targeting the cell cycle G1-restriction point), fragile histidine triad (FHIT) and proapoptotic TRAIL (for review, see Toloza et al. 2006).

Lung cancer has also been a model disease for antioncogene therapy. The K-ras oncogene is frequently overexpressed in lung cancer. Intratracheal transfer of retroviruses carrying an antisense K-ras construct markedly reduced tumor size and the number of lung tumors in nude mice (Georges et al. 1993). Another candidate for antisense therapy is the ErbB2 transmembrane protein kinase receptor whose aberrant expression has been shown to contribute to malignant transformation and progression. The promoter of the ErbB2 gene could be used for expression of toxic transgenes. Promoters that are activated by ionizing radiation (Weichselbaum et al. 1994) have also been used for this purpose. Researchers hope that sufficient specificity for tumor deposits will be achieved in the future, enabling even metastases to be efficiently transduced without toxicity for the surrounding normal tissue. Under these circumstances, the combination of gene therapy with conventional therapy could be a particularly attractive strategy as discussed above for p53 and cisplatin.

Using the powerful siRNA technology, preclinical antitumor efficacy was obtained by knock-down of the cell cycle regulator *skp-2* by intratumoral injection of adenoviral vectors harboring the respective *skp-2* siRNA for the treatment of subcutaneously established SCLC tumors (Sumimoto et al. 2005). Adenoviral vectors were also used for gene transfer of dominant negative insulin-like growth factor I receptor, which demonstrated antitumor effects in a preclinical model of lung cancer (Lee et al. 2003).

To date, there has been no published trial using suicide-gene therapy in patients with lung cancer. However, there are two reports of the treatment of patients with pleural melanoma (Molnar-Kimber et al. 1998; Sterman et al. 2000). In both trials, HSV tk-adenovirus was injected intratumorally and only minimal side effects were observed. A marked difference between the trials was that in one study, a high dose of glucocorticosteroids was applied to counteract

vector-related immune responses (Lin et al. 1998). In this study, partial tumor regressions were observed in some patients; two of them even remained tumor free 3 years after treatment.

Several phase I and II immunogene therapeutic clinical trials for the treatment of lung cancer have been conducted using the adenovirally GM-CSF-transduced allogenic NSCLC cell line GVAX (Simons et al. 1997). An interim analysis of 30 patients from a multicenter phase I and II trial demonstrated a major response rate in 18% of the patients, 10 of whom showed complete tumor remissions (Albelda et al. 2002). Complete clinical responses with this vector were observed in 3 out of 33 patients with advanced stage NSCLC (Nemunaitis et al. 2004). Less favorable outcomes were observed in a subsequent trial in which autologous tumor cells were admixed with allogeneic GMCSF-secreting tumor cells (Nemunaitis et al. 2006).

Partial regression of a lung mass was observed in one of 10 patients treated with IL-2-transfected TILs (Tan et al. 1996). Another immunogene therapeutic approach with promising preclinical results is the application of adenovirally IL-7-transduced DCs for the treatment of lung cancer (Miller et al. 2000). A clinical trial of direct intratumoral injections of vaccinia virus harboring IL-2 for the treatment of pleural mesothelioma led to diverse immunological responses although no significant tumor regressions were seen (Robinson et al. 1998).

Based on the observation that there is an imbalance of proangiogenic ELC+ and antiangiogenic ELC-CXC-chemokines in NSCLC samples, the ELC-CXC-chemokine MIG was transferred to NSCLC tumors, resulting in an inhibition of tumor growth and reduced vessel density in preclinical models (Addison et al. 2000).

In summary, some clinical efficacy with cancer gene therapy has been demonstrated. However, this is clearly neither satisfactory nor sufficient for this devastating disease.

36.4.9 MELANOMA

Malignant melanoma is a tumor of average incidence worldwide but with extremely high incidence in certain areas such as Australia. Worldwide, an annual increase in incidence of 6–7% was reported (Monson 1989). Melanoma is a tumor with a very high resistance to treatment. Treatment schedules including radiation, chemotherapy, and combinations of both have no significant impact on the overall survival of the patients (Ahmann et al. 1989; Ho and Sober 1990). Although the primary tumor can usually easily be excised, distant metastases cause the death of nearly all patients. Early and fatal metastasation is one reason why this disease is an important target for approaches like immunotherapeutic therapies from which a systemic antitumor efficacy can be expected. Fortunately, melanoma displays a naturally high immunogenicity, which facilitates the recognition of the tumor by the immune system.

Basically, all principles of immunomodulation described at the beginning of this chapter have been applied to melanoma. Trials in melanoma alone account for 54% of all open immunogene therapy trials in the United States. At the

time of writing, the number of clinical immunogene therapy studies for melanoma worldwide exceeds 50. The earliest trials were based on the transfer of TNF-transduced TILs (Rosenberg et al. 1990). Phase I trials are now closed, but due to minor success, no further trials entirely focusing on TILs have been initiated. However, in a later trial, TILs obtained from a patient's tumor nodules were injected with the HLA-B7 molecule, expanded, and reinfused, and direct immunological effects were demonstrated (DeBruyne et al. 1996). The use of chimeric T-cell receptors with cytokine or melanoma antigen domains is an interesting approach in the area of adoptive gene therapy with genetically modified immune cells. In this approach, CD8+ T-cells are redirected to the tumor and create a favorable cytokine-rich environment (Yee et al. 1997).

Recently, much has been expected from adoptive transfer of DCs, which are probably the most potent antigen-presenting cells in the body. They are also easy to transfect with several vectors. DCs have been transduced *ex vivo* with tumor antigens and costimulatory molecules. MART-1 antigen-transfected DCs in particular generated MART-1 specific immunity and arrested the growth of established tumors (Ribas et al. 1997; Butterfield et al. 1999). In a clinical trial transfer of T-cells engineered to express a MART-1 targeted T cell receptor led to objective responses in two out of 15 patients (Morgan et al. 2006). Recently, it has been clearly shown that CD8+ T cells receive CD4 help directly through the receptor CD40 and that this interaction is fundamental for CD8+ T cell memory generation (Bourgeois et al. 2002). Intratumoral injections of DCs, which had been transduced *in vitro* with CD40-ligand, led to regression of injected as well as distant B16 melanoma nodules (Kikuchi et al. 2000).

The majority of preclinical and clinical data for melanoma immunogene therapy has been generated in vaccination trials. Vaccination is performed traditionally with autologous tumor cells, but allogeneic vaccines consisting of autologous fibroblast or standardized gene-transduced cell lines are used as well (reducing cost and time). Many human trials using either cytokines (e.g., IL-2, -4, -6, -7, -12, IFN- α , and IFN- γ) or costimulatory molecules have been completed or are still ongoing. The best results in clinical vaccination trials have probably been obtained with granulocyte-macrophage colony-stimulating factor (GM-CSF); this had already shown the greatest degree of systemic immunity among 10 different cytokines in preclinical models (Dranoff et al. 1993). In a melanoma vaccination trial with GM-CSF-transduced autologous melanoma cells, extensive tumor destruction and pronounced immunologic responses were observed in 11 of 16 patients (Soiffer et al. 1998). GM-CSF was also transferred intratumorally using vaccinia virus (Mastrangelo et al. 1999) or transfected into tumor cells to prime tumor-derived lymph node cells in a trial of adoptive gene transfer (Chang et al. 2000). Excellent responses, including complete remissions, have been obtained in both types of clinical studies.

More than 50 patients in five different studies have received intratumoral injections of HLA-B7 DNA using

liposomes (Hersh 1996; Vogelzang et al. 1996). DNA or protein was detected in the great majority of the patients. Toxicity not attributable to the mechanical irritations was the exception, and local or even general responses were seen in one-third of the cases.

Published results of a trial involving multiple intratumoral injections into melanoma metastases of a retroviral vector carrying the IFN-gene showed either stable disease or partial or complete response of the injected lesions (Fujii et al. 2000). In another trial, adenovirus was used to package the IL-24 (MDA-7) cytokine, which can induce cancer cell apoptosis. Following on two phase I trials, which reported systemic immune activation and local apoptosis (Tong et al. 2005) and even complete or partial response in 2/28 patients, a phase II trial is now under way.

Besides the immunological approaches illustrated above, which clearly dominate gene therapy of melanoma, preclinical suicide gene (Table 36.1), and tumor suppressor gene (p53) (Table 36.1) therapies have also been performed. Combinatorial approaches (e.g., cotransfer of suicide genes and cytokines) have resulted in additive tumor growth inhibition (Bonnekoh et al. 1995; Cao et al. 1998). A clinical phase I/II trial (Klatzmann et al. 1998) for suicide therapy of metastatic melanoma with retroviral HSV tk vectors resulted in significant tumor necrosis in three of eight patients despite a low transfection efficacy of less than 1%. Intratumoral injections of a p53 adenoviral vector for the treatment of patients with breast and melanoma metastases were associated with minimal toxicity and the detection of p53 mRNA in biopsies of injected tumors (Dummer et al. 2000).

In the preclinical stage, treatment of melanoma cells with oncogene Ha-ras (Jansen et al. 1995) or c-myc (Putney et al. 1999) specific antisense oligonucleotides led to good antitumor efficacy in SCID mice. The application of dominant negative Stat3 cancer-related gene led to tumor regressions due to massive apoptosis (Putney et al. 1999). In one clinical trial for the treatment of malignant melanoma with dacarbacin and antisense-bcl-2, one complete remission has been observed (Lebedeva 2001).

In summary, the preclinical and in particular the clinical results obtained with immunogene therapy of melanoma are among the most encouraging findings in the field of cancer gene therapy.

36.4.10 OSTEOSARCOMA

Osteosarcoma primarily afflicts young people within the first decades of life and accounts for 5% of all childhood malignancies (Hudson et al. 1990). The overall 2-year metastasis-free survival rate approaches 66% (Link et al. 1986; Goorin et al. 1987). Metastases, mainly to the lung, are the predominant cause for mortality. Therefore, immunological approaches such as the *in vivo* transfer of the B7 gene (Hayakawa et al. 1997) may be particularly fruitful. However, the osteocalcin promoter constitutes an available tissue-specific promoter, which potentially allows systemic or regional treatment with cytotoxic genes. It has already been proven to be efficient

in vivo in an adenoviral context (Ko et al. 1996). The osteocalcin promoter expressing the adenoviral E1A gene to allow for tumor-specific replication has been proposed for intravenous application in a clinical trial for the treatment of metastasized osteosarcoma (Benjamin et al. 2001). Other successful preclinical approaches include aerosolic adenovirus-IL-12 (Worth et al. 2000), PEI-IL-12 (Jia et al. 2002), or PEI-p53 complexes for the treatment of lung metastases; adenovirus-IL-3- β gene transfer for isolated limb perfusion (de Wilt et al. 2001); and intratumoral injection of retrovirus VPCs-HSV tk (Charissoux et al. 1999).

36.4.11 OVARIAN CANCER

Ovarian cancer is the leading cause of death from gynecological malignancies in women (Ko et al. 1996). Due to improvements in surgery, radiation, and chemotherapy techniques, the 5-year survival rate has improved over the last 20 years. However, over two-thirds of the patients have advanced stage disease at presentation; despite transient responses, the long-term survival of these patients rarely exceeds 15%–30%. Although even patients with advanced stages often have their disease confined to their abdomen for extended periods of time, intraperitoneal chemotherapies have only moderate success. Basically, this is because they do not provide the reduced toxicity profiles initially hoped for. Therefore, ovarian cancer has become one of the model diseases for gene therapeutic approaches with intracavitary vector applications.

Several clinical studies have been initiated with HSV-tk as transgene in which vectors or modified cells were applied intraperitoneally. Transfer of adeno-HSV tk at doses up to 1×10^{11} pfus led to stable disease in 5 of 14 patients and transient fever in four patients. Transient hematologic grade 3 and 4 toxicities were observed if an adeno-HSV tk was combined with topotecan chemotherapy, but since toxicity was not related to vector dose, these side effects are more likely related to the chemotherapy (Hasenburg et al. 2001). In a vaccine/suicide trial with patients receiving irradiated PAI-1 ovarian cancer cells, *ex vivo* transfected with HSV tkHSV tk, a high incidence of fever and abdominal pain was seen in several patients along with resolution of ascites or decreased CA-125 levels (Buttgereit and Schmidt-Wolf 2002). Results of a trial using retroviral VPCs (Link et al. 1996) have not yet been published.

Phase I trials have also been initiated for adenoviral delivery of an anti-erbB-2 single chain antibody gene (Deshane et al. 1995; Alvarez and Curiel 1997). This intrabody approach could become a potent alternative to antisense strategies. In a clinical trial, adeno-anti-erbB-2 was injected intraperitoneally. Despite the relatively low dose of up to 1×10^{11} pfus, 5 of 13 evaluable patients had stable disease (Hasenburg et al. 2001).

The results of two trials using p53-adenovirus have been published. In one trial, 2 of 11 patients had a partial response, four patients had stable disease, and no major toxicity was reported despite multiple injections of up to 3×10^{12} viral particles (Alvarez et al. 2000). In the second phase I/II trial enrolling 36 patients, adeno-p53 was administered either

alone or combined with chemotherapy at single or multiple doses. A comparison with historical controls led the authors to suggest one of two explanations: either the combination of chemotherapy and gene therapy had a synergistic effect or gene therapy changes the nature of the cancer, contributing to a chronicity of the disease that favorably impacts survival (Buller et al. 2002a,b).

A trial with replication-competent adenovirus showed significant toxicity but no efficacy (Vasey et al. 2002).

Finally, intraperitoneal injection of a retrovirus harboring a BRCA-1 splice-variant showed partial responses in 3 of 12 patients in a phase I study. However, the lack of any response led to an early termination of a subsequent phase II study (Tait et al. 1997, 1999). The authors discuss differences in tumor burden and immune system status of the patients as possible reasons for the differing response to BRCA1 gene therapy. Liposomal transfer of adenoviral E1A in a reduction of the tumor marker CA-125 and one stable disease but grade 3 and 4 toxicity in 9/12 patients (Madhusudan et al. 2004).

In summary, intracavitary gene therapy of ovarian cancer showed clinical antitumor effects with immunologic and nonimmunologic approaches.

36.4.12 PANCREATIC CANCER

This disease has a low incidence but a very bad prognosis, mainly because the primary tumors are not resectable at the time of discovery. It accounts for only 2% of all newly diagnosed cancers in the United States but for 5% of all cancer deaths (Kasuya et al. 2001). Moreover, the tumors are highly chemoresistant. Partial remissions of up to 15% of the cases have been seen with the new drug gemcitabine (Mertelsmann 1998), which remains the standard chemotherapy at present.

More than 80% of pancreatic tumors contain a mutation of the ras oncogene in position 12 (Abrams et al. 1996). Since this mutation (as well as others) is recognized by the immune system, ras-peptide based immunotherapy has been successful in mice. Clinical studies have been performed and an association between prolonged survival and an immune response against the vaccine was seen (Gjertsen et al. 1996; Abrams et al. 1997; Gjertsen et al. 2001). Recently, antigen-presenting cells, genetically modified to express tumor antigen, were shown to induce antigen-specific cytotoxic T cell responses *in vitro* and *in vivo* (Kubuschok et al. 2002). H-ras antisense oligos have also been used in a phase II clinical trial and clinical stabilization was seen in two out of 16 patients (Perez et al. 2001). The combination of this oligo with gemcitabine in a phase II study including 48 patients with metastatic pancreatic cancer was well tolerated and led to one complete remission and one partial remission (for review, see Bhattacharyya and Lemoine, 2006). More recently, the combination of genetic expression of K-ras and IFN- α has shown overadditive preclinical efficacy (Hatanaka et al. 2004). Clinical efficacy has been observed by the combination of gemcitabine with the oncolytic

adenovirus Onyx 015 (Hecht et al. 2003) whereas application of Onyx 015 alone had no antitumor efficacy in a number of clinical trials (Kirn 2000). In preclinical studies, a different oncolytic adenovirus alone inhibited tumor growth, which was attributed to an inhibition of VEGF production and subsequent inhibition of angiogenesis (Saito et al. 2006).

Effective preclinical gene therapy for pancreatic cancer was also seen by combining oncolytic conditional replication-competent adenoviruses and IL-2 or IL-12 adenoviruses (Motoi et al. 2000). Replication-deficient IL-2 adenoviruses were used in a phase I/II trial for digestive cancer and a single intraoperative intratumoral injection did not cause any adverse effects (Gilly et al. 1999). Mild liver toxicity and mild antitumor effects were observed if patients with advanced GI-cancer including seven patients with pancreatic cancer were given intratumoral injections of IL-12 adenovirus (replication defective) (Sangro et al. 2004).

In a phase I study, allogenic pancreas cells engineered to secrete GM-CSF were intradermally applied and three patients who had received higher doses of cells seemed to have increased survival times (Jaffee et al. 2001). A combination of a tumor antigen, several immunostimulatory genes harbored by two sequentially applied immunogenic viruses (vaccinia and fowlpox) (PANVAC-VF, Petruccio and Kaufman 2006) is probably in the most advanced stage of clinical examination since recently a phase III trial has been completed. This indicates that at least in immunogene therapy, a combination of synergistic principles may be highly beneficial.

The cell cycle inhibitor p16 (G1/S transition) is frequently mutated in pancreatic cancer. Although adenoviral expression of p16 in pancreatic cell lines induced significant suppression of proliferation (Kobayashi et al. 1999), apparently no preclinical or clinical studies have been published. Larger phase I and II trials have been initiated to treat pancreatic carcinoma patients with a retroviral vector transferring a gene designed to interfere with the cell cycle driver cyclin G1 (Rexin-G). In a preceding phase I trial, three out of three patients experienced tumor growth arrest with two patients experiencing stable disease (Gordon et al. 2004). This drug is the first injectable gene therapeutic agent to achieve orphan drug status from the U.S. Food and Drug Administration (Gordon and Hall 2005).

The tumor suppressor smad4, which is inactivated in more than 50% of pancreatic cancers, has shown tumor growth inhibition in immunodeficient mice after adenoviral gene transfer (Duda et al. 2003).

Because the local disease is often life-limiting in pancreatic cancer, the disease is attractive for cytotoxic gene therapy approaches (Aoki et al. 1995; Block et al. 1997; Evoy et al. 1997). A combination of HSV oncolysis and HSV tk/GCV cytotoxicity increased the percentage of mice with peritoneal pancreatic tumors obtaining significantly prolonged lifespan to 70% as compared to 40% with oncolysis alone (Kasuya et al. 1999). A very interesting trial used *ex vivo* suicide gene-transduced autologous tumor cells for localized activation of

chemotherapy. Genetically modified allogeneic cells, which expressed a cytochrome P450 enzyme, were encapsulated in cellulose sulfate and delivered by supraselective angiography to the tumor vasculature. These cells locally activated systemically administered ifosfamide. The tumors of four of 14 patients regressed after treatment and those of the other 10 individuals who completed the study remained stable. Median survival was doubled in the treatment group by comparison with historic controls and 1-year survival rate was three times better (Lohr et al. 2001).

siRNA technology has recently been utilized for knockdown of the antiapoptotic bcl-2 oncogene, which is overexpressed in most pancreatic cancers. Intraperitoneal administration of bcl-2 siRNA delayed the growth of pancreatic cancer xenografts (Ocker et al. 2005). Also directly targeting tumor cell apoptosis adenoviral gene transfer of TRAIL (tumor necrosis factor-related apoptosis-inducing ligand) either alone (Katz et al. 2003) or in combination with gemcitabine (Jacob et al. 2005) significantly suppressed pancreatic tumor growth. The transgene is driven by the tumor-specific human telomerase transcriptase (hTERT) promoter in this vector.

Another approach aiming at tumor-specific transgene expression is the use of radiation-inducible promoters. The TNFerade vector is an adenovirus, which delivers the TNF- α cytokine under the control of such a radiation-inducible promoter. Based on response rates of 85% inkling, two complete responses in patients with soft tissue sarcoma (Mundt et al. 2004), TNFerade is now in late phase II clinical trials. Larger studies are conducted for other cancers including pancreatic cancers as well (Senzer et al. 2004; McLoughlin et al. 2005).

36.4.13 PROSTATE CARCINOMA

Prostate cancer is the most frequently diagnosed cancer in men in the United States and the second leading cause of death from malignancy (Carter and Coffey 1990; Boring et al. 1994). Locally restricted tumors can be treated by surgical resection or radiotherapy. Androgen-ablative therapy often induces dramatic responses, but virtually all patients progress to an androgen refractory state with a median survival of 12–18 months. The prostate is a unique accessory organ and expresses several hundred unique gene products as potential targets for gene therapy especially for tumor-specific gene expression. Prostate cancer can therefore serve as a model disease for tumor-specific gene therapy. The efficacy and specificity of the PSA promoter has been proven in animal experiments (Gotoh et al. 1998). This promoter has also been used to confer prostate-specific replication of conditionally replication-competent adenoviruses (Rodriguez et al. 1997). A clinical trial using this vector for injection into locally recurrent prostate carcinoma provided relative safety with no grade 4 toxicity and a more than 50% reduction in PSA levels in all patients treated with the highest dose (DeWeese et al. 2001).

Prostate cancer has proven to be highly responsive to immunomodulatory gene therapy. The most advanced drug is probably GVAX™, a GM-CSF secreting vaccine created with

lethally radiated prostate cancer cell lines. Currently, a phase III trial is ongoing in which GVAX™ is compared to the standard chemotherapy for metastatic hormone-refractive prostate cancer (docetaxel plus prednisolon). Initiation of such a trial was possible because a number of phase I/II trials had shown survival times greater than in historical controls (Simons and Sacks 2006), declines of PSA levels, and stabilization of bone scans (Simons et al. 2006).

A second approach that had extensive clinical testing with encouraging clinical results (for review, see Stanizzi and Hall 2007) is the use of immunogenic viruses such as vaccinia virus, fowlpox virus, or adenovirus expressing candidate antigens such as PSA either alone or in combination with costimulatory molecules or cytokines.

Other immunogene therapy trials include direct intratumoral injection of liposomal IL-2 plasmid led to decreases in serum PSA levels in 80% of patients (Pantuck et al. 2000); Vaccinia virus MUC-1-IL-2 also decreased PSA levels (Pantuck et al. 2000). A large-scale phase II study based on a fowlpox/Muc-1 virus is under way (Liu et al. 2004).

As an example of gene replacement therapy, a trial with direct injection of retrovirus-BRCA-1 should be mentioned: while it did not reveal any antitumor efficacy, it did at least demonstrate the safety of the approach (Steiner and Gingrich 2000).

Clear objective responses were observed when an adenovirus-HSV tk vector was injected into the tumorous prostate. At the highest treatment dose, PSA levels declined by 50%. However, reversible grade 4 thrombocytopenia and grade 3 hepatotoxicity occurred (Herman et al. 1999). Importantly, an adenoviral vector harboring the HSV tk gene under the control of the prostate cancer cell-specific osteocalcin promoter has made it into a clinical trial, which demonstrated the absence of severe toxicity and necrosis, apoptosis, and the induction of T-cells in 64% of treated patients (Kubo et al. 2003). Such a vector utilizing tissue-specific gene expression holds the promise to widen the therapeutic window.

When combined with radiation therapy, Ad-HSV tk approaches proved to be superior to historical controls (Teh et al. 2001), which apparently is due to HSV tk/GCV acting as a radiation sensitizer. If combination therapy included a replication-competent adenoviral vector harboring the HSV tk gene, PSA half-life was significantly shorter than reported for patients treated with radiotherapy alone (Freytag et al. 2003). The promising toxicity profile was further improved by using second generation adenoviruses (Freytag et al. 2007).

Successful preclinical experiments have been reported for the transfer of the anti-IGF-1 receptor (Burfeind et al. 1996), p21 (Eastham et al. 1995), p53 (Eastham et al. 1995; Ko et al. 1996), p16, and antisense myc (Steiner et al. 1998). Three clinical trials have already been initiated with antisense myc.

Immunogene therapy of prostate cancer is in the forefront of candidates for approval for clinical application in the Western world. The future use of prostate-specific regulatory elements for expression of suicide genes or conditional replication-competent viral vectors holds promise in the treatment of disseminated disease, the major cause of death in prostate

cancer patients. Treatment will eventually be possible if systemic application of the vectors harboring cytotoxic genes can be done without major toxicity.

36.5 CONCLUSIONS

We have now seen nearly two decades of clinical gene therapy. A wide variety of vectors and transgenes have been successfully tested in animals. Several types of vectors and many different therapeutic principles have been evaluated clinically, producing more than 850 studies of cancer gene therapy.

The general outcome of these clinical studies indicates that gene therapeutic vectors are usually tolerated with mild to medium acute toxicity. The toxicity has been reversible in all cases. No cases of long-term toxicity have been reported. In the majority of clinical trials, at least some efficacy was seen. In some trials, a clear benefit for the patient was observed in comparison with either historical controls or (in some exceptional cases) with internal controls. Apparently, in all cases where the best results in clinical trials have been achieved, the cancer target was naturally most well suited to current cancer gene therapeutics. Examples of this are the good accessibility of superficial bladder cancer for intravesically installed viruses, the easy access to manifestations of head and neck cancer for the intratumoral transfer of replication competent vectors, and the good infectability of HCC by adenoviral vectors or of glioblastoma by HSV (which is a neurotrophic virus by nature). Particularly encouraging results have been obtained in many immunogene therapeutic trials, which do not depend as heavily on efficacy of gene transfer as nonimmunologic approaches. The sometimes astonishing modulability of vectors gives rise to the hope that cancers that are less well-suited for cancer gene therapy will also have particular vectors designed against them.

Although most clinical studies were designed as phase I or phase I/II trials with the aim of dose finding and toxicity evaluation, the lack of a real breakthrough in clinical efficacy has been disappointing at least for those who had envisioned a very rapid development of gene therapy into a routine treatment modality. The discrepancy between excellent preclinical data and the clinical outcome has been particularly difficult to understand, especially for the public. There are several reasons for this discrepancy. First of all, animal models are artificial models, which have inherent simplifications as compared to the clinical situation. A well-known argument is that animal tumors are usually developed from one fairly homogenous cell line, whereas human tumors are often very heterogeneous though they have also originated from a single clone. Consequently, a strategy, which targets one specific molecular event in an animal tumor, may only be effective against a fraction of tumor cells in a patient. But there are less sophisticated reasons such as the mere difference in size of tumors between a rodent and a human. This may also dramatically affect clinical outcome. Another explanation is that dose-limiting toxicity has not been reached in most of the trials performed so far. In addition, mice are probably more robust and will probably tolerate higher doses. It is evident that some

kinds of treatments well tolerated in mice would hardly ever be considered for humans.

Other setbacks for cancer gene therapy have included the first severe adverse events in gene therapy: the death of a young man in a trial for the metabolic disorder OTC and the occurrence of three cases of leukemia in what was a very successful trial for SCID up to that point.

All these considerations lead to the conclusion that the therapeutic window of most cancer gene therapeutic strategies is apparently still too narrow to allow prominent antitumor efficacy. However, nearly all kinds of medical therapy have been confronted with this problem during their development into routine clinical applications. This therapeutic window can be broadened by either creating less toxic medicines, which allows one to increase the dose, or by creating more efficient medicines, which allows one to obtain efficacy without the necessity of increasing the dose. Both avenues have been followed in cancer gene therapy. An example of a less toxic vector is HD-Ad as compared to first-generation Ad. An example of a more efficient therapeutic principle is the combination of conventional suicide gene strategies with replication-competent viral vectors to increase the efficacy of gene transfer. A third strategy, which allows a reduction in the dose without losing efficacy, is vector targeting, either in the form of transductional or transcriptional targeting. This extremely promising approach will eventually reveal the real potential of gene therapy: the design of intelligent drugs that are capable of overcoming intelligent cancer.

But will not the design of small molecular drugs be intelligent enough to solve the cancer problem? Do we need gene therapy if small molecules can do the job? Especially if one considers the recent genomics-related dramatic increase in knowledge about potential drug targets? Maybe, in some cases. Admittedly, the use of a vehicle to transfer a gene into the human body is less direct and usually more complicated than conventional methods of cancer therapy. However, the interposition of several steps between the application of an active substance and the generation of an observable effect allows an unusual high degree of freedom of regulation. In cancer gene therapy, one can comply with the biology and especially the weak spots of the cancer cells to a degree never seen before. Fortunately, nature seems to be predictable to a certain degree, which makes such complex therapeutic strategies possible. Since we are still far away from such a tight adaptation of our vectors and transgenes to the specificities of the cancer cells; it comes as no surprise that to date clinical efficacy of cancer gene therapy has not been convincing. However, the potential fruitfulness of a new method cannot be judged by its initial success but rather by the general limitations of the whole concept. Since in the area of cancer gene therapy such limitations have not yet been seen, a broad breakthrough in therapeutic efficacy will most likely be a matter of time.

The prevalence of diabetes worldwide has been on the rise over the last century. According to the International Diabetes Federation (IDF), the disease affects 246 million people worldwide in 2006. The IDF projects that, if nothing is done, the total number will skyrocket to 380 million by 2025 [1]. In the United States, the rise in incidence has been especially steep in the last decade [2]. The increase in incidence is also accompanied by a relative decline in the risk of death among diabetic patients, at least in men [3], which further increases the overall prevalence of the disease. It is projected that if the rate of increase continues, almost 50 million people in the United States will carry the diagnosis of diabetes by the year 2050 [4].

Most diabetic patients do not die of the acute complications such as diabetic ketoacidosis, which are becoming increasingly uncommon as a cause of death, as they are mostly preventable by modern therapy. Patients with diabetes live longer lives and are increasingly being afflicted by the chronic complications [5]. These include the microvascular complications of retinopathy, nephropathy, and neuropathy, and the macrovascular complications resulting from the consequences of accelerated atherosclerosis, including myocardial infarction and stroke.

Diabetic complications are thus the major cause of morbidity and mortality among type 1 and type 2 diabetics. The pathogenesis of the chronic complications is complex. There is good evidence that inadequately controlled hyperglycemia

is an all important causative factor. The best way to prevent or delay the onset of complications is the prevention or reversal of hyperglycemia.

Recent developments in therapy have greatly expanded our armamentarium in tackling the disease. As a consequence, blood glucose control of most diabetic patients today is much better than that accomplished only a decade ago. However, despite the introduction of different kinds of diabetes medications, it is still impossible to consistently reverse hyperglycemia in diabetes without occasional or frequent hypoglycemic episodes [6]. The problem is that it is very difficult, if not impossible, to attain physiological blood glucose control using oral agents or parenteral medications.

A biomechanical artificial pancreas is one way of restoring euglycemia. In theory, a well-designed closed loop system can accomplish this without significant risk of hypoglycemia. Unfortunately, a portable, user-friendly, and foolproof system is not yet available despite intense research in industry over the last few decades [7]. In the meantime, academic investigators and industry have initiated research programs to develop cell and gene therapy for diabetes based on increasing understanding of islet development and immune dysregulation in type 1 diabetes and the interacting signaling networks and metabolic interactions of different organs underlying the insulin resistance and β cell failure in type 2 diabetes (Figure 37.1).

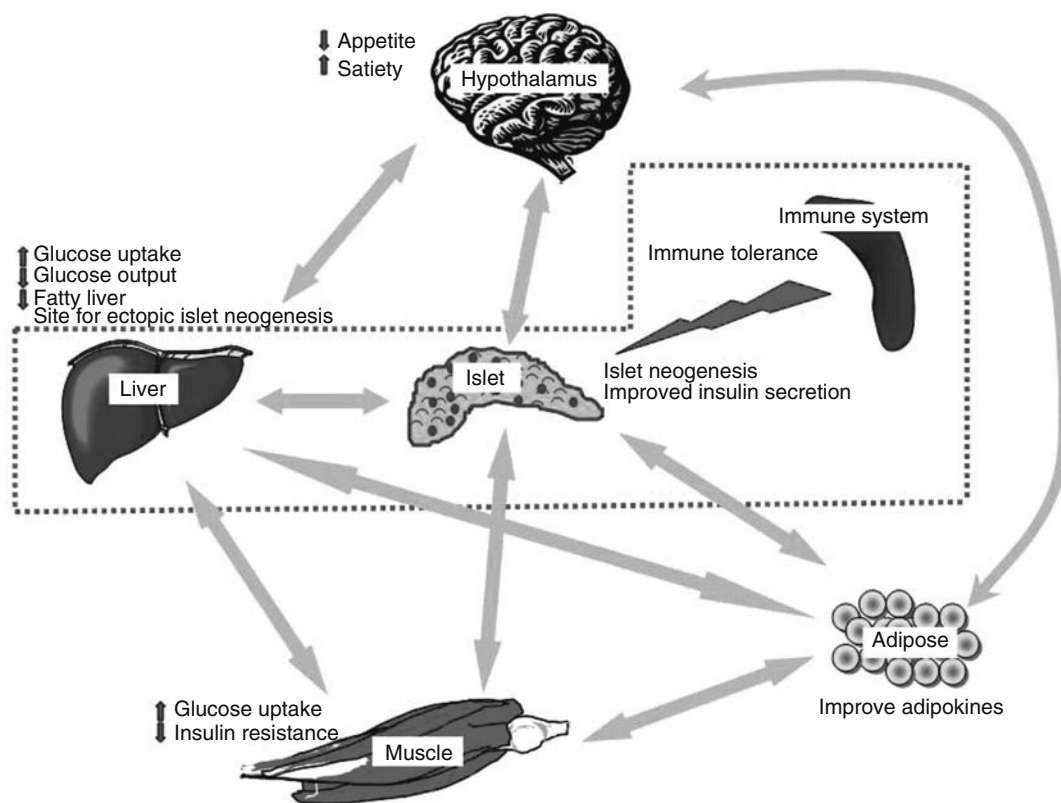

FIGURE 37.1 Interacting signaling networks of organ systems underlying diabetes mellitus. All of these are targets for therapy for type 2 diabetes. Type 1 diabetes targets, represented by the dashed box, are primarily limited to the pancreas, liver, and the immune system. The desired therapeutic effects in each organ are listed.

37.1 GENE THERAPY FOR TYPE 1 DIABETES MELLITUS

This chapter deals exclusively with *in vivo* gene therapy, as it is the method of choice at the present time because the regimen can be delivered to a recipient like a pharmaceutical reagent. A major challenge is the development of safe efficient vectors for *in vivo* gene delivery, which is the subject of other chapters in this volume.

There are two major problems to be addressed in any curative treatment of type 1a diabetes, the autoimmune form of diabetes that is the cause of severe β cell destruction in the vast majority of type 1 patients leading to absolute insulin deficiency and hyperglycemia. The approaches for *in vivo* gene therapy to correct the underlying metabolic derangements in diabetes, all with the ultimate objective of restoration of euglycemia [8], can be broadly divided into three strategies that involve the delivery of genes to express (1) glucose-regulatable insulin, (2) proteins that facilitate glucose utilization or inhibit hepatic glucose production, and (3) developmental/transcription factors that induce the production of new β cells. The last approach must be coupled with a strategy to address the autoimmune β cell destruction to protect the newly formed islets from persistent immune attack. In fact, there is recent evidence that even in long-standing type 1a diabetes, the pancreas continues to make valiant though futile

attempts at regeneration [9]. Thus, gene therapy to correct, or circumvent, the autoimmunity, could by itself enable β cell regeneration to take place, leading to improvements in islet function. Modulation of autoimmunity has been tried both as a primary and secondary prevention strategy in mouse models; at this time, it could have potential practical application only as a secondary prevention approach in humans as discussed later in this chapter.

37.1.1 GENE THERAPY TO ADDRESS THE HYPERGLYCEMIA AND METABOLIC DERANGEMENTS

Some of the strategies discussed in this section can be applicable in type 2 diabetes and those discussed in the section on type 2 diabetes may also find application in type 1 diabetes therapy. Many of the strategies reviewed below have been tested in type 1 insulin-deficient animal models.

37.1.1.1 Transfer of Glucose-Responsive Insulin Transgene

The vast majority of publications on diabetes gene therapy involve the delivery into liver cells of versions of the insulin gene, which have been modified (i) either to make the proinsulin expressed susceptible to processing into mature insulin or to obviate the need for processing and (ii) to render gene

expression responsive to changes in blood glucose concentration [10,11]. As liver cells do not produce the islet prohormone convertases Pc1/3 and Pc2, many investigators have introduced new proteolytic cleavage sites into the proinsulin molecules that are recognized by furin, a protease present in many tissues including liver cells [12–15]. Alternatively, the insulin gene can be modified to encode single-chain insulin [16], which has 20%–40% of the activity of normal mature insulin [17]. The most challenging part of insulin gene therapy is to confer glucose responsiveness to insulin transgene expression that mimics that of normal β cells, wherein, the onset of hyperglycemia is met with an almost instantaneous burst of insulin (in less than a minute) from primed preformed insulin-containing vesicles, the first phase response followed by a more sustained delayed response resulting from transcriptional and translational regulation, the second phase response. The most popular strategy to accomplish this objective has been the use of different glucose-responsive promoters, e.g., promoters from phosphoenolpyruvate carboxykinase (PEPCK, [18]) gene, elements from the L-pyruvate kinase gene [19], the glucose-6-phosphatase [20], and other genes (reviewed in Refs. [10,21]), which allow the insulin transgene transcription to be upregulated by hyperglycemia within 1–2 h, and stimulated insulin protein production and secretion within 3–4 h. The increased insulin production and secretion also take a long time to be turned off when blood glucose is normal or low. Because of the lag in the secretory response, glycemic control by transcriptionally regulated insulin transgenes is erratic and hypoglycemia is a major complication. Another approach is to control secretion at the level of endoplasmic reticulum by drug-induced protein disaggregation [22]. However, any manipulation requiring pharmacological agents defeats the purpose of gene therapy, as there is considerable flexibility with the wide array of pharmacological therapy using the different forms of insulin formulations that are currently available.

37.1.1.2 Transfer of Genes Other Than Insulin to Lower Blood Glucose

There are two types of noninsulin transgenes, which have been used to lower blood glucose: (i) transgenes that inhibit glucose production in the liver and (ii) those that enhance glucose utilization by the liver or skeletal muscle.

In the first group, glucokinase (Gck) gene transfer in rodents has been used by many different groups [23–27]. Although Gck has been categorized as a transgene that lowers glucose production in the liver [28], hepatic glucose production was not measured in any of these studies and it is likely that a major downstream effect of Gck is increased glucose utilization [24]. High-dose Gck gene transfer causes hyperlipidemia and fatty liver [24,27], and Gck gene transfer is best used as adjuvant treatment (a debatable role for gene therapy) to complement insulin therapy [27]. Gck regulatory protein gene transfer produces a very similar effect as Gck gene transfer [29]. A mutant form of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase has been used to activate

phosphofructokinase-1 and to simultaneously inhibit fructose-1,6-bisphosphatase to downregulate gluconeogenesis. Its overexpression has been shown to downregulate glucose-6-phosphatase and upregulate Gck levels, stimulating glucose disposal and inhibiting hepatic glucose production in a mouse model of type 2 diabetes [30]. Another way to downregulate hepatic glucose production is to divert the glucose to glycogen by overexpression of protein targeting to glycogen (PTG) [31,32]. PTG is a member of the family of glycogen-targeting subunits of protein phosphatase-1 that regulate glycogen metabolism. Adenovirus-mediated transfer of PTG stimulates glycogen synthesis in the liver and lowers blood glucose in rats, and represents a potential therapeutic approach to diabetes gene therapy [31]. As alluded to earlier, hepatic overexpression of Gck appears to enhance glucose utilization and thus is one of the potential therapeutic genes that simulate glucose disposal. Interestingly, skeletal muscle overexpression of Gck also stimulates glucose disposal and protects against hyperglycemia in streptozotocin (STZ)-induced diabetic mice [33].

In summary, there are different strategies to modulate blood glucose by targeting genes (other than insulin) that affect glucose production and utilization. However, most of these represent adjuvant therapy. Gene therapy may not be the best strategy for upregulating enzymes that modulate glucose metabolism; a better strategy to target enzyme activity is the screening and development of small molecular weight compounds (e.g., see Ref. [34]), a time-honored method that has worked well in pharmaceutical companies.

In addition to the enzyme overexpression approach summarized above, different gene therapy strategies to downregulate gene specific gene expression have also been tested. Most of the targets are applicable to both type 1 and type 2 diabetes and will be discussed later in the section on type 2 diabetes.

37.1.1.3 Transfer of Developmental/Transcription Factors to Induce the Production of β Cells in the Liver

An increasing understanding of the ontogeny of pancreatic and islet organogenesis has enabled investigators to initiate studies on gene therapy-based induced islet neogenesis as a curative therapy for diabetes. In comparison with insulin transgene delivery, induction of new islets/ β cell formation has many potential advantages (Table 37.1). Strategies to induce new β cells, either in the pancreas or more commonly in the liver, have been tested in different laboratories in the last few years with some encouraging results.

To understand the rationale underlying gene therapy-induced islet/ β cell neogenesis as a form of therapy, it is necessary to briefly review the development of the pancreas and the pancreatic islets. The pancreas develops during embryogenesis by cell-type specification and subsequent differentiation orchestrated, in the gut endoderm, by various transcription factors including, among others, Hlx9, Sox9, Pdx1 (also known as Ipfl), Hex, Isl1, Ptf1a, Hes1, and Ocl1 [35,36]. A distinct multipotent progenitor cell population in the developing

TABLE 37.1

Limitations of Insulin Gene Therapy as Compared to Native or Induced Islets/ β Cells

Islet/ β Cells	Insulin Gene Therapy
Regulated by the insulin promoter	Usually by a glucose regulated promoter
Post-transcriptional regulation	None
Post-translational regulation	None
Have a first phase and second phase response due to primed preformed insulin granules	Only one phase that lags in response
Other islet cell contribution	None

pancreas that is Pdx1⁺ Ptf1a⁺ cMyc^{High}Cpa1⁺ and negative for differentiated lineage markers ultimately produces the exocrine, endocrine, and duct cells [37]. Once the ventral and dorsal pancreatic buds develop, the endocrine cell specification is initiated in them by the bHLH transcription factor neurogenin3 (Ngn3) within the domain of Pdx1-positive cells [38–40], which is accompanied by a suppression of notch signaling in these cells. This results in the determination of the islets of Langerhans that ultimately produce important hormones that control glucose homeostasis, including insulin from β cells. Ngn3 turns on a downstream cascade of transcription factors including Neurod1, Pax6, Isl1, Pax4, Nkx2.2, Nkx6.1, and MafA in β cells and Arx and Brn4 to specify glucagons-secreting α cells. Investigators interested in induced islet neogenesis as a therapeutic approach have postulated that in competent lineages, induced expression of some of these transcription factors may cause the target cells to differentiate into islet or β cell types.

Attempts to use the pancreas as the target organ to induce islet neogenesis have been limited primarily by the technical difficulty of getting the gene into the target cell type. Recent work demonstrated that adenoviral vectors may be used to transfer gene payloads to the pancreas either retrograde through the pancreatic duct, or by intravenous injection via systemic circulation, or via the duodenal vein [41–43]. In contrast to the pancreas, the liver is a much more accessible target for various vectors, e.g., adenovirus “naturally” targets the liver efficiently [44], and, alternatively, hepatic gene delivery can be readily accomplished for almost any vector by catheter-based delivery via the hepatic artery or portal vein.

Pdx-1 is the master regulator of pancreatic organogenesis, the lack of which leads to agenesis of the pancreas [45,46]. Pdx-1 expression thus defines the pancreatic (both exocrine and endocrine) lineage. Investigators have attempted to take advantage of this in using Pdx-1 to induce islet/ β cells. There was initial success at lowering blood glucose levels up to 10 days in insulin-deficient STZ-induced diabetic mice that were treated intravenously with first-generation adenovirus expressing Pdx-1 (FGAd-PDX-1). The glucose-lowering effect was ascribed to the induction of rare insulin positive cells in the liver though the blood insulin level remained uncorrected [47]. Subsequently, it was noted by others that there was coexpression of trypsin, a pancreatic exocrine enzyme, in the

insulin-producing cells in the liver. With expression of Pdx-1 in the liver at a level that would influence glucose homeostasis, the concomitant production of exocrine enzymes was found to lead to severe morbidity and substantial mortality resulting from a fulminant hepatitis caused by ectopic pancreatic enzyme production in the absence of a normal pancreatic ductal system to divert the locally produced digestive enzymes into the intestine [48]. In a different model, conditional transgenic expression of Pdx-1 in albumin-producing cells in the liver was also found to lead to considerable morbidity and mortality associated with hyperbilirubinemia and severe hepatic dysmorphogenesis, caused by the concomitant production of exocrine enzymes (elastase and chymotrypsinogen 1B) in cells in the liver that also expressed endocrine markers (islet hormones including insulin) [49]. This was not an unexpected outcome as Pdx-1 is a master developmental factor that specifies both endocrine and exocrine lineages in the gut endoderm from which both liver and pancreas develop. Hence, application of Pdx-1 as the sole transgene would not be the best strategy for inducing β cells in the liver *in vivo*.

To avoid the problems with Pdx-1, others have used endocrine lineage-specific factors that are downstream of Pdx-1, such as Ngn3, Neurod1, and MafA. These have been used singly, in combination, and along with Pdx-1. Hepatic delivery of hybrid adeno-associated virus (AAV) vectors carrying Ngn3, Neurod1, and MafA has been shown to lower blood glucose levels in diabetic mice [50], with expression of insulin and other islet markers in the liver. Hepatic delivery of a combination of Pdx-1 with Neurod1 and MafA produced similar results in another laboratory [51]. The latter group also tested a modified version of Pdx-1, one fused with the strong transactivation domain of herpes simplex virus protein VP-16, and noted that, when delivered with Ngn3 or Neurod1, the modified Pdx-1 effectively reversed hyperglycemia in insulin-deficient mice [52]. All studies reviewed above involving Pdx-1 and downstream factors consisted of short-term observations that were made within 2 weeks of gene delivery. One recent study used hydrodynamic delivery to coinjected naked DNA constructs of Ngn3 with an adenovirus carrying an unrelated gene (which by itself had no effect) in STZ-diabetic mice led to correction of hyperglycemia in these animals up to 2 months after treatment [53]. The most promising data to date involved the hepatic delivery of Neurod1 by

helper-dependent adenovirus (HDAd), by itself or in combination with an islet growth factor (beta cellulin), in STZ-diabetic mice. The treatment induced the appearance of clusters of insulin-positive cells in the liver, a complete reversal of hyperglycemia, and restoration of plasma insulin and glucose tolerance for over 4 months of observation [48]. The liver cells isolated from the treated mice exhibited pancreatic β cell markers and functions, including glucose-stimulated insulin secretion. They also responded appropriately to glibenclamide, a sulfonylurea class of drug used in diabetic patients, similar to the response seen with pancreatic β cells. However, the newly formed insulin positive cells coexpressed other islet hormones, in contrast to adult islet cells that each normally expresses only a single hormone. The occurrence of neo-islet cells that express multiple islet hormones suggests that they are immature islet cells, as insulin-glucagon double positive cells are seen commonly during embryonic islet development.

The function of many transcription factors involved in β cell development has been determined by the use of knockout mouse models, and many were found to play key roles in normal islet organogenesis and β cell function; their effects when overexpressed ectopically often have been short of expectation. This probably stems from the fact that these transcription factors act in lineage-competent cells during embryonic development. It is unclear if they are competent in inducing the complete *trans*-differentiation of already differentiated cells like hepatocytes into a fully differentiated endocrine pancreas lineage. *Trans*-differentiation has been defined as the lineage switching from one differentiated state to another with an intervening undifferentiated intermediate stage. Although *trans*-differentiation was claimed in several of the reports cited above, none of the aforementioned studies have rigorously examined whether lineage switching from the treated hepatocytes to an islet lineage has indeed happened.

Mechanistic experiments are clearly needed for future studies on induced islet neogenesis to determine if true *trans*-differentiation has occurred. Unlike induced differentiation from a progenitor cell population, long-term stable induced *trans*-differentiation from another differentiated lineage is a tall order for a transcription factor and for gene therapy. Thus, if we want to generate new islets to treat diabetes, the identification of receptive progenitor cells that are competent to differentiate into an islet cell lineage is an important component of any gene therapy regimen utilizing lineage-defining transcription factors.

37.1.2 GENE THERAPY TO MODULATE IMMUNE DERANGEMENT

Immune modulation is an important therapeutic strategy in type 1a diabetes. It finds application in the disease at multiple levels: (1) As alluded to earlier, there is evidence for persistent foci of islet neogenesis in the pancreas of most type 1 diabetics, even after many decades of disease. It is conceivable that long-term success with correction of autoimmunity in a type 1a diabetic might eventually lead to restoration of β cell function. Even a small improvement in insulin reserve may convert

a brittle diabetic to a much more stable one, as exemplified by the improvements shown by some type 1a patients who have been treated by islet transplantation who exhibit minor improvement in insulin requirement but marked improvement in the quality of life because of reversal of their "brittleness" [54]. (2) It can be used to circumvent the toxic immunosuppression cocktails given to type 1 diabetics after islet transplantation. (3) It may be an essential adjuvant therapy for induced islet neogenesis. Regimens that successfully induce islet neogenesis in STZ-mice have been found to work very poorly in autoimmune models due to the inflammatory response to the neo-islets (Yechool et al. unpublished results). One approach is to use standard immunosuppressive therapy to prepare the diabetic animal (or eventually, patient) for the islet induction, but an attractive strategy is to modulate the immune system, either locally or systemically. There have been some primary prevention strategies that have been attempted in mouse models of autoimmune diabetes that may hold promise as secondary prevention strategies for immune modulation in concert with inducing new islets/ β cells. These have predominantly focused on genes to modulate the known β cell death-inducing cytokine pathways such as IFN- γ , TNF- α , IL-1 β , and methods to induce tolerance [55–63].

Immune modulation by gene therapy is discussed in detail elsewhere in this book; we will discuss below specific aspects that are applicable to type 1 autoimmune diabetes. Immune modulation by inducing tolerance to known antigens or by expressing known autoimmune-resistant MHC Class II genotype related proteins has had some success in both preventing diabetes in nonobese diabetic (NOD) mice and also in reversing some of the insulinitis associated with established diabetes. In these studies, GAD 500–585 (glutamic acid decarboxylase, an autoantigen) transferred via an AAV vector intramuscularly [64] or transferred as a fusion protein with an immunoglobulin chain using a retroviral vector *ex vivo*, to stimulated splenocytes and then transferred into prediabetic NOD mice [65], decreased insulinitis and the incidence of diabetes significantly in treated mice by eliminating autoreactive T cells and enhancing the protective suppressor T regulatory (Treg) cells. Similarly, proinsulin fused with the cholera B toxin and expressed by a recombinant vaccinia virus in prediabetic NOD mice decreased the incidence of diabetes significantly [66]. Unfortunately, none of these approaches have demonstrated long-term success nor have they been shown to be effective as a secondary prevention measure in established diabetes, making their application to human autoimmune diabetes untenable at this time. Another strategy is to express the autoimmunity-resistant genotype-associated MHC Class II I-A1 β molecule on autologous bone marrow stem cells *ex vivo* by retroviral transduction; although effective for primary prevention in NOD diabetes, it has not been tested for treating clinically overt autoimmune diabetic animals [67].

Other successful strategies for primary prevention include approaches that target the autoreactive T cells using systemic IL-10, IL-4, and TGF- β to change the immune response from a destructive Th1 response to a protective Th2 response. Systemic overexpression of IL-10 administered as a single

intramuscular injection using rAAV vector induces Treg (CD4 + CD25+) cells *in vivo* and significantly reduces insulinitis in treated animals while completely preventing diabetes in NOD mice [56]. Interestingly, gene therapy of diabetic NOD mice with FGAd-TGF- β not only induces native pancreatic islets to regenerate but also protects syngenic islets after transplantation from being destroyed by autoimmunity [68]. An increase in Tregs was once again seen with this approach. An *ex vivo* approach by infecting dendritic cells with adenovirus carrying IL-4 [69] or converting antigen-specific diabetogenic T cells into Tregs by retroviral transduction of Treg-defining transcription factor FoxP3 [70] *ex vivo* and subsequently infusing them into prediabetic NOD mice was effective in primary prevention of diabetes. Similar studies abound with similar results; we have selected the examples above as representative of the approaches and preliminary outcomes [71].

In summary, many approaches have been used to induce tolerance with the common pathway being the induction of Tregs and a switch from a destructive Th1 response to a protective Th2 response. Studies testing secondary prevention of autoimmunity in animal models are few and wanting in rigor in establishing efficacy and durability of response. In human diabetes, there are no available markers that identify at risk patients definitively before the onset of overt diabetes, making it impractical to implement immune modulation as a primary prevention strategy. However, if an *in vivo* gene therapy induced islet neogenesis proves efficacious, it is paramount that adjuvant strategies be developed to induce tolerance to these neo-islets. Hence, gene therapy for type 1a diabetes would involve a combination of new islet induction to correct the β cell deficit and immune modulation of autoimmune-mediated suppression of Treg cells to allow the neo-islets to survive. The ideal scenario is to administer genes to accomplish both objectives in the same gene therapy regimen such that one can reverse diabetes in individuals with overt type 1a diabetes in a single treatment.

37.2 GENE THERAPY FOR TYPE 2 DIABETES MELLITUS

As discussed above, a major goal of gene therapy for type 1 diabetes mellitus is to replenish insulin production and secretion, and the most successful approach may be through the development of “neo-islets” using expression of pancreatic developmental transcription factors. The importance of immune destruction in the pathogenesis of type 1 diabetes also requires that new avenues are explored to circumvent or dampen autoimmunity to protect the newly formed β cells.

Gene therapy for type 2 diabetes mellitus (Dm2) has its own unique challenges because it is the culmination of two pathologic processes: insulin resistance and β cell failure [72]. Through most stages of this disease, there is hyperinsulinemia, rather than the absolute insulin deficiency seen in type 1 diabetes. Hyperglycemia occurs because the insulin levels are inadequate due to peripheral insulin resistance.

Even though high levels of insulin can be secreted under these circumstances, diabetes occurs because of relative β cell failure, since the β cells are unable to secrete enough insulin to meet physiologic requirements and maintain glucose homeostasis. Over the long term, the overtaxed β cells gradually will lose their glucose-sensing and insulin-secretory abilities, and absolute insulin deficiency will become an issue. Boosting insulin production through islet neo-genesis or cell replacement therapies, as described for type 1 diabetes, potentially could assist in reducing the relative insulin deficiency of β cell failure in Dm2. However, this does not correct the pathogenic contributions of insulin resistance, which is the stress that drove the endogenous β cells to “exhaustion” in the first place. Further, intrinsic defects in the native β cells are now believed to exist in many of the Dm2 patients, which contributed to their failure; replacement β cells or neo-islets may suffer a similar fate under the challenge of insulin resistance. Therefore, a comprehensive gene therapy approach to Dm2 requires a two-pronged tactic: namely, that both problems of insulin resistance and β cell failure be addressed (Figure 37.2).

37.2.1 GENE THERAPY TO COMBAT INSULIN RESISTANCE

Identification of Dm2-associated genes has the potential to provide new targets for pharmacologic and gene therapies to prevent or reverse Dm2. However, Dm2 is considered by many to be a polygenic disease, so that replacement of a single “deficient” gene product may not have significant effects overall. Also, there are large contributions by environmental and epigenetic factors, which contribute to the development of diabetes [73]. Perhaps the most crucial of these factors is obesity. The dramatic increase in the prevalence of Dm2 parallels that of obesity in developing as well as developed nations, emphasizing its contribution to the development of Dm2 mostly through increased insulin resistance. However, not all obese individuals develop diabetes, reminding us that both genetic and environmental factors combine to cause Dm2.

37.2.1.1 Targets for Peripheral and Central Control of Obesity

The mechanisms by which obesity leads to insulin resistance are multifold and are the focus of many research laboratories. In simple terms, with excess adipose tissue, there is an increase in circulating free fatty acids, which are directly responsible for inducing insulin resistance, likely through their intracellular accumulation in key metabolic tissues, liver and muscle, leading to impaired insulin signaling [74–76]. Adipose tissue is not an inert storage tissue, but is actually an endocrine organ, secreting both adipokines (such as adiponectin, leptin, and resistin), as well as cytokines (such as TNF α and IL-6), which are dysregulated and also have pathologic effects on insulin signaling [76,77]. Therefore, reducing adipose tissue mass can abrogate a key factor in the pathogenesis of insulin resistance leading to Dm2.

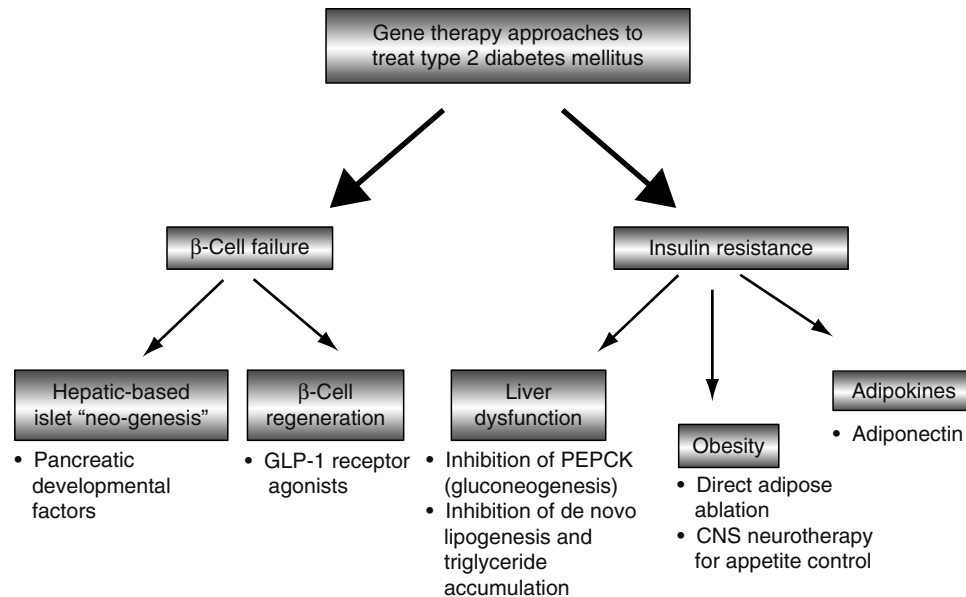

FIGURE 37.2 Variety of gene therapy approaches have been applied to treat type 2 diabetes, obesity, and β cell failure in rodent models. (Abbreviations: CNS, central nervous system; GLP-1, glucagon-like peptide-1; PEPCK, phosphoenolpyruvate carboxykinase.)

37.2.1.1.1 Peripheral Adipose Tissue Ablation

To tackle the problem of obesity, the gene therapy approaches can be direct, attacking the adipocytes themselves, or indirect by inducing a decrease in energy intake and increase in energy expenditure to result in a negative energy balance and weight loss. The direct approach has been demonstrated using molecular therapy with targeted ablation of adipose tissue in an obese mouse model. Using phage-display techniques, Kolonin et al. [78] identified a novel peptide motif, which targets adipose blood vessels specifically via specific surface proteins or “zip-codes” on the vasculature. By linking the fat “homing-peptide” to an apoptotic signal (called KLAKLAK), which causes cell death, peptide treatment of *Lep^{Ob/Ob}* mice resulted in a sustained reduction in adipose tissue mass, decreased lipid accumulation in muscle and liver, and increased energy expenditure. Importantly, there were no phenotypic manifestations of lipodystrophy, namely insulin resistance and dyslipidemia, and fat ablation actually improved glucose homeostasis. In this respect, if this form of treatment proves safe and efficacious in humans, it may be superior to surgical liposuction. A well-controlled study involving obese women with or without diabetes showed that surgical liposuction does not improve glucose or lipid homeostasis, or ameliorate diabetes, despite the removal of over 20 kg of fat [79]. A major difference between adipose reduction by liposuction and targeted apoptosis of adipose-specific vasculature is that liposuction selectively removes subcutaneous fat whereas targeted vasculature apoptosis simultaneously ablates visceral and subcutaneous fat, because adipose depots in different parts of the body appear to share similar “zip-codes” in their vascular supply. Visceral fat differs markedly from subcutaneous fat in its metabolism and secretory profile [76,80] and visceral fat

expansion is associated with much more deleterious metabolic consequences than is subcutaneous fat expansion [80,81]. Targeted adipose tissue vasculature ablation as a form of molecular therapy for obesity and Dm2 is being tested in nonhuman primates.

37.2.1.1.2 Central Appetite Regulation

Another approach to induce weight loss is by decreasing food intake or increasing energy expenditure, or both. A large portion of the integration of peripheral nutrient and energy signals takes place in the central nervous system (CNS), mainly in the hypothalamus and the brainstem [82]. The hypothalamus is housed adjacent to the third cerebral ventricle and contains important neural nuclei involved in appetite regulation [82,83]. The neuropeptide Y (NPY) neurons in the arcuate nucleus (ARC) express NPY, agouti-related peptide (AgRP), and GABA, which stimulate appetite (orexigenic). Other neurons are anorexic and express the product of the cocaine- and amphetamine-regulated transcript (CART) and the pro-opiomelanocortin (POMC) peptide, which is processed to produce α - and β -melanocyte stimulating hormone (MSH) [84]. MSH acts to decrease appetite through melanocortin receptors (MCR3 and 4) in the paraventricular nucleus (PVN), dorsomedial (DH), ventromedial (VMH), and lateral (LH) regions of the hypothalamus, as well as the nucleus of the solitary tract in the brainstem [82,85]. These two opposing sets of orexigenic and anorexigenic neurons are regulated by signals from the periphery.

Leptin is secreted from adipose tissue and acts centrally at receptors on the hypothalamic neurons to increase satiety by inhibition of NPY neurons and activation of POMC neurons [84,86]. Activation of the leptin receptor on hypothalamic

neurons activates several intracellular signal transduction pathways including JAK/STAT3, phosphoinositide-3-kinase (PI3K), and mitogen-activated protein kinase (MAPK) [82,87]. STAT3 phosphorylation increases transcription of the POMC gene but reduces that of NPY. An opposing peripheral signal is ghrelin, which is released from specialized oxyntic cells in the stomach to stimulate appetite through activation of NPY neurons and inhibition of POMC neurons. These peripheral signals are able to reach the hypothalamus through a permissive blood brain barrier (fenestrated capillaries) or specific transport mechanisms [88–90].

The centralized nature of appetite control and energy expenditure provides a target for gene therapy. However, one challenge is that systemic approaches, such as liver-based expression of anorectic peptides, may not be potent enough to have effects in the hypothalamus. A physiologic example of this problem is that of leptin. Leptin levels increase proportionately with adipose tissue mass, which would be expected to inhibit central appetite centers, causing decreased energy intake in the face of obesity. In genetically obese mice lacking leptin (*Lep^{ob/ob}*), adenovirus-mediated peripheral leptin therapy is partially effective in causing decreased food intake and weight loss [91,92]. This mouse model is a monogenic deficiency of the Ob (leptin) gene, and direct replacement of leptin is expected to be successful. However, the promise of leptin therapy for the treatment of generalized obesity has not been realized due to central leptin resistance [86,93,94]. In high-fat diet (HFD) rodent models, there is decreased STAT3 phosphorylation with CNS leptin injections compared to nonobese controls, suggesting that there is a postreceptor defect leading to leptin resistance [95]. Moreover, the higher peripheral leptin levels that accompany obesity are unable to compensate because leptin transport mechanisms appear to be saturable, providing a second mechanism for leptin resistance [88,89].

There may also be decreased local leptin expression from hypothalamic neurons, further contributing to central leptin “insufficiency” in obesity [86].

If peripheral therapies are unlikely to succeed to control appetite, one solution is to directly target appetite centers in the CNS using “neurotherapy.” Vectors derived from AAV are the most common gene therapy tool used for CNS transduction. AAV serotypes 2, 3, and 5 have tropism for neuronal tissue and have been shown to transduce brain cells when directly injected into CNS regions of interest [96–98]. These vectors are replication-deficient and virtually nonimmunogenic [97]. The minimal spread of the AAV vectors throughout the brain may be a disadvantage when more global CNS gene therapy is desired, such as for Alzheimer’s disease or lysosomal storage disorders, but it is sufficient for transduction of discrete areas in the hypothalamus for appetite regulation. Compared to AAV, FGAds may have less utility due to their immunogenicity and the wide distribution of their receptor, the coxsackie and adenovirus receptor (CAR) [99]. To solve this problem, more cell-type restricted transgene expression is accomplished using neuronal cell-specific promoters [99]. HDAds also have been studied, which are less toxic and much better tolerated. Canine adenovirus-2 (CAV-2) is able to transduce neural tissues and transgene expression is detectable in striatal neurons, the substantia nigra, and the basal nuclei of Maynert 1 year after striatal injections [100] suggesting that further development of these vectors may have important applications for long-term gene therapy in the CNS.

Directed injection of gene therapy vectors into the CNS of rodents is accomplished under anesthesia using specialized stereotaxic injection equipment and specific coordinates (Figure 37.3; [97]). Both intracerebroventricular and direct hypothalamic injections have been successful for studies of

(A)

appetite regulation using AAV in rodent models [101–103]. Overexpression of leptin in the hypothalamus decreases appetite and weight gain in most rodent models of obesity, unlike with systemic leptin gene therapy [86,104,105]. The expressed leptin also is able to override an orexigenic stimulus by exogenously administered ghrelin [105]. AAV-mediated leptin expression in the hypothalamus was shown to decrease body weight in regular chow and HFD fed rats [106,107]. Only some of the weight loss was explained by reduced food intake because pair-fed control rats had higher weights at the end of the experiment [106]. One explanation was the finding that expression levels of uncoupling protein-1 (UCP-1) were upregulated in the brown adipose tissue (BAT) of central leptin-treated rats, causing increased thermogenesis to promote energy dissipation [106,107]. AAV-leptin treatment of HFD-fed rats also displayed improvements in triglycerides, free fatty acids, and reduced insulin levels compared to pair-fed mice, suggesting that central leptin expression improves peripheral metabolic parameters beyond the effects of weight loss [107]. However, in this study, HFD feeding was started at the time of AAV treatment and was more of a prevention than a treatment study [107]. Other groups who have studied central AAV-leptin gene therapy administered after chronic feeding with HFD have not observed such marked effects [108]. With long-term HFD, only control chow fed and HFD-resistant rats showed appropriate hypothalamic STAT3 phosphorylation and increased BAT UCP-1 expression in response to leptin, while HFD susceptible rats failed to show these responses to central leptin gene therapy [108].

There may be other approaches to circumvent leptin resistance. Leukemia inhibitory factor (LIF) is a member of the IL-6 cytokine family and has anorectic effects [82]. The LIF receptor shares homology with the CNS leptin receptor (Ob-R) and is present on neurons in the rat hypothalamus including the PVN and ARC nucleus [109]. The LIF receptor is part of the class I cytokine receptor family and causes phosphorylation of STAT-3 similar to leptin [82]. A single intracerebroventricular injection of AAV-LIF has been shown to decrease food intake and body weight in rats over several weeks, suggesting that LIF and its receptor may constitute another possible target to combat obesity [110].

Central gene therapy using downstream mediators of leptin, such as POMC, also has been successful for the regulation of appetite in rodent models of obesity. Zucker fatty (*fa/fa*) rats are deficient in leptin, like *Lep^{Ob/Ob}* mice. AAV-mediated POMC overexpression in the ARC nucleus of *fa/fa* rats results in decreased food intake and visceral adiposity with a concomitant improvement in glucose homeostasis and insulin resistance [101]. During aging, increased weight gain and leptin resistance are observed in rodent models on regular diet, but central AAV-leptin gene therapy is able to abrogate the effects of aging in F344/BN rats [111]. One caveat is that the central POMC gene therapy does not have similar effects in young, lean rodents. In fact, POMC gene therapy paradoxically increased diet-induced obesity when lean rats were challenged with an HFD [112]. Although the underlying mechanisms are not fully understood, the findings were attributed to MCR

desensitization or overriding orexigenic signals in lean animals. AAV-POMC expression in the brainstem nucleus solitarius also results in similar, but more prolonged, anorectic effects in aging obese rats compared to hypothalamic expression, which may be due to a lack of counter-regulatory orexigenic neurons in this region [85].

Our knowledge of appetite regulation is increasing exponentially through experiments in animal models of hyperphagia and obesity. In addition, the repertoire of available anorexigenic peptides is expanding. There are at minimum over 28 neuropeptides known to inhibit appetite (Table 37.2) [87]. Many of these peptides are produced in the periphery by the gastrointestinal tract including cholecystokinin (CCK), glucagon-like peptide 1 (GLP-1), oxyntomodulin, amylin, and peptide tyrosin-tyrosine (PYY_{3–36}) [87,90]. Others are produced centrally in the hypothalamus: brain-derived neurotrophic factor (BDNF), melanin-concentrating hormone (MCH), prolactin-releasing peptide (PrRP), and galanin-like peptide (GALP) [113]. As their mechanisms of action become better defined, these peptides may also prove efficacious for central gene therapy approaches to appetite and obesity. The major challenge in applying this approach to combat obesity is to devise methods that ensure sustainability over time, and to develop treatment methods that circumvent repeated CNS deliveries.

37.2.1.2 Other Targets for Glycemic/Metabolic Control

37.2.1.2.1 Adiponectin Gene Therapy

The majority of adipokines and cytokines secreted by adipose tissue have negative effects on insulin sensitivity and glucose homeostasis. With increased adiposity, elevated secretion of these molecules is pathogenic, leading to the metabolic dysregulation seen with obesity. One exception is the adipokine, adiponectin (Acpr30), which circulates in high levels in the serum ($\mu\text{g/ml}$ quantities), with a concentration that is inversely correlated with adipose tissue mass and insulin resistance [77,114]. Adiponectin is one of few endogenous molecules that can be exploited to increase insulin sensitivity. The impact of adiponectin on glucose homeostasis and metabolism is significant. Enhanced secretion and circulation of adiponectin in a transgenic mouse model is able to rescue the insulin-resistant phenotype caused by leptin deficiency in *Lep^{Ob/Ob}* mice even though the treatment causes increased weight gain and fat mass [115]. Several mechanisms contribute to the positive effects of adiponectin on glucose homeostasis and insulin sensitivity. These include increased lipid oxidation in skeletal muscle, decreased free fatty acid flux and uptake by the liver, and decreased hepatic glucose production [77,114,116]. Systemic overexpression of adiponectin using gene therapy technology has had promising results in animal models of obesity and insulin resistance. For liver-based expression and secretion, intraportal injection of AAV-adiponectin into rats decreased food intake and weight, with an improvement in glucose tolerance [117]. Similar results were obtained in a diet-induced obesity mouse model with minicircle gene

delivery of adiponectin, which demonstrated improved fasting glucose and insulin sensitivity as measured by homeostatic model assessment [118].

37.2.1.2.2 Hepatic Enzyme Gene Therapy

Liver is a metabolically active tissue, which responds to nutrient signals mediated by insulin and its counter-regulatory hormones, such as glucagon. Elevated glucose, such as after a meal, induces insulin secretion, which will suppress hepatic gluconeogenesis and glycogenolysis and promote glucose storage as glycogen. The effects of insulin are direct, at the level of the hepatocyte, as well as indirect, through inhibition of glucagon secretion from the pancreatic islet. Both mechanisms are impaired in insulin resistance and type 2 diabetes, contributing to hyperglycemia.

One approach to decreasing hepatic glucose output in both type 1 and type 2 diabetes is to directly inhibit the expression of enzymes required for hepatic gluconeogenesis. However, inhibiting gene expression by gene or molecular therapy is more challenging than simple overexpression. The synthesis of a protein can be inhibited by repression of

translation or degradation of its message using interfering RNA (RNAi) [119]. Once a specific RNAi is confirmed to be effective, its sequence can be expressed *in vivo* using plasmid-based or viral vector approaches. PEPCK is the rate-limiting enzyme for the initial step in gluconeogenesis. Gomez-Valades et al. [120] used hydrodynamic systemic injection of a plasmid to express a short-hairpin RNA (shRNA), which significantly decreased hepatic PEPCK expression and activity, was found to normalize glucose tolerance in STZ-diabetic mice.

Glucokinase is the glucose-sensor for β cells and the first step in metabolism of glucose by hepatocytes (see discussion earlier in chapter under therapy for type 1 diabetes). Glucokinase (GcK) activity in the liver is controlled by binding to its regulatory protein (GKRP), which sequesters GcK in the nucleus [121]. GKRP has been described as an inhibitor of GcK activity, which releases GcK to translocate to the cytoplasm only in the presence of high glucose. However, GKRP appears to protect and stabilize GcK so that adenovirus overexpression of GKRP in the liver of HFD mice improved glucose metabolism, with decreased fasting glucose and insulin as discussed earlier in this chapter (under type 1 diabetes therapy) [29].

Additional effects were decreases in circulating free fatty acids and triglycerides.

Other possible hepatic targets have been revealed by the use of antisense oligonucleotides to repress the expression of enzymes involved in hepatic lipid metabolism. Obesity leads to hepatic steatosis because of increased free fatty acid flux from adipose tissue and uptake by the liver; there is also increased de novo lipogenesis and reesterification of fatty acids to be stored as triglycerides [122]. Hepatic steatosis then completes the circle by interfering with insulin signaling. If the accumulation of hepatic lipid can be prevented, hepatic insulin sensitivity can be restored. For example, diacylglycerol acyltransferase (DGAT2) is the final enzyme in the production and storage of liver triglycerides [123,124]. Inhibition of DGAT2 expression resulted in decreased liver triglyceride accumulation along with improved hepatic and peripheral insulin sensitivity measured as increased glucose uptake and insulin signaling [124]. Similarly, inhibition of other enzymes, such as acetyl CoA carboxylase [125], and stearoyl-CoA desaturase-1 [126] has led to parallel decreases in hepatic fat accumulation and insulin resistance.

37.2.2 GENE THERAPY FOR β CELL FAILURE

Although obesity and ensuing insulin resistance contribute to the development of type 2 diabetes, hyperglycemia would not develop if the β cells could compensate for the increased insulin requirements. The familial nature of many cases of Dm2 implies that there is an important inherited component. Although obesity is a risk factor, not all obese individuals develop diabetes, suggesting that those who do have diabetes, an intrinsic and likely heritable defect that allows β cell failure [72,127]. The identification and characterization of genes involved in β cell failure will be an important step toward preventing and curing Dm2.

Over the last decade, geneticists have attempted to identify single genes associated with Dm2, with the greatest success from genome-wide association and candidate gene studies [128–130]. These methods have identified variants in genes encoding the potassium inwardly rectifying channel (*KCNJ11*), involved in the function of the β cell sulfonylurea receptor, and peroxisome proliferator-activated receptor- γ , the adipocyte differentiation transcription factor. Other recently identified genes include variants of transcription factor-7-like 2 (TCF7L2) involved in WNT signaling [130,131], Calpain-10, which has a role in islet cell apoptosis [132], and others with less well-characterized functions [128].

Of all of the genes identified by genome-wide analysis, the association of the TCF7L2 gene to Dm2 is the strongest. TCF7L2 was identified through classical linkage analysis and genotyping of microsatellite markers among a cohort of type 2 diabetics in Iceland; this was further confirmed with cohorts from Denmark and the United States [133]. Homozygosity and heterozygosity for the “at risk” T allele increased the risk of type 2 diabetes by 2.41 and 1.45, respectively. The importance of TCF7L2 was further substantiated by genotyping

patients from the Diabetes Prevention Program [134], and the Scandanavian MPP and Botnia studies [135] with an increased risk for progression from impaired glucose tolerance to Dm2. Importantly, these individuals did not have increased insulin resistance, but instead had decreased insulin secretion, suggesting that TCF7L2 gene product influences β cell function [134]. Characterization of the β cell defects revealed a decreased “incretin” response [135]. Incretins are hormones released from specialized L cells in the intestine in response to an oral glucose load or a meal. The incretin hormones are GLP-1 and glucose-dependent insulinotropic peptide (GIP). Upon release, these peptides augment glucose-regulated insulin secretion from the β cell so that an oral nutritional load causes greater insulin secretion than parenteral glucose administration. GLP-1 receptor agonists have attracted much attention with their recent debut for clinical use in human diabetes. In long-standing Dm2, the first phase of insulin release can be dampened, but GLP-1 agonists improve the early β cell response, decreasing hyperglycemia. Significantly, TCF7L2 is involved in the transcription regulation of the pro-glucagon gene, which encodes GLP-1 and GIP. TCF7L2 also is implicated in WNT signaling, which has a role in β cell proliferation [135,136]. Although the consequences of TCF7L2 polymorphisms need further characterization, it seems reasonable that differences in incretin levels or action could regulate β cells and their ability to compensate for increased insulin resistance. In this way, incretins could be an important avenue to improve β cell function in Dm2.

It is convenient that GLP-1 is a peptide hormone, which makes it amenable to expression from gene therapy vector systems. One disadvantage is the short half-life of the peptide, which is degraded in minutes by peptidases, especially dipeptidyl peptidase IV (DPPIV). For this reason, attempts have been made to stabilize the GLP-1 peptide and to extend its half-life by rendering it resistant to DPPIV action. These approaches have included engineering amino acid substitutions in the GLP-1 sequence [137] or use of the similarly active but DPPIV-resistant exenatide (exendin 4) sequence from gila monster (*Heloderma suspectum*). Others have used peptide dimerization or noncovalent or covalent binding to albumin for extended systemic circulation [138].

In addition to their immediate effects on insulin secretion, GLP-1 receptor agonists are documented to increase functional β cell mass, at least in rodent model systems, through a decrease in apoptosis and an increase in β cell proliferation [139–141]. GLP-1 also contributes to regeneration of β cells after partial pancreatectomy [140]. For type Dm2, this property could be exploited to prevent β cell loss and to rebuild β cell mass after failure due to prolonged hyperglycemia. In both toxin-induced (STZ) insulin-deficient mouse model and an obesity model (*db/db*), adenoviral-mediated systemic expression of GLP-1 resulted in remission of diabetes, with restoration of insulin levels and increased insulin-staining cells in the pancreas [137,142]. Thus, prolonged expression of GLP-1 receptor agonists, such as from gene therapy vectors, may have potential to restore functioning β cells.

TABLE 37.3
Potential Contributions of GLP-1 to Improve Glucose Homeostasis and Insulin Sensitivity in Type 2 Diabetes

Tissue	GLP-1 Action
Islet	<ul style="list-style-type: none"> • Increased β cell mass • Augmented glucose-regulated insulin secretion (incretin effect)
Liver	<ul style="list-style-type: none"> • Increased insulin signaling • Decreased hepatic steatosis • Decreased gluconeogenesis
Muscle	<ul style="list-style-type: none"> • Increased glucose uptake • Increased insulin signaling
CNS	<ul style="list-style-type: none"> • Satiety and decreased food intake
Adipose tissue	<ul style="list-style-type: none"> • Weight loss

These peptides also have numerous other properties that make them attractive for Dm2 gene therapy (Table 37.3). They decrease the inappropriately high glucagon levels seen in type 2 diabetes, reducing the contributions of hepatic gluconeogenesis to hyperglycemia [143]. In addition to their desirable hormonal effects on insulin and glucagon secretion, GLP-1 receptor agonists appear to improve insulin sensitivity. Some of this effect may be promotion of weight loss since GLP-1 receptor agonists are documented to decrease food intake and body weight in both humans and rodents. Two different groups [137,144] have reported decreased food intake and decreased weight gain in hyperphagic rodent models of *fa/fa* Zucker rats and *Lep^{ob/ob}* mice, respectively, when they treated them with an FGAd expressing a GLP-1 receptor agonist. The decreased food intake is attributed to a slowing of gastric emptying and increased satiety [145]. Although the precise mechanisms remain to be elucidated, some of the properties may be mediated through effects on CNS feeding centers [146] such as through leptin [147], POMC [148], or CART [149].

In addition to effects on obesity, GLP-1 and its analogs also directly increase insulin sensitivity, which has been documented in several rodent systems. The insulin-sensitizing effects seen with GLP-1 receptor agonist infusion also is seen with the steady-state expression attained by gene therapy [144,150,151]. Adenoviral expression of GLP-1 in *Lep^{ob/ob}* mice improves insulin tolerance testing, an *in vivo* test of insulin sensitivity. Surrogate markers of insulin sensitivity also are improved, with increased insulin-stimulated phosphorylation of IRS-1 and PKC activity in muscle and liver and increased Akt phosphorylation in muscle [144]. Although one argument could be that improved insulin sensitivity is a direct result of decreased weight gain and fat mass, the improved insulin sensitivity weight in *fa/fa* rats was reported to be independent of changes in body weight [151].

From the above discussion, it is clear that GLP-1 receptor agonists have great potential for Dm2 gene therapy because they address the two key pathologic processes that lead to Dm2: β cell failure and insulin resistance. They accomplish this through multiple mechanisms which include: (1) promoting

increased β cell mass, (2) increasing insulin sensitivity through indirect (decreased weight) and direct mechanisms, and (3) decreasing hepatic glucose output.

37.3 CONCLUDING REMARKS

Type 1a diabetes is the clinical consequence of autoimmune destruction of β cells, whereas type 2 diabetes is a manifestation of a severely compromised β cell function in the presence of insulin resistance, often caused by obesity. Herein, we have summarized the recent advances in the molecular therapy of type 1a and type 2 diabetes. To date, all therapies are still at the preclinical phase. A major hurdle to moving these regimens toward clinical trial is the availability of safe and efficient vectors that are suitable for *in vivo* gene delivery in humans, an issue that is discussed in detail in other chapters. Despite this limitation, we have witnessed important developments in diabetes gene therapy in the last two decades, including many exciting proof-of-concept experiments. Diabetes is a serious growing health problem worldwide that justifies a continued search for novel treatment options, including gene therapy.

ACKNOWLEDGMENTS

Research performed in the authors' laboratories that was discussed in the chapter was supported by U.S. National Institutes of Health Grants R01-HL51586, DK068037, R21-DK075002, K08-DK68391, and by the Betty Rutherford Chair in Diabetes Research at Baylor College of Medicine and St. Luke's Episcopal Hospital in Houston, the Iacocca Family Foundation, and the T.T. and W.F. Chao Global Foundation.

38.1 INTRODUCTION

Cystic fibrosis (CF) is a common monogenic disorder affecting approximately one in 2500 Caucasian births in the United States [1]. The disease affects epithelia throughout the body including the lungs, pancreas, and the digestive system, but lung disease is the leading cause of morbidity and mortality [2]. Located on chromosome 7 [3–6], the CF gene encodes the CF transmembrane conductance regulator (CFTR) protein [7]. CFTR is a cyclic AMP-regulated chloride channel that is expressed in epithelial cells of the airways, sweat ducts, pancreatic ducts, intestine, and the vas deferens [8]. Over 1400 mutations within the CF gene have been identified that are associated with varying severities of disease [10]. The most common mutation, a deletion of phenylalanine (F) at position 508 of the protein product ($\Delta F508$), is found in 70% of CF chromosomes worldwide [9,10]. This mutation leads to a misfolded CFTR that is degraded in the endoplasmic reticulum such that little or no CFTR trafficks to the apical membrane of affected epithelia. The lack of CFTR at the apical membrane prevents secretion of salt and water into the luminal airway surface liquid periciliary layer. Because wild-type CFTR inhibits epithelial sodium channels (ENaC) in the apical membrane, absence of CFTR leads to uninhibited ENaC activity and enhanced sodium absorption from the lumen. The inability to secrete chloride combined with enhanced sodium absorption leads to a decrease in the height and volume of the

periciliary liquid layer on the luminal surface airway epithelia, resulting in decreased mucociliary and cough clearance of secretions, bacterial infection, inflammation, airways obstruction, lung destruction, and premature death.

Since CF heterozygotes exhibit a normal phenotype, introduction of a single normal copy of the gene into the defective CF epithelial cells should result in the restoration of the CFTR-mediated Cl^- transport function and a normal airway epithelial phenotype. *In vitro* studies suggest that as little as 6%–10% of normal CFTR function may be required to reverse the chloride channel defect [11,12], although enhanced sodium transport in CF airways may require correction of all the cells within the epithelium. These and other *in vitro* studies have established the feasibility of gene transfer for CF following introduction of a normal CFTR into CF airway epithelial cells using viral and nonviral vectors [13–17].

Identifying the cellular targets for CF gene transfer in humans has been controversial. The site where CF lung disease begins remains controversial with both the superficial columnar epithelial cells lining the lumen of the small airways and the serous cells of submucosal glands having been identified as potential sites. Clinical data support the theory that the disease begins in the small airways [16,17], whereas the submucosal glands were previously reported to be the predominant site of CFTR expression [18]. A subsequent study of CFTR expression in the lung with immunohistochemical and biochemical techniques demonstrated localization of

wild-type CFTR protein to the apical membrane of ciliated cells within the superficial epithelium and gland ducts, with little CFTR expression in the gland acinus and alveolar epithelial cells [19]. Current approaches have almost exclusively focused on luminal delivery of gene transfer vectors.

Despite its initial role as the prototypical disease for direct delivery of vectors for human gene transfer, progress toward development of gene therapy for CF has been disappointing due to a variety of host- and vector-specific barriers. In this chapter, we review the progress and pitfalls of gene transfer systems used in CF gene delivery, the barriers to gene transfer for CF, and the progress made in the development and application of these gene delivery systems to enhancing efficiency and overcoming these barriers.

38.2 CYSTIC FIBROSIS CLINICAL TRIALS UPDATE

More than 20 clinical gene transfer safety and efficacy trials have been performed in CF subjects with a variety of vectors [22]. Two clinical trials have been published in the past 4 years. One trial was based on the use of compacted DNA nanoparticles to deliver the CFTR transgene whereas the other trial used an adeno-associated virus-2 (AAV-2) vector to deliver the transgene to lower airways.

Konstan et al. performed a double-blinded, dose escalation, phase I clinical gene transfer safety and efficacy trial of intranasal administration of compacted DNA nanoparticles or placebo (saline) in 12 CF subjects. The vector in this trial consisted of single molecules of plasmid DNA carrying the CFTR gene compacted into DNA nanoparticles with 10 kDa polyethylene glycol (PEG) substituted poly-L-lysine peptides [20]. All subjects received either compacted DNA or saline in one nostril and saline (vehicle) in the other nostril (2 mL of each). However, because of spillage of vector into the contralateral nostril during vector administration, the saline nostril could not be used as a placebo control. The doses of the nanoparticles administered were 0.8, 2.67, or 8.0 mg. Primary end points of the trial were safety and tolerability with efficacy evaluation as a secondary endpoint.

Safety evaluation included serum and nasal washings for measurement of cytokine levels, complement, and C reactive protein. One subject demonstrated a transient elevation in serum IL-6, but no significant local or systemic toxicity was otherwise detected. No significant changes in complement or C reactive protein levels were measured either. Significant levels of vector DNA were observed in the nasal epithelial cells at 2 weeks following gene transfer. Efficacy as assessed by nasal potential difference measurements demonstrated partial to complete restoration of CFTR chloride channel function in 8 out of 12 subjects. The correction persisted for 6 days after gene transfer and for up to 28 days in one subject. Raised sodium transport as defined by a change in basal nasal potential difference (PD) with vector administration was not detected.

A randomized, double-blinded, placebo-controlled phase II clinical trial of repeated aerosol delivery of an AAV2-CFTR

vector to the lower respiratory tract of CF subjects was performed by Moss et al. [21]. The primary end points were safety and tolerability of repetitive administration of aerosolized AAV2-CFTR vectors. The vector or placebo was delivered to the lungs of 37 CF patients with mild lung disease by inhalation of three aerosolized doses. Twenty subjects received at least one dose of the vector and 17 subjects received placebo. Thirty days after vector administration, a small improvement in FEV1 was measured in the subjects who received the tgAAVCFTR as compared to placebo controls. No significant toxicity was detected in this study and a significant decrease in IL-8 levels in subjects randomized to the tgAAV2-CFTR was detected on day 14 as compared to an increase in IL-8 levels in subjects who received the placebo. No differences in IL-8 and IL-10 were measured on days 45 and 75. Vector DNA was detected in bronchial cells from bronchial brushings of all six subjects who received vector, but gene expression (vector-specific CFTR mRNA) was not detected. Although the results from this trial of multiple doses of aerosolized AAV-2 CFTR demonstrated both safety and tolerability, evidence for efficacy was limited.

These latter clinical studies for CF gene transfer were consistent with the prior studies that demonstrated evidence for gene transfer based on the surrogate markers that were measured, but highly variable and limited evidence for efficacy.

38.3 VECTORS FOR CF GENE TRANSFER

Both viral and nonviral vector systems have been administered to subjects in CF clinical trials. An ideal vector system for airway gene transfer should have an adequate capacity for the CFTR cDNA and a suitable promoter, efficiently transduce airway cells from the lumen, be nonimmunogenic and noninflammatory, and produce either long-term transgene expression or have the ability to be readministered without loss of gene transfer efficiency. No vector to date has been identified that meets all of these criteria.

38.3.1 VIRAL VECTORS

Adenovirus (Ad) and AAV vectors have each been used to deliver the CFTR transgene in clinical human gene transfer trials. Lentivirus vectors have undergone extensive preclinical development, but have not yet been entered into CF clinical trials.

1. *Ad vectors.* Replication-deficient adenoviral vectors have been extensively developed as tools for gene transfer into mammalian cells [22]. Ads are double-stranded DNA viruses that have a 36 kbp genome consisting of a series of early genes that are responsible for virus replication, antigen presentation, and surveillance, and a series of late genes that encode viral structural proteins [23–26]. Several generations of Ad vectors have been developed based on Ad serotypes 2 (Ad2) and 5 (Ad5). First generation vectors have had the early region one (E1) genes deleted to make the vector replication-defective [27,28], whereas deletion of the E3 region creates room to insert therapeutic cDNAs with a suitable promoter.

E1-deleted second generation vectors have been developed in which the E2a region has been mutated to form a temperature-sensitive mutant virus that replicates in 293 cells at 32°C, but not at 39°C, bringing an additional safety feature to this vector during production [29–31]. E1-deleted second generation vectors with deletions in most (except for open reading frame six, ORF6) or all of the E4 region to limit late viral gene expression [32–34] have also been developed. All viral genes have been deleted from third generation Ad vectors, retaining only a small packaging signal and the inverted terminal repeats [35–41]. These vectors can accept insert cDNAs or even genomic DNA in excess of 30 kb [25], but may require a stuffer sequence for adequate packaging of vector constructs containing smaller cDNAs [39,41]. Because these completely deleted vectors require coinfection of producer cells with an Ad helper virus for production of viral structural proteins, they are commonly referred to as gutless or helper-dependent (HD) Ad vectors. Although the use of Ad helper virus for production may contaminate vector production stocks, the advent of Cre-lox recombination with newer virus production techniques has reduced helper contamination to as low as 0.01% [42–44].

Ad binds to a high-affinity coxsackie and adenoviral 2/5 receptor (CAR) [45] and is internalized through an $\alpha_v\beta_{3/5}$ integrin-mediated vesicular (endocytic) process [46]. As a result of endosomolytic properties mediated by the Ad penton base, Ad avoids lysosomal degradation and efficiently translocates to the nucleus where it exists as an episome (extrachromosomal DNA) mediating expression of therapeutic genes (cDNAs). Because Ad vectors do not integrate at high frequencies, transient expression occurs so repetitive administration will be required for CF gene therapy.

2. *AAV vectors.* AAV vectors were derived from the naturally defective and nonpathogenic wild-type human parvoviruses based on serotypes 2 and 3, AAV-2 and AAV-3 [47–51]. AAV requires the presence of a helper virus, e.g., Ad or herpes simplex virus, to replicate or to cause a lytic infection. In the absence of a helper virus, AAV integrates into the host cell genome and becomes latent. Upon a subsequent wild-type Ad or wild-type herpesvirus infection, the AAV genome can be rescued (excised) from the chromosome to generate a lytic infection [47–51]. AAV-2 is a single-stranded DNA virus with a genome size of ~4.7 kb that consists of the following: (1) inverted terminal repeats at the 5' and 3' ends of the molecule [47–50], which play a role in replication and are important for integration into the host cell genome and (2) the viral genes *rep* and *cap*, which mediate viral replication and nucleocapsid formation. Deletion of the *rep* and *cap* genes permits 4.5 kb for DNA insertion into the AAV-2 vector. This small insert size limits the cloning capacity for large coding sequences such as the CFTR cDNA (4.5 kb) and the regulatory elements required to drive CFTR transcription [52].

The receptor for AAV-2 is a membrane-associated heparan sulfate proteoglycan with fibroblast growth factor 1 and $\alpha_v\beta_5$

integrins serving as coreceptors for AAV-2 entry [53–55]. Similar to CAR, heparan sulfate proteoglycans and the coreceptors are localized predominantly to the basolateral surface of airway epithelial cells [56]. The ability of AAV vectors to transduce nondividing cells makes them a good candidate for CFTR gene transfer. Although AAV-2 vectors exhibit poor entry across the apical membrane of well-differentiated (WD) human airway epithelial (HAE) cells following apical application, a variety of serotypes may offer hope for CFTR gene transfer.

3. *Lentiviral vectors.* Retroviruses are members of a large group of viruses called the Retroviridae [57,58]. Several different classification schemes have been delineated for retroviruses including those based on biology as well as those based on morphology. Despite these classification schemes, most members of the retroviral family can generally be characterized by the either simple or complex composition of their individual genomes. Simple retroviruses are RNA viruses whose genomes consist of two viral long terminal repeats (LTRs), a packaging signal, and a series of structural genes, *gag*, *pol* and *env*. These structural genes encode the capsid protein, reverse transcriptase, protease, an integrase, and the envelope glycoprotein. Deletion of the structural genes *gag*, *pol*, and *env* makes the virus replication defective and enables the insertion of therapeutic cDNAs plus promoter elements into the retroviral genome, forming a replication-defective retroviral vector [57]. The genomes of lentiviruses are more complex, encoding a variety of regulatory accessory proteins and pathogenesis factors that are not present in the genomes of simple retroviruses [58–61]. Furthermore, genes encoding proteins that utilize the cellular nuclear import machinery e.g., MA, IN, and Vpr of HIV-1, to target the preintegration complex to the nucleus are also encoded within this complex genome. Major deletions in these accessory and pathogenesis factor genes have enabled the development of lentiviral vectors for gene transfer [58–61]. Exogenous (internal) promoters have also been included within the sequences of the inserted gene cassette since transcription from the viral LTR may constitute a safety hazard. Deletions in the LTR to prevent transcription (self-inactivating vectors) have been introduced as a safety feature of retroviral and lentiviral vectors [62,63].

The envelope glycoproteins of wild-type retroviruses and lentiviruses bind to cell surface receptors to facilitate entry of the virus into the cytoplasm where the viral RNA is reverse transcribed to form a cDNA, the provirus. This provirus is translocated to the nucleus where it integrates into the host cell chromosomes and through the normal process of DNA transcription, encodes new viral proteins and new viral RNA, which are assembled at the cell surface into new viral particles. Replication-defective lentiviral vectors infect cells by similar mechanisms, but unlike wild-type viruses, the integrated provirus from these vectors encodes the therapeutic gene and viral particles are not produced. As a safety measure, the endogenous envelope proteins of lentiviral vectors have been deleted and replaced by envelope proteins from other viruses, a process known as pseudotyping. The vesicular

stomatitis virus glycoprotein (VSV-G) has been among the most commonly used envelope [64]. Initial studies demonstrated that pseudotyped lentivirus vectors can transfect differentiated airway epithelial cells in some systems, but much work is required *in vivo* to move them toward clinical trials. Lentiviral vectors, derived from the human immunodeficiency viruses (HIV), feline immunodeficiency virus (FIV), and equine infectious anemia virus (EIAV) have each been developed as gene transfer vectors for CF.

38.3.2 NONVIRAL VECTORS

Since viral vectors can elicit immune and inflammatory responses and the induction of neutralizing antibodies potentially preventing vector readministration [65], some investigators, particularly the United Kingdom Gene Therapy Consortium, have focused their efforts on developing nonviral vectors as gene transfer tools. Nonviral vectors explored for CF gene transfer to date include naked DNA, cationic liposomes, and polymers.

1. *Naked DNA*. Naked plasmid DNA has been used as a gene transfer vehicle in airway epithelial cells both *in vitro* and *in vivo*, but has generally been ineffective at delivering genes to CF airways. Although delivery of naked DNA to airways is a simple and safe technique, gene transfer efficiency in prior studies was inadequate for further development of this vector system for lung gene delivery [66].

2. *Cationic liposomes*. Cationic liposomes have been extensively evaluated in clinical trials. Cationic liposomes are composed of cationic lipids mixed in varying molar ratios with cholesterol and dioleoylphosphatidylethanolamine (DOPE), a neutral phospholipid [67,68]. Commonly used cationic lipids for gene transfer include *N*[1-(2,3-dioleoxy)propyl]-*N,N,N*-trimethylammonium (DOTMA), 1,2-dimyristyloxypropyl-3-dimethylhydroxyethylammonium bromide (DMR1E), or 3 β [*N,N,N'*-dimethylamino ethane-carbamoyl] cholesterol (DC-Chol), *N*[1-(2,3-dioleoxy)propyl]-*N,N,N*-trimethylammonium methyl sulfate (DOTAP), *p*-ethyl dimyristoyl phosphatidyl choline (EDMPC) cholesterol, and *N*⁴-sperminine cholesteryl carbamate (GL-67). Cationic liposomes bind to negatively charged plasmid DNA to form DNA–liposome complexes, which may, under conditions of excess molar DNA, have a net negative charge. DNA–liposome complexes (also known as lipoplexes) enter cells primarily by endocytosis [69,70], although the mechanism and specificity of binding to the cell surface has not been clearly delineated. Cationic liposomes also promote the release of plasmid DNA from the endosome into the cytoplasm [70]. Like Ads, cationic liposomes do not integrate into the host cell genome, so that expression may be lost with cell division. Thus, repetitive administration of lipoplexes will be required for CF gene therapy. Lipoplexes have been shown to induce host cytotoxic responses associated with bacterial unmethylated cytosine-pyrimidine-guanine (CpG) sequences present within the plasmid DNA [71].

3. *Polymers*. Complexes of cationic polymers with plasmid DNA (polyplexes) that often condense the DNA and prevent it

from degradation have also been developed. These complexes enter epithelial cells on binding to specific cell surface receptors followed by receptor-mediated endocytosis. Poly-L-lysine, polyethyleneimine (PEI), and polyamidoamine have been commonly considered as tools for gene transfer research [72], but only poly-L-lysine has actually been developed sufficiently to form a gene transfer product for human gene transfer. The cationic polymer PEI when complexed to plasmid DNA has been reported to transfect up to 5% of pulmonary cells after intravenous administration [73], but has not undergone significant development for clinical trials in CF. Polyplexes based on poly-L-lysine conjugated to a Fab fragment of IgG against human secretory component have been shown to deliver reporter genes to the airway epithelia *in vitro* and *in vivo* following intravenous administration [74,75], but may suffer from immune surveillance due to the protein component. A PEG-substituted poly-L-lysine has been used to generate compact DNA into nanoparticles for gene transfer to airways *in vivo* and a phase II trial has been completed with this vector (see Section 38.2).

38.4 BARRIERS TO GENE TRANSFER FOR CF

Multiple barriers to airway gene transfer exist in the lung. Nonspecific host barriers include airway mucus, cell surface glycoconjugates, and the inflammatory milieu, while vector-specific barriers include factors affecting cell binding and entry, nuclear translocation, and factors limiting transgene expression postnuclear entry. These barriers combine to make *in vivo* gene transfer to human airways inefficient.

38.4.1 HOST BARRIERS TO GENE TRANSFER

1. *Luminal contents*. Luminal components of the chronic pulmonary infection and inflammation in the CF airway have been shown to inhibit gene transduction by a variety of vectors. Fresh sputum obtained from CF patients has been shown to inhibit liposomal (DC-Chol/DOPE) and adenoviral gene transfer *in vitro* [76]. Sterilization of the sputum with ultraviolet light demonstrated that active infectious organisms alone were not required. Rather the simulation of this inhibitory effect on gene transfer by pretreatment of cells with genomic DNA prior to transduction combined with reversibility of CF sputum-induced effects on gene transfer by pretreatment with recombinant DNase (rDNase) suggested that excessive DNA could also inhibit liposomal and adenoviral gene transfer [76].

Separation of sputum collected from CF patients with acute exacerbations receiving antibiotics and rDNase into aqueous (sol) and gel components by ultracentrifugation demonstrated that the aqueous components or sol of the airway lumen could inhibit Ad gene transfer to airways [77]. This effect arose from the presence of Ad-specific antibodies in the sol of CF sputum, an effect that could be overcome by heat inactivation of CF sol. BAL fluid from CF patients has been shown to inhibit AAV gene transfer *in vitro* [78]. This effect was reversible when CF BAL fluid was incubated with alpha 1-antitrypsin (α_1 AT). Subsequent experiments with neutrophil

elastase (NE) and purified human neutrophil peptide (HNP) demonstrated that HNP mediated the inhibitory effect on AAV gene transfer.

The inflammatory milieu induced by *Pseudomonas* is a formidable barrier to transduction [79]. Murine studies in which mice inoculated with *Pseudomonas aeruginosa*-laden agarose beads develop chronic bronchopulmonary infection exhibit a greater than twofold reduction in gene transfer efficiency following nasal instillation of an Ad-*lacZ* vector as compared to mice that had sterile beads or Ad vector alone instilled and a 10-fold reduction on Ad gene transfer efficiency following delivery of Ad-*lacZ* vector to nasal airways of *Pseudomonas* (PAO1 strain)-infected mice as compared to noninfected nasal airways is consistent with this concept [79,80].

Airway and alveolar macrophages may play a major role in the rapid loss of vector genomes following luminal airway delivery of gene transfer vectors. Worgall et al. demonstrated a 70% loss of Ad-*lacZ* genomes in both immunocompetent and immunodeficient mice within 24h of transtracheal administration of an Ad-*lacZ* vector [81]. Elimination of macrophages from murine lungs by pretreatment with liposomes containing dichloromethylene biphosphonate to eliminate macrophages prior to Ad vector administration overcame this effect. Alveolar macrophages have also been shown to inhibit retrovirus-mediated gene transfer to airway epithelia *in vitro* [82,83]. Transduction of HAE cells by an amphotropic enveloped retroviral vector was inhibited ~40% by alveolar macrophages and by more than 60% by lipopolysaccharide (LPS)-activated alveolar macrophages. Dexamethasone (1 μ M) partially reversed this inhibition of retroviral transduction. Consistent with the Ad studies, a rapid loss of vector retroviral DNA was detected consistent with rapid degradation. Thus, luminal gene transfer approaches targeting the superficial airway epithelium will have to overcome the barriers induced by the inflammatory response in lumen to gain access to the airway epithelium.

2. *Cell surface components.* The glycocalyx may also have inhibitory effects on airway gene transfer. This structure forms a matrix of complex carbohydrate moieties, glycolipids, and glycoproteins on the apical surfaces of airways. At least five mucin glycoproteins have been localized to airway surfaces: MUC1, MUC4, and MUC16, which are tethered mucins and the secreted mucins MUC5ac and Muc5b [84–87]. Overexpression of the mucin MUC1 *in vitro* has been linked to inefficient Ad gene transfer to Madin Darby canine kidney (MDCK) and bronchial epithelial cells that could be reversed by removal of sialic acid residues from the apical surface by neuraminidase [87–89]. The role of the glycocalyx as a barrier to gene transfer has been further explored by overexpression of glycosylphosphatidyl inositol (gpi)-linked CAR, which localizes to the apical membrane of polarized cells [90,91]. Ad5-mediated transduction of polarized MDCK cells overexpressing gpi-linked CAR was inefficient following apical application, but was enhanced by removal of sialic residues with neuraminidase [90]. A similar finding was reported in MUC1-deficient mice *in vivo* [92]. In contrast, apical application of an Ad2 vector in a prior study efficiently

transduced polarized HAE cells overexpressing gpi-linked CAR, an effect not enhanced by neuraminidase pretreatment [91]. This incongruity may result from different levels of expression of glycocalyx components in the cell cultures, rather than differences in vector serotype.

38.4.2 VECTOR-SPECIFIC BARRIERS TO LUMINAL AIRWAY GENE TRANSFER

Barriers specific to each vector considered or tested in human clinical gene transfer trials for CF to date have been identified. These vector-specific barriers to airway gene transfer are discussed below.

1. *Ad vectors.* Preclinical studies and clinical trials have established that luminal Ad gene transfer to airways is inefficient [93–95]. This inefficiency of Ad gene transfer results from localization of the coxsackie B and adenovirus receptor (CAR) and $\alpha_v\beta_{3/5}$ integrins, which mediate uptake of Ad vectors [46], to the basolateral rather than the apical membrane, of columnar cells limiting vector binding and entry and hence efficient gene transfer [90,94,96,97]. Significant concern still remains for the adaptive immune response to Ad, even for HDAd vector, which may have a longer duration of expression, but still require vector readministration for CF gene therapy [98].

2. *AAV vectors.* Several barriers to AAV-mediated gene transfer remain. The small insert size, which is at the upper size limit for insertion of full-length wild-type CFTR (coding region of ~4.5 kb) driven by an exogenous promoter, is one potential significant barrier for CFTR gene transfer. The generation of small promoters to drive transcription and the development of shorter versions of CFTR (minigenes) may overcome this limitation, but may not be ideal.

Lack of functional apical membrane receptors due to the basolateral localization of the membrane-associated heparan sulfate proteoglycans receptor and its coreceptors fibroblast growth factor-1 (FGF-1) and $\alpha_v\beta_3$ integrins has been a limitation for AAV-2-mediated gene transfer to airways [53–56,99]. However, binding studies of radiolabeled AAV-2 support the existence of nonfunctional apical membrane receptors for AAV-2 [56,99]. Recent developments in AAV serotypes may soon overcome the limitations of AAV-2.

A postentry barrier to transduction is the persistence of AAV-2 genomes as single-stranded episomes (ssDNA), which are inefficiently converted to double-stranded DNA (dsDNA), a requirement for transgene expression [100,101]. This limitation leads to a delay in the onset of transgene expression, which may be overcome by waiting long enough for maximal transgene expression to occur (~4 weeks) or by the use of DNA damaging agents, topoisomerase inhibitors, and Ad early gene products [102–104]. Thus, barriers to AAV-mediated transduction of CFTR into CF airways include small insert size, decreased binding, and uptake of vector due to absent or decreased functional receptor expression on the apical membrane, and inefficient single-strand to double-strand conversion of AAV genomes.

3. *Lentiviral vectors.* The development of HIV, EIAV, and FIV vectors [58,59,61,63,105,106], which can transduce non-dividing airway cells, has overcome potential limitations caused by the low rate of cell proliferation in human airway epithelia [107]. Advances in retroviral production techniques and pseudotyping of vectors to create stable envelopes that permit concentration of vector stocks have also overcome the limitations of titer [108]. However, titers of retroviruses remain ~1–2 logs lower than that of Ad and AAV vectors.

Apical membrane barriers to efficient transduction of WD airway cells are also limiting. *In vitro* and *in vivo* studies of polarized airway epithelial cells have localized low levels of functional amphotropic receptors (RAM-1 or Pit-2) to the basolateral surface of polarized WD airway cells. *In vivo* studies have confirmed low levels of expression of RAM-1 or Pit-2 in murine lung [109]. Similar findings have been reported for lentiviral vectors pseudotyped with the VSV envelope glycoprotein (G). VSV-G pseudotyped HIV, EIAV, and FIV vectors have been shown to transduce polarized WD HAE cells *in vitro* and *in vivo* from the basolateral surface [105,106,110–112].

4. *Nonviral vectors.* Barriers to nonviral gene transfer have been identified at several steps. Nuclear entry was identified as the rate-limiting factor for efficient liposome-mediated gene transfer into cell lines resistant to transfection [113,114], whereas gene transfer to WD airway epithelial cells has been limited by both inefficient nuclear entry and failure of DNA–liposome complexes to enter the cell [115]. Loss of phagocytic entry mechanisms, decreased cell surface binding, and decreased uptake in differentiated airway epithelial cells (central cells) as compared to poorly differentiated cells (edge cells) were the reasons for inefficient transduction. Subsequent studies confirmed these observations by demonstrating decreased amounts of cell-associated lipoplexes in differentiated airway epithelia as compared to poorly differentiated epithelia [113,114]. Liposome-mediated gene transfer into proliferating cells was also enhanced relative to quiescent cells, raising the possibility of enhanced nuclear transport of DNA during mitosis due to breakdown of the nuclear envelope. Thus, barriers to efficient transduction of WD airway cells by lipoplexes include decreased binding and uptake of lipoplexes and poor nuclear translocation of DNA.

Molecular conjugates are typically designed to target specific receptors on cell surfaces to improve binding and uptake. However, poor nuclear translocation with trafficking of significant portions of vector to lysosomal compartments for degradation remains a concern for molecular conjugates.

38.5 STRATEGIES FOR IMPROVING GENE TRANSFER EFFICIENCY

The apical membrane of WD airway cells remains the major barrier to efficient transduction by all the current gene transfer vectors such that strategies still focus primarily on this site. Current strategies have not fully addressed the problem with luminal contents, i.e., neutrophils, bacteria, excess DNA,

and inflammation, focusing instead on improving apical membrane binding and entry. The hope is that pretreatment with α_1 AT, rDNase, or antibiotic therapy will limit the effects of luminal contents on gene transfer.

Two general strategies have been proposed for overcoming barriers to airway epithelial gene transfer: (1) modification of the host airway to enhance gene transfer and (2) modification of the vectors to target receptors expressed on the apical membrane of airways *in vivo*.

38.5.1 HOST MODIFICATION

1. *Modulation of paracellular permeability.* Treatment of the airway epithelium with agents that transiently increase permeability through the tight junctions to facilitate access of the vectors to the basolateral membrane is one strategy for enhancing gene transfer efficiency to airway epithelia. Pretreatment of nasal airways with povidone-iodine enhanced gene transfer mediated by an Ad-*lacZ* vector and facilitated partial correction of the Cl⁻ transport defect in the nasal epithelium of CF mice following a single dose of vector [80]. The single dose of Ad-CFTR vector used following pretreatment with the surface agent povidone-iodine generated the same degree of CFTR correction previously reported by Grubb et al. in which four doses of an Ad vector were required to generate a 40%–50% correction of Cl⁻ transport [93].

Luminal or apical application of the calcium chelator ethylene glycol bis-(β -aminoethyl ether)-*N,N,N',N'*-tetraacetic acid (EGTA) in hypotonic solutions followed by luminal application of an amphotropic retroviral vector has enabled investigators to correct the Cl⁻ transport defect in WD CF HAE cells stimulated to proliferate with keratinocyte growth factor (KGF) and has also enhanced luminal FIV-based lentiviral gene transfer to rabbit airways *in vivo* [106,112]. EGTA/hypotonic solution has also been reported to enhance AAV and Ad gene transfer to WD HAE cells *in vitro* and Ad gene transfer to airway epithelia *in vivo* following luminal application [56,116,117]. However, much higher concentrations of EGTA (0.1–0.4 M) may be required for optimal enhancement of Ad gene transfer to nasal and lower airway epithelia of mice *in vivo* [117].

Medium chain fatty acids have also been shown to enhance airway gene transfer [118–120]. The sodium salt of capric acid (sodium caprate) has been shown to more effectively enhance Ad gene transfer than EGTA *in vitro* and to enhance Ad gene transfer to murine airways *in vivo* [118–121].

Water-induced hypoosmotic shock alone may transiently permeabilize tight junctions temporarily to enhance vector uptake [122]. PEI–pDNA polyplexes nebulized in hypoosmotic distilled water were shown to enhance transgene expression by 57-fold more than polyplexes in 5% glucose, and by 185-fold than those in Hepes-buffered saline. However, no formal studies of tight junction function were performed in the study and the size of the PEI polyplexes in water was significantly smaller than those measured in glucose or saline.

Lysophosphatidyl-choline (LPC), a natural component found in lung surfactant, has also been used to increase vector access to basolateral membrane receptors. A prior study demonstrated that treatment of the airways with LPC resulted in enhanced long-term gene transfer *in vivo* with a VSV-G pseudotyped lentivirus and partial correction of CFTR function in the nasal epithelia of CF deficient mice [123]. Formulating a HD *AdlacZ* vector in LPC also enhanced transduction efficiency in rabbit airways with detection of transgene expression in the small and large airway epithelial cells, from trachea to terminal bronchioles [122]. All cell types of the surface epithelium were transduced and extensive transduction of the epithelium was obtained with virus formulated in isotonic 0.1% LPC.

The apical application of the occludin peptide OP₉₀₋₁₀₃ in WD HAE cells has also shown to enhance Ad and AAV viral vector transduction by transient disruption of the epithelial tight junctions resulting in alterations in paracellular permeability in a concentration-dependent manner [124]. AdLacZ and AAV2GFP vectors each showed significantly higher levels of transduction in WD HAE cells pretreated apically with an OP₉₀₋₁₀₃ [124]. Relatively specific and transient redistribution of tight junction proteins were detected with minimal toxicity *in vitro* in this study.

These studies established the feasibility of transient permeabilization of the paracellular path to enhance airway gene transfer mediated by vectors with receptors that are localized on the basolateral membrane. However, major concerns have been raised in the CF community regarding the safety of modulating paracellular permeability to enhance airway gene transfer efficiency. Chelating agents, medium chain fatty acids, polidocanol, and LPC have each been associated with some toxicity [80,120,122,123]. Efforts to develop agents to that target proteins in the apical junctional complex, e.g., occludin or one of the claudins, with high specificity offer promise, but much work needs to be done to perfect the technology.

2. *Enhancing endosomal processing.* The significantly lower transduction efficiency of AAV transduction from the apical surface of airway epithelial cells as opposed to basolateral application appears to be due to differences in endosomal processing and nuclear trafficking of apically or basolaterally internalized virions [56,99,125,126]. Since AAV capsid proteins are ubiquitinated after endocytosis, gene transfer using these vectors was shown to be significantly enhanced by proteasome or ubiquitin ligase inhibitors [127,128]. Tripeptidyl aldehyde proteasome inhibitors increased luminal AAV transduction efficiency by >200-fold, to a level almost equivalent to that observed with basolateral application of the vector. *In vivo* application of these proteasome inhibitors in murine lungs increased AAV-mediated gene transfer from undetectable levels to a mean of 10.4% ± 1.6% of the epithelial cells in large bronchioles. These results support potential use of proteasome inhibitors for AAV-mediated gene transfer to circumvent the barriers of endosomal processing and nuclear trafficking.

3. *Increasing dwell time.* Formulation of gene transfer vectors such as Ad and AAV with viscoelastic gels such as carboxymethyl-cellulose (CMC) and methylcellulose (MC) to increase the residence time of the vectors on the epithelial cells may result in enhanced gene transfer efficiency. Mucociliary clearance of gene transfer vectors from the surface of airway epithelial cells by the coordinated beating of the cilia may reduce contact time of the gene transfer vectors with the epithelial surface, which could prevent uptake of the vector by the epithelial cells. Previously, recombinant Ad formulated in a thixotropic solution containing 1% Avicel RC-591, a mixture of microcrystalline cellulose and CMC, enhanced gene transfer efficiency in airway epithelial cells by inhibiting mucociliary clearance [129,130]. The viscoelastic gels CMC, MC, and poloxamer 407 (P407) were tested for their ability to enhance gene transfer of adenoviral, AAV5, and lentiviral vectors in the airways of mice. MC and CMC enhanced the efficiency of gene transfer to the airways mediated by Ad, AAV5, and GP64-pseudotyped FIV gene transfer. The safety of this approach has not been carefully evaluated, but may raise concerns since decreased clearance can lead to impaired lung function in CF patients.

38.5.2 VECTOR MODIFICATION

Modifications of specific gene transfer vectors are an alternative approach for enhancing gene transfer efficiency. Targeting the vector to receptors that are endogenously expressed on the apical membrane of WD HAE cells is the goal of this approach.

1. *Ad vectors.* While proof-of-concept studies have shown the feasibility of retargeting Ad vectors to alternative receptors on airway apical surfaces, little meaningful progress has been made [90,131,132]. Rather the advances in gene transfer efficiency with HDAd vectors in rodent, rabbit, and primate lungs can be attributed to the use of agents that modulate paracellular permeability [65,98,133].

Studies of chimeric Ad vectors that target apical membrane of airway cells have been proposed. Zabner et al. screened 12 adenoviral serotypes from Ad subgroups A–F for their ability to bind and infect the apical surface of polarized WD HAE cells in culture [134]. Wild-type Ad17 bound to WD HAE cells more efficiently than wild-type Ad2. Subsequently chimeric Ad2 vectors with Ad17 fiber transduced WD HAE cells ~100-fold more efficiently than the original Ad2 vector. These data suggested that it may be possible to generate chimeric Ad vectors that more efficiently transduced HAE cells following luminal application. However, development of chimeric vectors would not be able to eliminate potential problems with neutralizing antibodies.

To overcome the immunological barriers of neutralizing antibodies that prevent Ad vector readministration, nonhuman Ad vectors developed from primate Ad serotypes, to which humans do not possess neutralizing antibodies, have been evaluated [135–137]. A rotation of Ad vector serotypes

(serotype switching) could prolong the time between readministration of the same serotype in an attempt to avoid pre-existing immunity to common Ad serotypes. However as with human Ad vectors, primate vectors still need to gain entry to the receptors located on the basolateral surface of the epithelial cells. In the first study involving readministration of HD Ad vectors to the lung, a second administration of these vectors to murine lungs was effective, with minimal loss of transgene expression [133]. In contrast, reduced transgene expression was detected in mice that were administered a first generation Ad vector followed by repeat delivery of a HD Ad vector. While these data suggest that HD Ad vectors can be readministered at least once, multiple administrations were not performed.

2. *AAV vectors.* Some progress has been made in addressing barriers to AAV2-mediated gene transfer to CF airway epithelia. The restriction on insert size that limits efficient packaging of wild-type CFTR with a suitable promoter remains a significant concern. Although trans-splicing strategies have been considered in which different portions of the CFTR carried on different vectors can splice together to form a complete CFTR molecule, the complexity of achieving efficient transduction of two different vectors into the same cell to permit trans-splicing has slowed progress in this area [138]. However, spliceosome-mediated RNA trans-splicing (SmaRT) with AAV vectors has been explored as a means for functionally correcting endogenous $\Delta F508$ CFTR transcripts both *in vitro* in human CF polarized airway epithelia and in human CF bronchial xenografts [139]. Previously, Ad vectors encoding a pre-trans-splicing molecule (PTM) targeted to intron 9 of CFTR-induced partial correction of endogenous $\Delta F508$ messenger RNA and protein and human CF bronchial xenografts infected with Ad. CFTR-PTM also demonstrated partial correction of CFTR-mediated chloride channel activity suggesting the feasibility of SmaRT-mediated repair of mutant endogenous CFTR. The low level of correction was probably due to the inefficient infection of these vectors from the apical surface of the airway epithelium. Recently the SmaRT technique has been applied to AAV vectors, resulting in correction of CFTR function following luminal application in human CF airway epithelia [139]. Adeno-associated viral vectors carrying a PTM targeted to bind intron 9 of CFTR pre-mRNA and trans-splice the normal sequence for human CFTR into the endogenous pre-mRNA were generated. Human CF airway epithelia were infected from the luminal surface with rAAV2 or rAAV5 CFTR-PTM vectors and cells were treated with proteasome-modulating agents to enhance the efficiency of transduction. Partial CFTR restoration was observed with both the rAAV2 and rAAV5 CFTR-PTM vectors and wild-type CFTR transcripts in CFTR-PTM-corrected epithelia were detected by RT-PCR analysis. These data suggested that the SmaRT technology with its ability to repair endogenous CFTR mRNA could overcome the insert size limitation of AAV due to its smaller CFTR-PTM cassette.

Concerns also remain about which promoters might be best for CFTR gene transfer mediated by AAV vectors.

A pseudotyped AAV5-CFTR vector containing a CFTR minigene and a chicken β -actin promoter with a CMV enhancer has been shown to significantly enhance transgene expression in primates [140]. Aerosolization of this pseudotyped rAAV5-CFTR or rAAV5-GFP genes to nonhuman primate lungs resulted in CFTR and GFP expression in the airway epithelium, suggesting that the CFTR minigene construct could potentially be a promising candidate for CF gene transfer promoters. Another study, which evaluated the effects of promoter sequences on transduction rates and gene expression levels in the lung, showed that the Rous sarcoma virus (RSV) promoter performed significantly better than a human cytomegalovirus (CMV) promoter in the airway epithelium [141]. A hybrid promoter consisting of a CMV enhancer, beta-actin promoter and splice donor, and a beta-globin splice acceptor (CAG promoter) showed even higher expression than either of the strong viral promoters alone, with a 38-fold increase in protein expression over the RSV promoter. Vectors containing either the RSV or CAG promoter also showed good expression in the nasal and tracheal epithelium, suggesting that efficient transduction in airways can be achieved by using the appropriate AAV serotypes and promoter sequences.

Retargeting AAV2 vectors to enhance uptake via the apical surface of airway epithelia can be accomplished by introducing ligands for receptors on the apical membrane into the viral capsid or by using capsids of alternative serotypes to target the apical membrane. Current research efforts to improve apical membrane targeting of AAV2 vectors have focused on identifying wild-type AAV vectors of other serotypes. Once identified, the alternative serotypes can be developed into new gene transfer vectors or alternatively, their capsid proteins can serve as pseudotypes for AAV2 vectors. Over 40 different AAV serotypes have been considered for gene transfer [142] and more than nine AAV serotypes have been tested as gene transfer vectors [142,143]. The most efficient for airway epithelia have been AAV5 [144,145], AAV6 [146,147], and AAV9 [148]. A prior study demonstrated that rAAV-5 vectors were able to transduce murine lungs more effectively than AAV-2 vectors. Intranasal delivery of pseudotyped AAV-2 genomes with AAV-5 capsids (AAV2/5) resulted in a 250-fold-higher level of transgene expression in murine lungs than rAAV-2 capsid-mediated infection [144,145]. Previous reports show that the AAV6 pseudotyped vectors can mediate high transduction efficiency in large and small airways, with up to 80% transduction in some airways [146]. While both AAV2 and AAV6 serotypes transduce alveolar epithelia with similar efficiencies, the transduction efficiency of bronchial and distal airway epithelial cells with AAV6 was significantly higher than AAV2.

In more recent studies, a human AAV2/9 vector transduced murine nasal and lung airway epithelia *in vivo* with persistence of expression for 9 months. The AAV2/9 vectors could be readministered as early as 30 days following initial exposure with a minimal effect on transgene expression despite the presence of high levels of neutralizing antibodies in the serum [148].

Nevertheless, most investigators accept that readministration of AAV vectors will be required for lifelong therapy of CF. One strategy to circumvent the problem of repeat administration hinges on modification of the surface of AAV vectors with PEG to mask them from the immune system. PEGylation of the viral capsids with tresyl chloride (TMPEG) resulted in enhanced efficacy of AAV2 vectors in murine lungs by five-fold following repeat administration [149], suggesting that TMPEG provided protection from AAV neutralizing antibodies *in vivo*.

Serotype switching is another method that has been considered for overcoming immune inhibition of AAV gene transfer. The use of nonhuman primate serotypes has been explored as a method to overcome neutralizing antibodies that limit the efficiency of gene transfer. A recombinant primate AAV vector containing a capsid derived from the rhesus macaques and the AAV2 internal terminal repeats (AAVrh.10) has been shown to boost alpha-1 antitrypsin levels when administered intrapleurally to mice preimmunized to AAV2/5 vectors, thus circumventing immunity to AAV [150]. The efficiency of this vector in airways has not been reported in detail to date, but it may offer yet another serotype that could be used to circumvent humoral immunity to other AAV serotypes.

The limitations of single-strand to double-strand conversion previously mentioned can be overcome by the application of self-complementing AAV vectors (sc-AAV) to CF gene transfer. The sc-AAV vector includes both the sense strand as well as the reverse-complement sequence of the promoter-transgene-polyadenylation insert. An AAV2-hairpin loop located between the sense and reverse complement enables the vector DNA to immediately fold back upon itself into a double-strand form as soon as it is uncoated. This configuration reduces the time for second strand conversion of vector genomes and the onset of transgene expression is accelerated [126,151,152].

3. *Lentiviral vectors.* Transduction of airway cells following luminal delivery remains rate-limiting for lentiviral vectors. Lentiviral vectors pseudotyped with the VSV-G can transduce nondividing cells, but these pseudotyped vectors transduce airway epithelia via receptors that are located predominantly on the basolateral surface of the airway epithelium. As a result, their transduction efficiency is low. However, altering the envelope glycoprotein by pseudotyping lentiviral vectors with the Ebola Zaire envelope glycoprotein (EboZ) has been shown to significantly increase uptake of the vector when applied luminally, since the receptors required for binding and entry of the EboZ virus are located on the apical surface of the airway epithelial cells [126,151–154]. Recently, production of lentiviral vectors pseudotyped with the avian plague virus hemagglutinin was significantly improved by coexpression of influenza virus M2 in vector-producing cells. These vectors efficiently transduced murine tracheal epithelia cells *in vitro* and murine tracheas *in vivo* following luminal application [155].

An FIV, pseudotyped with a baculovirus GP64 envelope glycoprotein resulted in persistent expression for up to 50

weeks in murine nasal epithelia. This pseudotyped lentivirus recognizes a receptor that is almost 10 times more abundant on the apical surface than the basolateral surface of the airway epithelium [153]. However, efficient transduction occurred only when the virus was mixed with the viscoelastic gel MC, which increases the residence time of the vector [130]. Under these conditions, FIV vectors pseudotyped with the baculovirus GP64 envelope were more effective than FIV vectors pseudotyped with a modified Ebola virus envelope [156].

4. *Paramyxovirus systems.* A novel viral vector system under development is the paramyxovirus vector [157,158]. Sendai virus (SeV), also known as murine parainfluenza virus type 1, is a negative sense, single-stranded RNA virus of the Paramyxoviridae family that mediates cell attachment and entry via the envelope glycoproteins hemagglutinin-neuraminidase (HN) and fusion protein (F). Using reverse genetics, a nontransmissible SeV vector system has been developed from replication-competent SeV vectors [158]. Second-generation SeV, which are transmission-incompetent and potentially safer than first generation SeV, have been shown to reverse the defective chloride transport in CF knockout mice [159]. These recombinant SeV vectors recognize a sialic acid-containing receptor on the surface of airway epithelial cells. SeV vectors containing the reporter genes such as lacZ and luciferase were shown to transduce airway epithelium *in vivo* with high efficiency [158]. Recently, it was shown that the 4.5 kb CFTR cDNA can be inserted within the SeV vector and that the use of this SeV-CFTR vector for gene transfer to airway epithelial cells both *in vitro* and *in vivo* resulted in the expression of a functional CFTR protein [159]. However, the use of this vector elicited airway inflammation. Furthermore, transgene expression using these vectors is transient, and hence repeat administration, which has so far proven to be inefficient, will be required.

Respiratory syncytial virus and parainfluenza virus-3 (PIV) are other members of the paramyxoviridae family of viruses that have been explored as potential gene transfer vectors for CF [160–162]. *In vitro* studies using a replication-competent respiratory syncytial virus-GFP vector showed efficient transduction of human airway epithelia following apical application. Similar results have been reported with PIV-3 vectors [162]. These vectors specifically target ciliated airway epithelial cells from the luminal surface, and *in vitro* studies have shown restoration of CFTR function following transduction with a PIV-CFTR vector [162].

5. *Nonviral vectors.* Recent evaluations of nonviral gene transfer agents including naked DNA, PEI-pDNA polyplexes, PEG-substituted poly-L-lysine pDNA polyplexes, and a cationic lipid 67 (GL67) showed that delivery of a human CFTR plasmid complexed with GL67 into ovine lungs resulted in the production of equal amounts of human CFTR compared to levels of endogenous ovine CFTR with slightly higher efficacy than the other gene transfer agents [163]. These data have led to a clinical trial program by the United Kingdom CF Gene Transfer Consortium.

Since lipoplexes have been shown to induce toxicity with low efficacy in nondividing cells, their safety profile has been improved by removing unmethylated CpG sequences within the plasmid that are known to elicit a toxic response [164]. Following the elimination of 270 out of 526 CpG sequences in cationic lipid:plasmid DNA complexes, the CpG-reduced vector was found to be significantly less immunostimulatory compared to the unmodified vector as evidenced by a 40% to 75% reduction in the levels of IL-12, IFN- γ , and IL-6 in the serum 24h after intravenous delivery in mice. Similar reductions in cytokine levels were also observed in the bronchoalveolar lavage fluids after intranasal administration in mice, while the levels of reporter gene expression were not affected by these modifications. Inhibitors of the CpG signaling pathways, such as chloroquine and quinacrine, also significantly reduced the induction of IL-12 from mouse spleen cells *in vitro* and inhibited cytokine production in the lung by approximately 50% without affecting gene expression. These results demonstrate that the elimination of CpG sequences in a plasmid DNA vector or inhibitors of CpG immunostimulation can reduce toxicity associated with cationic lipid and plasmid DNA complexes. A CpG-reduced vector has been selected for the United Kingdom CF Gene Transfer Consortium Trial.

Poor apical membrane binding, entry, and nuclear translocation must be overcome to improve the efficiency of nonviral gene transfer in human airways. In general, polyplexes have been more successful at delivering genes to airways than lipoplexes. Branched chain PEI-DNA complexes can deliver genes to airways *in vivo* following luminal delivery [165], but are not biodegradable and induce inflammatory responses [165–167]. Other investigators have focused on PEG-substituted poly-L-lysine plasmid DNA polyplexes that form compacted DNA nanoparticles [149,150]. Although not targeted, these nanoparticles have a small size (~25 nm) that promotes entry across the apical membrane of airway epithelia and enhances nuclear translocation and transcription [168,169]. PEGylation also appears to protect them from inflammatory responses due to unmethylated CpG motifs in plasmid DNA. Correction (often complete) of the CFTR chloride transport defect in the nasal epithelia in CF mice has been reported and partial correction was reported in a clinical gene safety and efficacy trial [20,170].

38.6 SUMMARY

Although progress has been made in CF gene transfer techniques both with viral and nonviral vectors, several challenges still remain and several concerns need to be addressed. An ideal gene transfer vector system that is both effective and safe still needs to be developed, and the problems associated with vector immunogenicity and readministration remain unresolved. A better understanding of the interaction of viral capsid proteins with the innate immune system is required to address the problem of viral vector immunogenicity. Nonviral gene delivery systems also have important issues that need to be addressed. Nonviral vectors that can achieve long-term

expression and specifically target lung epithelia need to be exploited. Research directed toward these issues and toward developing a new generation of vectors with better performance profiles is currently under way and provides hope for success in gene transfer for CF lung disease.

39.1 INTRODUCTION

Highly effective methodologies for therapeutic gene delivery to cells of the central nervous system (CNS) have been developed from the exponential gains achieved in the area of molecular biology over recent decades. This capability has created promise for therapeutic intervention in neurodegenerative

disorders. Presently, the most widely employed treatments for neurodegenerative diseases are based upon symptom alleviation through the use of pharmacological compounds, but these approaches offer little curative, or even neuroprotective properties. An ideal therapy for a neurodegenerative disorder would stabilize and repair afflicted cells and prevent other cells from succumbing to the pathophysiological process.

TABLE 39.1
Viral Vector Platforms Employed in CNS Gene Transfer

Viral Vector	Payload Capacity	Tropism	Duration Expression	Other Properties
Adenovirus	7–8 kb (Gen ^a 1/2); 30 kb (Gutless)	Glial/neuronal	Months (Gen1/2); year (Gutless)	Episomal; immunogenic (Gen1/2); less immunogenic (Gutless)
AAV	4.5 kb	Neuronal	Years	Episomal and integrative; minimal immune response
HSV recombinant	~10 kb	Neuronal > glial	Months	Episomal; some cytotoxicity
HSV amplicon	~130 kb	Neuronal > glial	Months to a year	Episomal; all viral genes deleted; little immune response
HSV/AAV hybrid amplicon	>20 kb	Neuronal	Months to a year	Episomal and integrative; all viral genes deleted
Lentivirus	8–10 kb	Neuronal	Years	Integrative

^a Gen1/2, Generation 1 and 2.

Using gene transfer-based methodologies, it may be possible to create such therapies. The characteristics of presently available virus-based vectors are summarized in Table 39.1. Each vector platform exhibits a series of advantages and disadvantages that need to be assessed. However, prior to their implementation in the treatment of neurological disorders, a detailed understanding of the disease-specific mechanisms is crucial. These issues will be addressed in greater detail below.

39.1.1 THERAPEUTIC TRANSCRIPTIONAL UNIT

A thorough understanding of the molecular mechanisms underlying the neurodegenerative disease process is requisite for selection of a proposed therapeutic gene. In general, the therapeutic transcriptional unit should have one or more of the following properties: (1) neuroprotective, (2) neuroregenerative, (3) neurotrophic, or (4) antiapoptotic.

Equally important is choosing promoters and regulatory elements to drive expression of the desired genes. The choice of these components will determine the specificity, duration, and regulation of transgene expression. Once the transcriptional unit has been designed, a suitable vector for delivering the DNA must be selected. The vector must be capable of delivering and expressing the desired genes in the appropriate cells to be targeted.

39.1.2 VECTOR SELECTION

Subsequent to selection of the gene therapeutic effector gene, whether it possesses a neuroaugmentative or neuroprotective mechanism of action, the appropriate gene delivery vector can be chosen. The following points must be considered for informed selection of an appropriate gene therapeutic vehicle for the treatment of neurodegenerative disorders: vector capacity, vector specificity, vector genome maintenance, vector-mediated transgene expression duration and levels, and vector safety profile. The length of the therapeutic transcription unit is sometimes used as a first criterion to limit vector choice. This category also includes a given vector's ability to harbor multiple transcription

units, thereby potentially affording recapitulation of a complex biochemical pathway (i.e., dopamine [DA] biosynthesis in the case of Parkinson's disease [PD]). Potential applications for several presently available vectors are restricted by insertion size limitations and are sometimes excluded if multiple gene delivery is required for therapy. As demonstrated with adeno-associated vector (AAV), the coinjection of multiple vectors, where each expresses a different therapeutic gene, represents one approach to circumvent this issue [1].

Cell type specificity is also an important issue when developing a gene-based therapeutic intervention for neurodegenerative disorders. It would be most beneficial if the vector of choice could transduce and express in cell types that comprise the disease-affected neural pathway. Vector tropism can be regulated through modulation of cellular receptor interactions by one or more of the following approaches: alteration of virus docking proteins, utilization of alternate serotypes, pseudotyping, and introduction of cellular receptors into the viral envelope. Once a vector is optimally targeted to the brain region of interest, therapeutic transgene expression can be restricted to selected cell populations via the utilization of cell type-specific promoters or transcriptional elements [2–6]. Strict spatial control of transgene expression is important to ensure that the correct cells manufacture the gene product. This control, in turn, reduces the risk that ectopic transgene expression will occur and lead to untoward effects on adjacent neurological pathways.

Because many neurodegenerative disorders are protracted in duration, gene-based modalities will be required to impart therapeutic benefit for several decades of an individual's lifetime. To this end, a vector genome should be stably maintained within the transduced cell of the neural pathway for extended periods of time. Vector genome maintenance is, therefore, an important factor in selection of an appropriate gene therapy vehicle for such disorders. Vector genomes can exist episomally or as integrated forms within nuclei of transduced cells. The postmitotic property of CNS neuronal populations does not exclude the utilization of episomal vectors because genomes can be maintained without the fear of

progressive loss due to mitosis. Integrating vectors circumvent this issue but their use augments safety concerns including potential to transactivate nearby proto-oncogenes and to disrupt essential host genes via insertional mutagenesis. This fear has apparently become a reality as evidenced in the case of the children in Europe treated for X-linked severe combined immune deficiency disease (XSCID) with a murine retroviral vector expressing the T cell growth factor, GammaC. Two of ten enrolled infants developed similar leukemia-like illnesses and the trial was halted to determine the genesis of the adverse event [7].

Another similar issue regarding vector selection relates to the desired levels and duration of gene product expression for treatment of neurodegenerative disorders. Depending upon the vector and transcriptional elements chosen, pharmacologic or physiologic levels of transgene expression can be achieved for short or long-term periods of duration. As with other selection criteria, the decision of which level or duration of expression is preferred rests heavily on the underlying molecular mechanisms to be targeted and at which time during the disease course the intervention is to be implemented. Early interventions may require maintenance of long-term physiologic levels of transgene expression (i.e., neuroprotective strategies) since the neuronal system is likely to be intact at this time. A vector–promoter combination that safely and stably maintains gene expression at nearly physiologic levels in the CNS would serve as a potential candidate for such early treatment approaches. Treatment modalities that are implemented after presentation of clinical neurodegenerative disease symptoms may require long-term pharmacologic levels of transgene product to restore neurologic function to a brain region decimated by disease.

Safety is of utmost concern regarding the application of novel gene therapeutic strategies to the treatment of neurodegenerative disorders. Many presently available vectors trigger immunogenic or inflammatory responses when introduced into the CNS. These responses are known to arise from the humoral or cell-mediated arms of the immune system, and the magnitude differs depending upon which vector type is

employed. For example, repeat administration of early generation viral vectors has been shown to lead to lower transgene expression and serious inflammation, likely the result of a primed immune system [8]. Therefore, a vector that is stably maintained and that can express its encoded transgene for extended periods of time would likely prove to be a more favorable choice as a gene therapeutic vehicle for neurodegenerative disorders. Another aspect that is often overlooked regarding gene therapy safety is the role of transgene products in the elaboration of immune responses and toxicity. Transgene products that are of foreign origin, ectopically expressed, or pharmacologically expressed possess the potential to induce cytotoxicity or immune responses. Research addressing these issues is imperative to elucidate the role of transgene products in the elaboration of these potentially harmful responses, and how such responses can be successfully circumvented. Utilization of regulation-competent transcriptional or post-transcriptional elements in delivery vectors to provide “fine-tuning” of therapeutic transgene expression levels is a way to minimize harmful clinical outcomes.

39.1.3 VECTOR DELIVERY

Once a suitable vector has been chosen for treating a particular neurological disease, a safe means for delivery must be established to provide optimal therapeutic benefit. With recent refinements of stereotactic surgical procedures, highly precise and reproducible delivery to specific regions of the brain is now performed (reviewed in Ref. [9]). By placing the patient’s head within a rigid frame and using three-dimensional cartesian reference points, delivery of vectors or cells can be made to a defined space within the coordinate system. Gene therapeutic vectors can be introduced into the brain via direct or indirect means. Direct gene transfer involves either local or global delivery of a selected vector to the brain. Direct local delivery using stereotactic methods is highly suitable for treatment of certain neurological diseases due to the fairly circumscribed region that may be afflicted. Figure 39.1 illustrates the finely tuned and restricted delivery of a herpes simplex virus

FIGURE 39.1 (See color insert following blank page 206.) Stereotactic delivery of an HSV amplicon vector expressing β -galactosidase into the mouse striatum. Mice were injected with 1×10^5 transduction units of HSVlac using a microprocessor-controlled pump. Animals were sacrificed and perfused 4 days post-transduction and X-gal histochemistry was performed on 40 μ m sections. Sections representative of the injection site (Panel A), a site anterior of the injection (Panel B), and a site posterior of the injection (Panel C). All sections were counterstained with thionin and acquired at a magnification of 2.5 \times . The photomicrographs indicate that focal delivery of a viral vector can be achieved within the brain. (From Brooks, A.I., et al., *J. Neurosci. Methods*, 80(2), 137, 1998. © 1998 Elsevier Science B.V. With permission.)

(HSV) amplicon vector expressing the β -galactosidase gene within the striatum of a mouse [10].

Other investigative groups have utilized more global approaches to CNS gene delivery that have broader applications for many neurological diseases where the volume of affected brain region is beyond the feasibility of conventional stereotactic methods. Convection-enhanced delivery (CED) has been developed to distribute homogeneous tissue concentrations of vectors over a large region of rodent or primate brain [11–14]. This method has been utilized extensively in the development of gene therapeutic strategies for neurodegenerative disorders, but further research is required to determine if global distribution of vectors produces deleterious effects on neural pathway functioning. For example, global expression of vector-derived neurotrophic factors may induce uncontrolled neuritic sprouting and subsequently, altered neuronal activity and physiology.

Indirect gene transfer, or *ex vivo* therapy, utilizes transplantation of genetically altered (vector-transduced) or unaltered cells capable of restoring functionality to a diseased region. Although *ex vivo* therapy includes the use of neural stem cells for repopulation of the denervated dopaminergic system and restoration of pathway function, this type of therapy will not be discussed in this chapter. Vectors used to genetically modify transplanted cells typically express either secreted trophic factors for neuroprotection/neuroaugmentation of surrounding host tissues or cell-intrinsic survival factors for protection of grafted cells from the stress of transplantation. Vectors delivered via *ex vivo* therapy must be able to integrate into the host cell genome as transplanted cell populations are expanded prior to grafting. Utilization of gene transfer technologies may allow for the expansion of the graft cell population or

increased graft survival via expression of a growth or survival factor thereby minimizing the amount of starting fetal tissue [15,16].

39.2 NEURODEGENERATIVE DISEASES AMENABLE TO GENE THERAPY

The following discussion will illustrate the most common forms of neurodegenerative diseases (summarized in Table 39.2) and potential gene therapy approaches that have been employed based on current understandings of disease mechanisms.

39.2.1 PARKINSON'S DISEASE

PD is the second most common chronic neurodegenerative disease in humans. The incidence of PD was estimated in 1995 to be between 1:100 and 1:500 individuals [17,18]. This incidence translates to approximately 1%–2% of the population over the age of 65 [19–21]. The disorder, initially described in six patients by Dr. James Parkinson, is typified clinically by symptoms including bradykinesia, resting tremor, rigidity, and gait abnormalities followed by postural instability, dementia, and autonomic dysfunction. Pathologically, PD patients experience specific degeneration of dopaminergic neurons in the substantia nigra pars compacta (SNpc) as well as dopaminergic ventral tegmental area neurons and noradrenergic neurons of the locus coeruleus. Furthermore, neuronal loss has been reported in other brain areas such as the cerebral cortex, anterior thalamus, hypothalamus, amygdala, and basal forebrain. In addition to neuronal loss, accumulation of proteinaceous cytoplasmic inclusions called Lewy bodies is a neuropathologic hallmark of PD. The exact role of Lewy

TABLE 39.2
Neurological Disorders Amenable to Gene Therapy

Disease	Age Onset	Disease Mechanism	Basis
Parkinson's	50–70s	Loss pigmented DA neurons in midbrain	<i>Genetic (rare):</i> α -Synuclein, C-terminal ubiquitin hydrolase; parkin <i>Environmental:</i> Pesticides, fungicides, neurotoxicants
Alzheimer's	50–80s	A β accumulation; tau hyperphosphorylation; synapse loss	<i>Genetic (infrequent):</i> APP, PS (susceptibility): ApoE4 <i>Environmental:</i> Viral infection/Diet
Lysosomal storage	Infancy	Enzyme deficiency leading to lysosomal protein accumulation and eventual peripheral and CNS degeneration	<i>Genetic:</i> Lysosomal enzyme/transport gene deletion/mutation
Huntington's	20–50s	Loss of striatal medium spiny neurons	<i>Genetic:</i> Polyglutamine expansion in Huntingtin (Htt) gene locus
Stroke	Varies	Hypoxic insult leads to necrotic and apoptotic cell death	Potential genetic and environmental susceptibility interaction
Epilepsy	Childhood	Aberrant hypersynchronization of local or global neuronal networks	Unknown; potential early lifetime subclinical event
Motor neuron disorders	40–60s	Loss of spinal motor neurons	<i>Genetic:</i> missense mutations (ALS); gene deletions/aberrant splicing (SMA)

bodies in PD is unclear, but other neurodegenerative disorders also exhibit intracellular and extracellular protein aggregates. Understanding the molecular mechanisms underlying protein aggregates in neurodegenerative diseases may assist to illuminate a common target for gene therapy.

Although more than 180 years have passed since Parkinson's first description, the disease etiology is still largely unknown. Since the evolution of successful gene therapeutic strategies will rely heavily on a detailed understanding of the molecular and cellular processes governing the clinical presentations of PD, exploring the pathophysiology of PD is crucial. The following section will summarize possible mechanisms of PD and how methods in gene delivery and expression might be applied to interdict the pathogenic pathways of this neurodegenerative disorder.

39.2.1.1 Mechanisms of Disease

PD exists as both a sporadic and familial disorder. Although the exact etiology of PD is unknown, the common pathway of both sporadic and familial PD is a loss of DA neurons. Importantly, this decline in DA neuron number below a critical threshold produces early symptomatic PD (reviewed in Refs. [22–24]). Given that environmental factors such as pesticides, herbicides, and industrial chemicals have been identified as potential risk factors for PD and genetic mutations have also been identified, it is likely that either alone or in combination, these triggers will produce a clinical syndrome similar to PD (reviewed in Ref. [24]). Figure 39.2 outlines a common pathway for PD and suggests several targets for gene therapy without necessarily interdicting the

initiating mechanism [367]. In this “common pathway” model for PD, multiple triggering mechanisms such as genetic, toxicant, and environmental trigger plus genetic vulnerability converge on a shared common pathway to cell death. The first step along this pathway may encompass presynaptic injury and dysfunction followed by cellular compensation and metabolic stress. This preclinical injury and damage would result in DA deficiency and cell death. Gene therapy treatment opportunities would include (1) targeting specific triggering mechanisms, (2) targeting shared early pathway step prior to presynaptic dopaminergic dysfunction, (3) targeting shared later pathways when dysfunction occurs, and (4) restoring DA biosynthesis in the denervated striatum. As stated above, PD is likely the result of a combination of environmental, toxin, and genetic triggering factors. Because of this, it is difficult to review the impact of each individually but we will attempt to briefly outline the potential impact of these factors on the etiology of PD and summarize their convergence on the pathophysiology of this disease.

39.2.1.2 Environmental Factors

Several findings support an etiologic role for exogenous factors in PD. The earliest observation was that a synthetic by-product of meperidine production, 1,2,3,6-methylphenyltetrahydropyridine (MPTP), produced a syndrome similar to PD. MPTP treatment of mice and monkeys has become a common method to achieve dopaminergic neuronal loss and an animal “model” of PD. The toxic compound MPTP is converted in glia to the pyridinium ion (MPP+) by monoamine oxidase type B (MAO-B) and subsequently taken up by DA

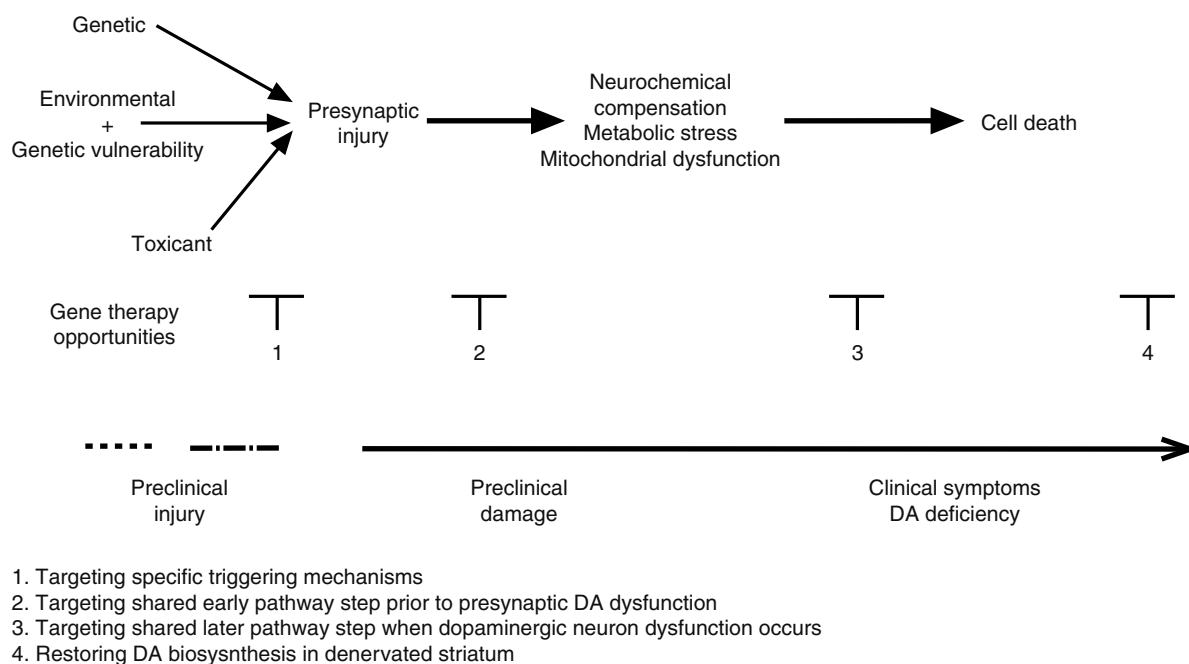

FIGURE 39.2 Schematic depicting the common pathway model for PD and points along this pathway where gene-based therapy may be applied. (From Bowers, W.J., et al., *Clin. Neurosci. Res.*, 1, 483, 2001. © 2001 Elsevier Science B.V. With permission.)

neurons via the DA transporter. MPP⁺ is then actively transported to the mitochondria where it inhibits complex I, interfering with mitochondrial respiration and resulting in increased production of the superoxide anion. [25].

Recent reports lend biological plausibility to pesticide exposure as both an alternative model of nigrostriatal dopaminergic degeneration and a risk factor for PD [26–28]. Greenamyre's group reported that chronic, systemic treatment of rats with the lipophilic pesticide, rotenone, resulted in highly selective nigrostriatal dopaminergic degeneration [27,29]. This degeneration is associated with PD-like behavioral changes including hypokinesia and rigidity. Neuropathologically, these animals accumulate fibrillar cytoplasmic inclusions that contain both ubiquitin and α -synuclein. This treatment represents an important alternate PD model since these inclusions resemble Lewy bodies, a hallmark of PD. Of equal importance is the suggestion from this model that mitochondrial dysfunction in dopaminergic neurons, in particular complex I inhibition, plays an important role in the pathophysiology of Lewy body formation and some cases of idiopathic PD. Other groups have implicated a combination of herbicide and fungicide exposure as a potent risk factor for PD [26,28]. Mice treated with a combination of paraquat and maneb demonstrated a sustained decrease in motor activity and reduced tyrosine hydroxylase immunoreactivity in the dorsal striatum. These effects were greater in combination than either paraquat or maneb alone, suggesting that multiple compound exposure alone or in concert with genetic vulnerability may trigger a cascade of events leading to a PD-like syndrome.

39.2.1.3 Genetic Factors

Several genetic factors have recently been identified to play a central role in the etiology of familial PD (summarized in Table 39.3). In 1996, genetic linkage strategies were applied to a large Italian family with early onset PD [17,30]. The susceptibility gene was identified within the *PARK1* locus on the

long arm of chromosome 4q21–q23, and positional cloning identified a missense mutation at position 53 (A53T) in the *SNCA* gene, which encodes for the α -synuclein protein [31]. Another mutation in α -synuclein, A30P, was identified in a German family [32]. Recently, a third missense mutation, E46K, was identified in a Spanish family with an autosomal dominant form of PD [33]. As of yet, the physiological role of α -synuclein has been elusive, but the A53T and A30P mutant forms of α -synuclein have been shown to aggregate *in vitro*, with the propensity to form oligomeric conformers capable of accelerating the progression of the disease [34]. The E46K mutation has also proven to accelerate α -synuclein filament formation, and unlike the A53T and A30P mutant forms, it harbors an increased ability to bind phospholipids *in vitro* [35]. Furthermore, overproduction of the wild-type α -synuclein protein is sufficient to cause PD as evidenced by a patient of the Contursi kindred who harbored a triplication of the α -synuclein locus [36]. Although mutant α -synuclein is responsible for a small number of PD cases, it has vaulted to the forefront of PD research since wild-type α -synuclein has been identified as a key component of Lewy bodies. In fact, α -synuclein staining is now widely utilized as a neuropathological criterion for PD [37–42].

Two other genetic mutations related to proteasome function have been identified in familial PD. One mutation in the *parkin* gene (*PARK2*) was discovered in an early onset juvenile autosomal recessive form of parkinsonism (AR-JP) that presents with mild symptoms, slow progression, and the absence of Lewy bodies [43–46]. Homozygous deletions and point mutations in *parkin* also account for the majority of autosomal recessive inherited PD [47–53]. A second mutation in the ubiquitin carboxy-terminal-hydrolase-L1 (*UCH-L1*) gene has been identified in the *PARK5* locus in a German family with PD [54]. Both Parkin and UCH-L1 are involved in the regulation of the ubiquitin–proteasome pathway that suggests dysregulation of protein processing in the pathophysiology of PD [21,55,56].

More recently, two other genes believed to be involved in cellular oxidative stress response have been implicated by linkage analysis to rare familial forms of PD. In 2003, Bonifati et al. discovered mutations in the DJ-1 gene (*PARK7*) to be associated with an autosomal recessive early-onset form of human parkinsonism [57]. Although the exact function of DJ-1 is unclear, it is proposed to act as a redox-regulated molecular chaperone important in combating oxidative stress. Two homozygous mutations in PINK1 (PTEN-induced kinase 1), a mitochondrial resident protein kinase, have also been linked with a hereditary early-onset form of PD mapped to the *PARK6* locus in a large Sicilian family [58]. Cell culture studies have speculated PINK1 to function during cellular oxidative stress to protect against mitochondrial dysfunction and apoptosis of neurons. In 2004, the mutant gene responsible for *PARK8*-linked autosomal dominant form of PD was cloned and identified as leucine-rich repeat kinase 2 (*LRRK2*), which encodes for the dardarin protein throughout the adult brain and proposed to function as a tyrosine kinase [59,60]. In some kindreds of Middle Eastern origins, a prevalent mutation in

TABLE 39.3
Identified Genes Associated with Familial PD

PARK	Locus	Gene	Proposed Function	References
<i>PARK 1</i>	4q21–22	α -Synuclein	Presynaptic	[31]

LRRK2 (G2019S) has been described as a common cause of disease. This multifunctional protein appears to suffer mutations, which deregulated its catalytic activity and cause a dominantly inherited form of PD [61–65]. Very recent data, obtained from whole genome scans, have identified several genes that confer increase risk for the development of PD [66–68]. Whether the mechanisms underlying their conveyance of increased vulnerability will be therapeutically relevant remains to be established.

As evidenced above, rigorous genetic linkage studies are identifying genes implicated in rare familial forms of PD, which will undoubtedly facilitate unraveling the etiology of PD and lead the way for timely diagnosis and novel gene-based therapeutics in the future.

39.2.1.4 Potential Gene-Based Therapies for PD

As outlined in Figure 39.2 and discussed above, toxicant and environmental triggers combined with genetic vulnerability are likely to converge on a common pathway toward cell death in PD [69]. These common downstream events that culminate in neuronal cell death are all possible targets for gene therapy in the treatment of PD. Teaming the appropriate gene with the most powerful vector system will enable the best experimental therapeutic approaches for patients with PD.

39.2.1.4.1 Ad Vectors and PD

Adenovirus-based therapies for PD have been tested extensively in rodent models. A first-generation Ad vector encoding the TH gene, when introduced into the striatum of 6-OHDA-lesioned rats, led to a reduction in amphetamine-induced rotational behavior [70]. Vector-directed TH gene expression was observed for 1 to 2 weeks following gene transfer but was accompanied by a vigorous inflammatory response, gliosis, and local tissue damage. Ad vectors expressing the TGF β family member, glial cell line-derived neurotrophic factor (GDNF) have also been tested in 6-OHDA-lesioned rats where protection of the dopaminergic phenotype from chemical induced damage is observed for up to 6 weeks postlesion [71]. The protection afforded in a prophylactic setting was of equivalent magnitude irrespective of the site of vector instillation: striatum or the SN [72,73]. Furthermore, using a glial fibrillary acidic protein (GFAP) promoter to restrict expression of GDNF to astrocytes, Do Thi et al. demonstrated neuroprotective effects of DA neurons up to 3 months post-transduction in a 6-OHDA rat model [74]. Additionally, the modified E1, E3/E4-defective, Ad-GFAP-GDNF vector employed in this study demonstrated a reduction in vector-induced cytotoxicity compared to “first-generation” Ad vectors, an important observation with potential relevance for the translational extension from preclinical studies. Connor et al. demonstrated that Ad-mediated GDNF delivery was only protective in aged rats when the virus was delivered to the striatum, whereas the dopaminergic system of young 6-OHDA-lesioned rats could be protected by delivery to either the SN or striatum [75]. This group hypothesized, based upon a thesis put forth by Zigmond et al., that compensatory changes occur in the CNS of the aged rat that likely increases its

sensitivity to Parkinsonian lesioning [76]. In these preclinical studies, Ad-GDNF was delivered shortly before or after the drug-induced lesion in the rodent model, which inadequately reflects a realistic clinical setting where the nigrostriatal pathway has substantially deteriorated. Therefore, Zheng et al. administered an Ad-GDNF vector 4 weeks postlesion into the striatum of a 6-OHDA rat model and observed an increase in DA levels and TH-positive neurons 10 weeks postinjection, thus demonstrating the potential of GDNF-based gene therapy even at a later time point of the disease in the rodent model [77].

As mentioned previously, oxidative stress may play a significant role in PD etiology in terms of exerting downstream effects on DA neurons, leading to their degeneration in the nigrostriatal pathway. Cu/Zn superoxide dismutase (SOD1) is a key enzyme in a cells' response to oxidative stress, serving to scavenge and mitigate the harmful effects of reactive oxygen species (ROS). Barkats et al. more recently demonstrated a neuroprotective role of SOD1 on DA neurons within the nigrostriatal pathway by overexpressing SOD1 in the striatum of an MPP⁺-lesioned rat model utilizing an Ad vector [78].

39.2.1.4.2 AAV Vectors and PD

Recombinant AAV vectors exhibit great promise in the arena of PD gene therapy. For example, Kaplitt et al. injected AAV vectors expressing either β -galactosidase or human tyrosine hydroxylase (hTH) into the brains of 6-OHDA-lesioned rats and demonstrated long-term transgene expression (3 months) and functional recovery [79]. Mandel et al. demonstrated longer-term transgene expression (at least 1 year) in the rat striatum [80]. In this series of experiments, AAV vectors were constructed to express either hTH or human GTP-cyclohydro-lase I (hGTPCHI) in the 6-OHDA lesioned rat striatum. Elevated levels of L-DOPA were observed in animals receiving both vectors, but disappointingly, no reduction in apomorphine-induced rotational behavior was apparent in these animals. CED-mediated delivery of AAV expressing the aromatic amino acid decarboxylase (AADC) gene to the striata of MPTP-lesioned monkeys resulted in stable L-DOPA-regulated DA production persisting for more than 2 years post-therapy in these Parkinsonian animals [11,81]. An illustration of an experiment from this study is shown in Figure 39.3. This study had profound clinical relevance for PD gene therapy, since it demonstrated for the first time the sustained expression of a transgene delivered via AAV vectors (up to 6 years) in a nonhuman primate. A phase I safety study using AAV serotype 2 vectors to deliver AADC to the striatum of advanced PD patients has been initiated and continues to accrue patients (NIH OBA Human Gene Transfer Clinical Trials Database entry number 593-(2003/07)). Another study using AAV vectors to deliver hTH and AADC genes to the brains of MPTP-treated monkeys showed that AAV vectors could direct long-term transgene expression devoid of significant toxicity [82]. Moreover, Shen et al. have utilized a triple AAV vector administration approach to preclinically assess therapeutic efficacy in a PD model [1]. These vectors direct the expression of TH, AADC, and GTPCHI and were shown

FIGURE 39.3 (See color insert following blank page 206.)

Immunohistochemistry of AADC in hemilesioned monkeys before and after AAV-hAADC treatment. (A) Three [^{18}F]FMT PET coronal images of an AAV-hAADC-treated monkey striatum at 18 months show the strongest AADC transgene expression in targeted area (midstriatum) and correlate with AADC immunostaining. (B–D) In (B) and (C), color-coded immunostaining against TH and AADC in progressive anterior to posterior coronal slices in two representative AAV-hAADC monkeys is shown at 3 years after AAV delivery. (D) shows TH and AADC staining in a representative AAV-LacZ monkey at 2 years after AAV delivery. The pattern of TH and AADC immunoreactivity, normally colocalized in intact dopaminergic pathways, is very different in these MPTP-lesioned animals. Note the dramatic reduction of anti-TH staining in the right striatum of all animals compared to the intact left side, confirming profound loss of dopaminergic fibers and terminals on the lesioned side (B–D). Anti-AADC staining shows endogenous AADC in the nonlesioned, left striatum and almost complete restoration of the enzyme within the right striatum of AAV-hAADC animals, demonstrating widespread distribution of AADC transgene expression (B and C). No such AADC staining or [^{18}F]FMT PET signal is seen on right side of control animals (D). The box in the PET image in (D) indicates the region of infusion of AAV-LacZ. (From Bankiewicz, K.S., et al., *Mol. Ther.*, 14(4), 564, 2006. © 2006 The American Society of Gene Therapy. With permission.)

in combination in rats to enhance levels of tetrahydrobiopterin (BH4) and DA production, as well as to improve apomorphine-induced rotational behavior for up to 1 year. Other studies have also demonstrated extended expression in the CNS using AAV vectors [83–85]. The complexity of this approach, however, mitigates against its rapid translation to clinical trials.

In 2002, Luo and colleagues [86] described the use of AAV vectors to express two isoforms of glutamic acid decarboxylase (GAD) gene, GAD₆₅ and GAD₆₇, in the setting of a rat toxicant model of PD. The conceptual approach was intended to phenocopy excitatory neurons (glutamate neurotransmitter-releasing) to inhibitory neurons (GABA neurotransmitter-releasing). The rationale behind this novel approach relates to the altered neurotransmission that occurs within the basal ganglia during PD. In this pathophysiological state, dopaminergic neuron projections from the SNpc to the striatum degenerate. The observed reduction in DA release in the striatum results in reduced GABA neurotransmission, also called “disinhibition,” in the subthalamic nucleus (STN). This state, coupled with direct disinhibition within the striatum itself, results in increased glutamate neurotransmission and thus excessive excitation of the substantia nigra pars reticulata (SNr) and the globus pallidum internal segment (GPI). Delivery of AAV expressing GAD_{65/67} to the STN led to increased GABA release in the SNr, shifted SNr single-unit recording responses from primarily excitatory to inhibitory, and when delivered prior to 6-OHDA lesioning protected rats from the neurotoxin. Based on these encouraging preclinical results, the first gene-therapy phase I clinical trial was launched in 2003 at New York Weill Cornell Medical Center (NIH OBA Human Gene Transfer Clinical Trials Database entry number 469-(2001/04)). The phase I clinical trial entailed delivery of an AAV-GAD vector to the subthalamus of 12 advanced PD patients refractory to standard pharmacological treatment. It will be interesting to determine what the long-term effects of neuronal phenocopy may have on the basal ganglia circuitry of these patients.

More recently, Ceregene has completed a phase I, open-label safety study of intrastriatal delivery of an AAV serotype 2 vector expressing the neurotrophic factor neurturin (NTN) to subjects with idiopathic PD (NIH OBA Human Gene Transfer Clinical trials Database entry number 689-(2005/01)). These patients did not manifest any SAEs and although the trial design was of an open label type marked reductions in the motor subscale of the unified PD rating scale (UPDRS) were reported. (Cite the RAC presentation). A phase II double-blinded sham surgical controlled trial with Cere120 has recently begun to enroll patients.

As previously mentioned, Parkin and DJ-1 are genes linked to rare inherited forms of PD and function to safeguard cells from the adverse effects of oxidative stress. Paterna et al. used recombinant AAV vectors to deliver and overexpress Parkin and DJ-1 in the substantia nigra of an MPTP mouse model of sporadic PD [87]. When compared to control mice that received injections of AAV-enhanced green fluorescent

protein virus, both AAV-Parkin and AAV-DJ-1 virus injected mice showed inhibition of DA neuron death, 1 week following MPTP insult. A caveat in this study was that unilateral expression of DJ-1 in nigral dopaminergic neurons caused reduced DA receptor signaling in normal mice evidenced by apomorphine-induced ipsilateral turning toward the AAV-DJ-1 injected side. Additionally, neither Parkin nor DJ-1 was able to protect against MPTP-induced loss of catecholamines (DA, DOPAC, HVA) in the striatum of these MPTP-lesioned mice. Therefore, thorough investigation into the effects of overexpressing Parkin and DJ-1 on presynaptic neurotransmission as well as DA biosynthesis is required before considering them as candidates for PD-gene therapy.

39.2.1.4.3 Lentivirus Vectors and PD

Lentiviral vector-based therapies for PD have been tested extensively in rodent and nonhuman primate models. Injection of a self-inactivating lentivirus vector expressing GDNF has been shown to be protective in the 6-OHDA rat and MPTP nonhuman primate models of PD and in nonlesioned aged rhesus monkeys [88–90]. An example of one of these studies

is shown in Figure 39.4. Long-term striatal overexpression of this potent factor by a lentiviral vector in nonlesioned rats has been shown to markedly downregulate TH expression [91]. Furthermore, a dose-dependent downregulation of TH-positive staining in the rat substantia nigra was observed 6 weeks after injecting a GDNF overexpressing lentiviral vector (rLV-GDNF) [92]. The mechanism responsible for GDNF-mediated repression of TH expression remains speculative, but proposals made by Georgievska and colleagues suggest that TH repression either at the protein level or enzyme activity level may offset the hyperstimulatory effects mediated by high levels of GDNF, which ultimately sustains long term benefit to DA neuron function. These observations warrant caution in implementation of gene transfer approaches clinically that involve long-term, uncontrolled GDNF expression. Addressing this concern, Georgievska et al. have developed a lentiviral vector system, which temporally regulates the expression of GDNF in a tetracycline-dependent manner [93]. GDNF expression was induced in the rat striatum by administering doxycycline (a tetracycline analog) in the drinking water, which transactivates the rtTAS2-M2 regulator element and permits GDNF production (Tet-on system). Consequently, TH

FIGURE 39.4 (See color insert following blank page 206.) Delivery of a lentiviral vector expressing the GDNF gene in Parkinsonian nonhuman primates. Rhesus monkeys received the dopaminergic toxin MPTP unilaterally (right side) to establish a parkinsonian state. One week later, the animals received ipsilateral infusions of lentiviral vector expressing GDNF (lenti-GDNF) or one expressing the reporter protein β -galactosidase (lenti- β Gal). Three months following treatment the animals were sacrificed and immunohistochemistry was performed. Panels A and B depict low-power dark-field photomicrographs through the right striatum of TH-immunostained sections of MPTP-treated monkeys treated with lenti- β Gal (Panel A) or lenti-GDNF (Panel B). There appeared to be a comprehensive diminution of TH immunoreactivity in the caudate and putamen of lenti- β Gal-treated animals, while a nearly normal level of TH immunoreactivity was seen in the animals receiving lenti-GDNF. Low power (Panels C and D) and medium power (Panels E and F) photomicrographs are shown of a TH-immunostained section through the substantia nigra of animals treated with lenti- β Gal (Panels C and E) and lenti-GDNF (Panels D and F). Note the loss of TH-immunoreactive neurons in the lenti- β Gal-treated animals on the side of the MPTP infusion. TH-immunoreactive sprouting fibers, as well as an above normal number of TH-positive nigral perikarya, are observed in lenti-GDNF-treated animals on the side of the MPTP injection. Panels G and H depict bright-field low-power photomicrographs of a TH-immunostained section from a lenti-GDNF-treated monkey. Note the normal TH-immunoreactive fiber density through the globus pallidus on the intact side that was not treated with lenti-GDNF (Panel G). In contrast, an enhanced network of TH-immunoreactive fibers is seen on the side treated with both MPTP and lenti-GDNF. Scale bar in (G) represents the following magnifications: Panels A, B, C, and D at 3500 μ m; Panels E, F, G, and H at 1150 μ m. (From Kordower, J.H., et al., *Science*, 290(5492), 767, 2000. © 2000 AAAS. With permission.)

protein expression was reduced during doxycycline-induced GDNF expression, but gradual recovery of TH protein levels was observed 2–8 weeks after discontinuation of doxycycline. Hence, the downregulation of TH associated with the above therapeutic approach cannot be averted by temporally regulating vector-directed GDNF expression.

In a recent study, Vercammen et al. assessed the neuroprotective capacity of the E3 ubiquitin ligase, Parkin, the mutant gene linked to autosomal recessive juvenile PD. Wild-type Parkin was overexpressed via a lentiviral vector to the substantia nigra of a 6-OHDA rat model 2 weeks prior to lesioning [94]. Results from this study showed significant inhibition of DA neuron loss at 1 and 3 weeks postlesion accompanied by behavioral improvements lasting 20 weeks as evidenced by amphetamine-induced rotation test and cylinder test.

Lentiviral vectors harboring different transgenes have demonstrated preclinical efficacy in models of PD. The nigrostriatal loss of DA biosynthetic capacity has been approached with lentiviral vectors by the transduction of multiple enzymatic components to restore DA within the striatum. Due to the moderate size capacity of lentiviral vectors, multicistronic versions of the vector platform have been developed. Azzouz et al. recently created a lentiviral vector that coexpresses aromatic L-AADC, tyrosine hydroxylase, and GTP cyclohydrolase I [95]. Delivery of this vector to the striata of 6-OHDA lesioned rats led to stable DA biosynthesis and functional improvement for up to 5 months post-treatment.

39.2.1.4.4 HSV Vectors and PD

Dependent upon the transgene size capacity of a given gene transfer vector, the use of cellular promoters to direct transgene expression appears to be another promising strategy for development of a gene-based therapy for PD, as these promoters tend to yield longer term, cell-specific expression. This has been demonstrated using HSV amplicons equipped with either the preproenkephalin or 9 kb tyrosine hydroxylase (TH) promoter *in vivo*. Kaplitt et al. showed extended expression duration and striatal cell specificity using a version of the preproenkephalin promoter inserted into an HSV amplicon [96]. Using 9 kb rat TH promoter to drive expression of the β -galactosidase (*lacZ*) reporter gene in the mouse striatum, Jin et al. observed expression of *lacZ* in TH-positive dopaminergic neurons in the substantia nigra due to retrograde transport of amplicon virions [97]. In some of the initial studies utilizing amplicons as the chosen gene therapy vector, During et al. treated 6-OHDA lesioned rats with an HSV amplicon expressing hTH [98]. Behavioral and biochemical recovery was maintained for 1 year following vector introduction. Since that initial observation, Sun et al. exploited the large transgene capacity of HSV-1 amplicon vectors as well as the helper virus-free packaging technology to coexpress four therapeutic genes: tyrosine hydroxylase (TH), aromatic AADC, GTP cyclohydrolase (GTP CHI), and vesicular monoamine transporter 2 (VMAT2), which are involved in DA biosynthesis and transport in striatal

neurons [99]. Long-term, neuron-specific expression of the four genes was achieved by a modified neurofilament gene promoter in the striatum of 6-OHDA neurotoxicant rat model of PD. The rats that received the four-gene-vector demonstrated expression for 14 months accompanied by correction of apomorphine-induced rotational behavior up to 6 months. Biochemical analysis revealed extracellular levels of DA and dihydroxyphenylacetic acid (DOPAC) comparable to normal rats proximal to the injection sites. This study further confirms the versatility of the HSV-1 vector in delivering multitherapeutic transcription units for the treatment of PD. Furthermore, Sun et al. compared the neuroprotective effects of GDNF and brain-derived neurotrophic factor (BDNF) on dopaminergic neurons of the nigrostriatal pathway using the HSV-1 vector. Their study concluded that GDNF was more potent in behavioral and biochemical recovery of the 6-OHDA lesioned mice when compared to either BDNF alone or when GDNF and BDNF were coexpressed.

39.2.1.4.5 Nonviral Vectors and PD

The use of nonviral means of DNA delivery for treatment of PD is appealing due to the inherent lack of immunogenic or cytotoxic viral gene products in the system. Nonviral delivery of genes includes the following means of transfer: “naked” DNA, DNA encapsulated within cationic lipids or polycationic polymers, or DNA attached to positively charged metal particles and introduced via particle bombardment [3,100–102]. Until recently, successful implementation of this gene transfer modality has largely been impeded by the low transfection efficiencies observed in neurons. *In vivo* nonviral means of DNA transfer were initially demonstrated to occur in muscle cells with surprising efficiency [103]. DNA transfer using polycationic lipid formulations to glia and neurons has been also demonstrated, albeit at low efficiencies [10,100]. Martinez-Fong et al. recently described their use of a neurotensin-SPDP-poly-L-lysine conjugate that was competent to bind and transfer plasmid DNA to neurotensin receptor-expressing cell lines (N1E-115 and HT-29, [104]). Because the high-affinity neurotensin receptor is expressed by a subset of neurons of the nigrostriatal and mesolimbic dopaminergic systems, this nonviral gene delivery modality may have the potential to be extended from preclinical studies. Additionally, the 25 kD cationic polymer polyethylenimine was shown by Abdallah et al. to mediate transfer of a luciferase-expressing plasmid to neurons and glia of adult mice [105].

Zhang and colleagues developed another nonviral gene delivery modality that has been recently tested in the 6-OHDA rat model of PD [106]. A TH-expressing plasmid, encapsulated in PEGylated immunoliposomes that were targeted to the brain with a rat transferrin receptor-specific monoclonal antibody, was administered intravenously. The plasmid was shown to effectively cross the blood–brain barrier (BBB) and lead to transient normalization of TH levels within the striatum of 6-OHDA lesioned rats. If issues regarding transgene expression silencing can be resolved and strict

targeting to the striatum can be achieved using brain-specific gene promoters, this approach may become promising.

39.2.2 ALZHEIMER'S DISEASE

39.2.2.1 Introduction

As the most common cause of senile dementia, Alzheimer's disease affects millions of people worldwide. Clinically, patients experience progressive cognitive impairment leading to dementia and ultimately death. The neuropathological hallmarks of AD are senile neuritic plaques (NPs) and neurofibrillary tangles (NFTs). NPs are extracellular aggregations of protein, including the fibrillar peptide, β -amyloid. NFTs are neuronal inclusions of filamentous structures containing hyperphosphorylated forms of the microtubule associated protein tau. While these tissue and cellular abnormalities are well described the role of each in producing neuronal demise is still actively debated.

AD is divided into two types based on age of symptom onset, early (before 60 years) and late (after 60 years). Early-onset Alzheimer's disease (EOAD) is primarily an inheritable form of the disease. Genetic linkage studies of several families exhibiting EOAD identified a locus on the long arm of chromosome 21 near the amyloid precursor protein (APP) gene [107]. Further studies revealed that mutations in the human APP gene increased the production of β -amyloid (a major constituent of senile plaques) [108]. The APP linkage represents <1% of early onset cases suggesting other genetic loci exist. Two loci, one on chromosome 14q and the other on chromosome 1 containing the presenilin (PS) 1 and 2 genes, have also been identified in linkage studies [109,110]. Many mutations in PS-1 have been identified in EOAD cases, which account for >50% of all EOAD cases. The function of the PSs is currently emerging and appears to involve signal transduction [111–113].

A genetic locus on chromosome 19q is implicated in late-onset Alzheimer's disease (LOAD) [114,115]. The apolipoprotein E gene is located in this region, but no mutations have been found in AD, however one of three isoforms of ApoE, E4, is a significant risk factor for LOAD [108]. In 2004, Dodart et al. utilized a lentiviral vector to express the human ApoE4 isoform in the hippocampus of an AD mouse model (PDAPP), which overexpresses a human APP mutation (V717F) under the transcriptional regulation of the platelet-derived growth factor (PDGF) promoter, and also lacks the mouse ApoE gene (ApoE^{-/-}) [116]. Their results revealed increased amyloid burden and A β_{1-42} levels 5 weeks postinjection in the hippocampi of these mice (PDAPP- ApoE^{-/-}) compared to control mice that received the lenti-GFP control vector. Other potential LOAD-linked genes have been identified [117–123] and further study is needed to substantiate the importance of their linkage. The vast majority of LOAD cases are sporadic with no identified genetic component. Studies using microarray gene expression profile analysis are beginning to identify altered gene expression in LOAD compared to normally aged brains (P. Coleman, personal communication, [124]). Such

analyses will lead to further studies characterizing the role of candidate genes in AD possibly allowing for a genetic screen to identify the best therapeutic strategy.

39.2.2.2 Putative Mechanisms Underlying Alzheimer's Disease

Based on the neuropathological findings of AD, NPs, and NFTs, extensive research efforts have focused on their role in the pathogenesis of AD. Many hypotheses are under examination: the acetylcholine hypothesis [125,126], the amyloid cascade hypothesis [127–129], the neuroinflammatory hypothesis [130], energy-metabolism hypothesis [131], and the oxidative stress hypothesis [132]. A comprehensive review of the research behind each of these hypotheses is beyond the scope of this chapter; instead, they will be discussed generally as potential target areas for gene therapy.

39.2.2.3 Potential Gene-Based Therapies for Alzheimer's Disease

One of the affected brain regions is the basal forebrain cholinergic complex as cholinergic deficiency correlates with both the magnitude of pathological severity and degree of dementia [125,133–136]. One therapeutic approach is to augment cholinergic function by increasing activity of the biosynthetic enzyme for acetylcholine, choline acetyltransferase (ChAT) to the affected area. Nerve growth factor (NGF) upregulates expression of ChAT [137] and promotes survival and maintenance of the septo-hippocampal pathway that is a major pathway for memory and learning [138]. Studies reporting that NGF increases β -amyloid production *in vitro* contrast with *in vivo* studies suggesting that NGF delivery does not increase plaque formation in primates [139]. Grafting of fibroblasts genetically modified to produce NGF via a Moloney murine leukemia virus vector has been shown to promote restoration and survival of the septohippocampal pathway [140–144]. Figure 39.5 depicts the bioactivity of transduced grafts *in vivo*. These initial *ex vivo* studies together with extensive preclinical studies in primates set the stage for the first, phase 1 clinical trial of *ex vivo* NGF gene therapy. Results from this trial revealed an improvement in the rate of cognitive decline in 6 patients, and no apparent detrimental effects of NGF expression from the grafted fibroblasts 22 months post-therapy [145]. Two patients had severe adverse events (SAEs), which were attributed to the neurosurgical procedure. As previously mentioned, *ex vivo* gene therapy has been shown to be transiently efficacious, and therefore focus has now been shifted to *in vivo* based strategies for protracted expression of NGF. In 2006, Ceregene launched a phase 1 clinical trial using an adeno-associated viral vector expressing NGF (AAV- β NGF) (NIH OBA Human Gene Transfer Clinical trials Database entry number 623-(2004/01)). NGF clearly has therapeutic potential but further clinical trials are warranted to evaluate its efficacy in subverting disease processes or ameliorating symptoms of AD.

FIGURE 39.5 (See color insert following blank page 206.) Trophic response to NGF in the human brain. (A,B) Nissl stain of autologous, NGF-secreting cell implant in brain of individual with Alzheimer's disease 5 weeks after treatment. Graft (g) adjacent to nucleus basalis of Meynert (nbm; arrows). Inset, robust mRNA encoding NGF by in situ hybridization within graft. Scale bar in (A) 247 μm ; in (B) 24 μm . Note proximity of graft to nbm seen in similar perspective in c at higher magnification. Higher magnification (d) shows dense penetration of cholinergic axons into graft. Scale bar in (C) 82 μm ; in (D) 11 μm . (From Tuszynski, M.H., et al., *Nat. Med.*, 11(5), 551, 2005. © 2005 Nature Publishing Group. With permission.)

Amyloid-containing plaques may be a cause of AD or a by-product of the disease process. Identified mutations in both the APP and the PS genes correlate with increased production of β -amyloid and potentially plaques. PSs are transmembrane proteins localized predominantly in endosomes and Golgi apparatus and are thought to promote the aggregation of β -amyloid by increasing the activity of γ -secretase, the enzyme responsible for liberating the $\text{A}\beta$ 1–42 fragment from APP subsequent to β -secretase (BACE1) cleavage [113,146]. Gene products that may modify the activity of β - or γ -secretase or proteins capable of disrupting β -amyloid aggregation may potentially slow progression of the disease. Proof-of-concept for such a strategy was provided in 2005 by Singer et al., where they utilized a short interfering RNA (siRNA)-expressing lentiviral vector to target and knockdown the expression of β -secretase (BACE1) in an APP transgenic mouse model of AD [147], since embryonic disruption of γ -secretase activity via a traditional knock-out strategy has been shown to be lethal [148]. Results from this study showed a reduction in APP processing, evidenced by reduced $\text{A}\beta_{1-42}$ peptide levels 4 weeks postinjection in the hippocampi of APP transgenic mice that received the lenti-siBACE1–6 vector. Furthermore, siBACE1–6 expressing transgenic mice demonstrated less neurodegeneration in the hippocampus as evidenced by immunohistochemical analyses. This pathological correlate was substantiated functionally by improved performance in spatial learning and memory compared to untreated APP transgenic mice using the Morris water maze behavioral test. In 2006, Hong et al. constructed and tested a replication defective HSV vector capable of downregulating the expression of APP using an RNA interference (RNAi) strategy [149]. Delivery of this vector to the hippocampus of a novel AD mouse model (LV-APP^{Sw}) resulted in a significant reduction in $\text{A}\beta_{40}$ peptide levels 4 weeks postinjection. Furthermore, this group examined the efficacy of neprilysin in $\text{A}\beta$ peptide clearance utilizing the same LV-APP^{Sw} mouse model. Neprilysin is an extracellular metalloendopeptidase, which Iwata et al. identified as an enzyme capable of degrading

extracellular $\text{A}\beta$ and thus preventing its accumulation in the brain [150]. Codelivery of an HSV vector expressing neprilysin together with the LV-APP^{Sw} construct into the hippocampus of C57BL/6J mice resulted in a significant reduction in $\text{A}\beta_{40}$ expression as evidenced by immunohistochemistry 4 weeks postinjection [149]. These findings corroborate those previously described by Marr et al. in which they demonstrated a significant reduction in $\text{A}\beta$ deposition in the hippocampus of PDAPP transgenic mice one month after being stereotactically injected with a lentiviral vector expressing neprilysin [151].

Other areas of therapeutic interest for AD are inflammation and oxidative stress. Many mediators of inflammation have been detected in postmortem AD brain (reviewed in Refs. [130,152]). Whether inflammation is promoted by the production of plaques and tangles or inflammation initiates production of plaques and tangles, which in turn propagates an inflammatory response is not clear. It is thought that the inflammatory response of glia contributes to neuronal demise [130]. Although there is no unequivocal evidence directly linking inflammation and AD etiology, Janelsins et al. propose that inflammation may play an early role in the progression of AD based on their observations in a novel triple-transgenic mouse model (3xTg-AD), which recapitulates the disease progression and pathological hallmarks of AD [153]. Their findings reveal a spatial and temporal increase in the mRNA transcript levels of inflammatory mediators, TNF- α and MCP-1, coupled with augmented numbers of microglia and macrophages in the entorhinal cortex of 6 month old 3xTg-AD mice compared to 2 month old 3xTg-AD mice. Epidemiological studies with antioxidants and nonsteroidal anti-inflammatory drugs suggest that decreasing free radicals and inhibiting inflammatory processes may confer protection against AD or slow the rate of cognitive decline seen in AD (discussed in Ref. [132]). The delivery of gene products capable of scavenging free radicals and blocking inflammatory processes may also prove to be an effective therapeutic approach.

Another promising therapeutic approach in combating AD is A β -based immunotherapy [154–156]. Numerous investigative teams have reported diminution in AD-like pathology (i.e., A β deposition) and behavioral improvements in different animal models of the disease as a result of A β peptide immunization or via the administration of A β -specific antibodies. The biological mechanisms by which these therapies act are still incompletely understood. However, two nonmutually exclusive hypotheses have emerged: (1) A β -specific antibodies whether raised intrinsically or passively administered act at the BBB to alter the equilibrium of soluble A β _{1–42} concentrations to favor its clearance from the brain. This is posited to prevent additional A β peptide deposition and perhaps promote aggregate dissolution. (2) A β -specific antibodies cross a compromised BBB and bind to A β within the brain parenchyma where antibody–A β complexes are postulated to be bound by complement, and recognized by microglia, which dissolve existing amyloid deposits. Both mechanisms of vaccine action can lead to possibly harmful side effects, with the most feared being systemic autoimmune disease and CNS inflammation as illuminated by recent findings from an Elan Pharmaceuticals peptide vaccine phase II clinical trial conducted in Europe (commentary in Refs. [157,158]). More extensive 4 year clinical follow-up from this Elan vaccine trial has been recently reported. No additional patients developed meningoencephalitis and, interestingly, there was blunted cognitive deterioration in the vaccine group. These data compel the development of safer vaccination approaches.

To circumvent such deleterious side effects caused by synthetic A β -peptide based vaccinations/immunizations, researchers have utilized and tested recombinant adeno-associated virus, adenoviral- and HSV-1 derived amplicon vectors to deliver A β -peptide encoding open-reading frames in the presence and absence of molecular adjuvants to various transgenic mouse models of AD [159–161]. These attempts have revealed a reduction in A β deposition accompanied by a Th2 type anti-inflammatory response against A β in transgenic mice receiving the A β -peptide expressing viral vector. Vector-based gene transfer technology due to its inherent versatility may allow for regulated antigen presentation and even codelivery of immunomodulatory gene products that could lead to safer and more efficacious vaccines for AD.

Recently, the use of anti-A β single chain variable fragment (scFv) antibodies to reduce or disrupt amyloid plaque formation in AD mouse models has been pursued as a passive immunotherapeutic modality for AD. The rationale for using only the variable fragment (Fv) of the anti-A β antibody stems from recent clinical trial results, where adverse immune responses were elicited and believed to be mediated by T cell or by the Fc portion of the antibody [162]. scFv antibodies constitute a single polypeptide chain bearing a heavy chain variable domain attached via a flexible linker to a light chain variable domain. In an early study, Fukuchi et al. utilized a recombinant AAV to deliver an anti-A β single chain antibody, termed scFv59, to the cortex and hippocampus of Tg2576 mice (hAPP^{swe}-expressing) and demonstrated via immunohistochemistry a reduction in A β deposition at the injection

site compared to PBS-injected Tg2576 control mice 6 months postinjection [163]. Moreover, immunohistochemical analysis did not reveal any cytotoxic effects upon scFv expression in the treated Tg2576 mice. Recently, Levites et al. conducted a similar study using three different scFv antibodies derived from anti-A β monoclonal antibodies raised against A β _{1–16}, A β ₄₀, and A β ₄₂ peptides [164]. Delivery of these anti-A β scFv-expressing AAV vectors (AAV-scFv) into the ventricle of newborn A β -overexpressing CRND8 transgenic mice resulted in a decrease in amyloid plaque deposition accompanied by attenuated A β ₄₀ and A β ₄₂ levels 3 months post-therapy (see Figure 39.6). These preclinical anti-A β scFv studies offer an attractive therapeutic modality for the development of “safer” AD-targeted immunotherapies that are potentially incapable of eliciting deleterious immune responses.

39.2.3 LYSOSOMAL STORAGE DISEASES

39.2.3.1 Introduction

Lysosomal storage diseases (LSDs) are a diverse group of more than 40 disorders that originate mainly from a deficiency of a lysosomal enzyme, which results in lysosomal distention followed by accumulation of partially degraded substrates and cellular dysfunction. The lysosome, which is the cellular reservoir for many pH-dependent acid hydrolases, is critical for the degradation and clearance of unwanted cellular or extracellular components: the end-products of endocytic, phagocytic, and autophagic processes in the cell. Many of the LSDs exhibit moderate to severe deleterious effects on somatic tissues as well as the CNS. These degenerative disorders differ from many of the neurodegenerative diseases in that the pathogenic mechanism responsible for most LSDs is known and results from loss of an enzymatic function (i.e., lysosomal enzyme deficiency, defects in cofactors/activators, or transport proteins). There are examples of LSDs, however, for which the missing lysosomal function or protein activity has not been identified (e.g., a subset of the ceroid lipofuscinosis diseases; reviewed in Ref. [165]). Depending upon the type of LSD, enzyme replacement therapy (ERT) by direct infusion of the missing enzyme into peripheral tissues has been a clinically useful strategy [166]. Such an approach has been viable due to a phenomenon referred to as “cross-correction,” where the majority of the exogenously supplied enzyme is sorted in the Golgi apparatus and targeted to the lysosome via the mannose 6-phosphate receptor-mediated pathway, while a small fraction is secreted into the extracellular space enabling its uptake by neighboring cells and leading to disease correction at distal sites (reviewed in Ref. [167]). This is no more evidence than in the case of Gaucher disease, which results from a deficiency of glucocerebrosidase. Loss of glucocerebrosidase, also referred to as β -glucosidase, leads to accumulation of glucocerebroside, a by-product of sphingolipid degradation, in macrophages resulting in spleen and liver enlargement, bone malformation, and pulmonary dysfunction [166]. Infusion of recombinant glucocerebrosidase leads to significant correction of peripheral tissue disease

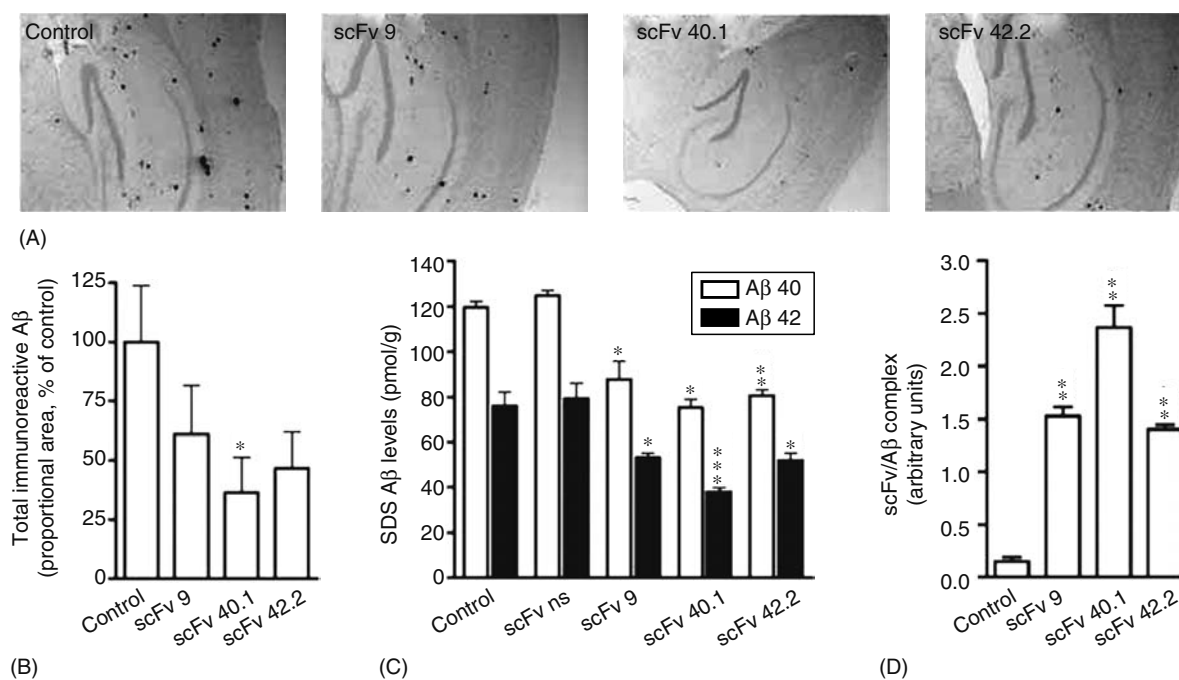

FIGURE 39.6 Anti-A β scFvs attenuate A β deposition in 3-month-old CRND8 mice. Newborn CRND8 mice were injected intracerebroventricularly with AAV1 expressing scFv9, scFv40.1, and scFv42.2. Control mice received AAV1-scFv ns or PBS. Three months later, mice were killed after treatment. One hemibrain was used for immunohistochemistry and the other was used for biochemical analysis. [168]. A similar approach has proven successful in the treatment of Fabry disease, another sphingolipid disorder that primarily affects kidney, heart, and skin (reviewed in Ref. [169]). In clinical trials, intravenous delivery of α -galactosidase A was found to be safe and led to marked reductions in plasma glycosphingolipid levels and microvascular endothelial deposits in major organs [170,171]. Other LSDs being considered candidates for ERT are mucopolysaccharidosis I (MPS I), MPS II, MPS VI, and Pompe disease.

Other LSDs exhibit both systemic and CNS involvement. The CNS component of the mucopolysaccharidosis (MPS) storage disorders and other LSDs has proven to be a more difficult task to correct using standard ERT. This difficulty lies in the inability of peripherally infused lysosomal enzymes to traverse the BBB. Another caveat to CNS-directed ERT is the possibility of triggering a deleterious immune response against the exogenously delivered protein in the brain by repeated administration, as observed in pre-clinical studies conducted by Kakkis and coworkers [172,173]. Development of methodologies to effectively deliver and distribute the deficient enzyme throughout the brain with minimal to no immune response involvement would represent a major advance in therapies for LSDs. To

that end, the implementation of gene-based technology in this endeavor has been vigorously pursued and has demonstrated initial promise.

39.2.3.2 Potential Gene-Based Therapies for Correcting CNS Dysfunction Caused by LSDs

Numerous mouse models for the various LSDs have been developed and have proven extremely useful in assessing novel therapies. *In vivo* therapeutic strategies have been developed employing adeno-associated virus, adenovirus, and lentivirus-based vectors to deliver the wild-type lysosomal enzyme-encoding gene to the CNS of its respective LSD mouse model to assess its efficacy in attenuating or reversing disease symptoms. Gus^{mpps} mice, which exhibit the β -glucuronidase enzyme deficiency associated with Sly disease (MPS VII), undergo progressive lysosomal accumulation of nondegraded glycosaminoglycans in multiple organs including the brain. Initial studies by the Sands laboratory demonstrated that AAV vector-mediated delivery of β -glucuronidase into the anterior cortex and hippocampus of newborn MPS VII mice led to a reduction in glycosaminoglycan deposition and concomitant improve-

ment in cognitive function as measured in the Morris Water Maze paradigm [174]. Although transgene expression levels were generally greater than normal β -glucuronidase levels, particularly at the injection site, no overt toxicity was observed. Recently, the same group utilized an AAV type 4 vector to specifically transduce and deliver the β -glucuronidase gene to the ependymal cells lining the ventricle of adult MPS VII mice with pre-established disease [175]. The treated mice demonstrated a significant improvement in biochemical and behavioral symptoms 4 weeks postinjection compared to untreated MPS VII mice. Their findings also revealed the ependyma to be a viable point source for continuous enzyme secretion with potential for cross-corrective distribution of the enzyme to distal areas of the brain, hence precluding the need for repeated vector administration. Several other groups

have also demonstrated the utility of AAV vector-mediated β -glucuronidase delivery in gus^{mps} mice [176–178].

Brooks and colleagues have utilized recombinant viral vectors based on feline immunodeficiency virus (FIV) to deliver the β -glucuronidase gene to the brains of MPS VII mice to determine if restoration of this enzyme diminished pre-established lysosomal accumulations and corrected associated CNS deficits [179]. FIV vector-mediated bilateral delivery of β -glucuronidase via the striatum led to bilateral correction of protein deposits and a reversal of spatial learning and memory impairments. The effect of FIV vector-mediated expression of β -glucuronidase on lysosomal storage is illustrated in Figure 39.7. Perhaps shedding light on potential mechanisms of action, gene expression profiling indicated significant increases in genes associated with neuronal plasticity mediation. An interesting extension of these studies was performed by Elliger et al. [180]. The coding sequences for the Ig κ secretion and HIV-1 TAT uptake signals were engineered into the β -glucuronidase open reading frame in order to effect therapeutic benefit in more distal organs. This modified transgene was delivered intrathecally via an AAV recombinant vector to newborn gus^{mps} mice. Treated mice were found to be more active, exhibited less stunted growth, and did not show evidence for abnormal storage deposits in the brain or liver or in tissues not harboring AAV vector genomes. Recently, a phase I study for lentiviral vector treatment of Sly's disease was reviewed by the Recombinant DNA Advisory Committee (RAC).

The Twitcher mouse, which harbors a genetic disruption in the galactocerebrosidase (GALC) locus, serves as an informative murine model for human globoid cell leukodystrophy (Krabbe disease). Loss of GALC activity in the CNS leads to the accumulation of galactolipids, such as psychosine, which

FIGURE 39.7 β -Glucuronidase expression following FIV-mediated gene transfer into the striata of MPS VIII mice and its effect on lysosomal storage. Eight-week-old MPS VII (gus^{mps}) mice were injected unilaterally into the striatum with 1×10^6 transduction units of an FIV vector expressing β -glucuronidase (FIV β gluc). Six weeks later, the animals were sacrificed and analyzed for transgene expression, β -glucuronidase enzyme activity, and lysosomal storage profiles. Transgene-positive cells were detected near the injection site as revealed by in situ RNA analyses (Panel A). β -Glucuronidase activity in the brain of an MPS VII mouse injected with FIV β gluc was found to encompass a wide volume of the brain as determined by histological staining (red staining; Panel B). Representative examples of lysosomal storage in the striatum (Panel C), cortex (Panel E), and hippocampus (Panel G) in nontreated 8–12-week-old MPS VII mice are shown. Noticeable lysosomal storage is evident at this age. Analysis of age-matched, FIV β glu-treated MPS VII mice shows significant correction of the storage deficit in the contralateral striatum (Panel D), cortex (Panel F), and hippocampus (Panel H). In data not shown, treated animals exhibited improved learning and memory behavior, indicating that lentivirus-based delivery of β -glucuronidase to the CNS of an animal with pre-established LSD can reverse the neurological deficits caused by the disease. (From Brooks, A.I., et al., *Proc. Natl. Acad. Sci. USA*, 99(9), 6216, 2002. © 2002 National Academy of Sciences. With permission.)

results in apoptotic death of myelin-producing cells and severe pathological aberrations and premature death in humans [181]. Intraventricular infusion of a recombinant adenovirus vector expressing GALC to newborn Twitcher mice led to marked reduction in lysosomal storage pathology [182]. However, unlike in the case of gene delivery to MPS VII mice, treatment of Twitcher mice with pre-established disease had no significant effect on disease pathology. These results indicate that timing of interventions for Krabbe disease is crucial or adenovirus vectors, due to their inherent immunogenicity and reduced duration of expression, are not as useful for treating this LSD. Moreover, various recombinant AAV serotype vectors have also been used to deliver mouse GALC to the CNS of neonatal Twitcher mice resulting in attenuated disease progression and increased life span compared to untreated mice [183,184]. It is interesting to note that there exist autosomal recessive forms of Krabbe disease that have been identified in dogs and rhesus monkeys [185]. As other gene transfer vector approaches are applied to this disease, these higher order mammalian models will become invaluable in the stepwise progression toward clinical application to the human form of Krabbe disease.

Until recently, the lack of appropriate mouse models for neuronal ceroid lipofuscinoses (NCLs) has hindered the development of therapeutic modalities for this premature death-causing family of LSDs. In 2004, Sleat et al. generated and characterized a CLN2 knockout mouse (CLN2^{-/-}), which recapitulates the neurological deficits observed in classical late infantile NCL (cLINCL) [186]. In humans, CLN2 encodes the lysosomal enzyme tripeptidyl peptidase-1 (TPP-1), and deficiency of the enzyme results in accumulation of autofluorescent storage material predominantly in the CNS, which is the pathological hallmark of all NCL family members. cLINCL in humans is characterized by ataxia, loss of motor function, brain atrophy, and axonal degeneration, resulting in premature death between the ages of 7 and 15 years [187]. The monogenic nature of cLINCL prompted Passini et al. to deliver the functional CLN2-encoding gene via AAV2 and AAV5 viral vectors into the CNS of a CLN2^{-/-} mouse model in order to ameliorate or reverse the pathological hallmarks associated with the disease. Their findings revealed that wild-type human CLN2 expression in the motor cortex, thalamus, and cerebellum of these CLN2^{-/-} knockout mice resulted in elevated TPP-1 activity in these regions accompanied by a significant reduction of autofluorescent storage material at the injection site with limited spread in adjacent regions [188]. In addition, the Sands laboratory has also demonstrated a similar reduction of autofluorescent storage material in palmitoyl protein thioesterase-1 null mice (PPT-1^{-/-}), a murine model of infantile NCL (INCL), following treatment using an AAV2 vector expressing wild-type human PPT-1 [189,190]. Although, these studies observed limited cross-correction of the disease in their respective murine models, they provide ample proof-of-principle for the further development of gene therapy strategies using recombinant AAV vectors for combating NCLs.

39.2.4 HUNTINGTON'S DISEASE

39.2.4.1 Introduction

Huntington's disease (HD) is a fully penetrant genetic neurodegenerative disorder that is inherited as an autosomal dominant mutation of the huntingtin (Htt) gene [191]. HD is one of a family of trinucleotide repeat disorders, which includes spinal and bulbar muscular atrophy, spinocerebellar ataxia (types 1, 2, 3, 5, and 7), and dentatorubropallidolusian atrophy. Affected individuals begin to exhibit symptoms in the third to fifth decade of life with some cases of juvenile (under 20 years old) and late onset (over 65 years old) [192,193]. Clinical manifestations of the disease include progressive chorea, emotional disturbances, and dementia. Neuropathological features of HD include an extensive loss of neurons and astrogliosis in the striatum, primarily the caudate nucleus. Histologically, intracellular inclusions consisting of ubiquitinated polyglutamine aggregates have been found in neurons of the striatum and other less affected areas such as neocortex.

The Htt gene encoding the Htt protein was first localized to chromosome 4p16.3 in 1983 [194]. The normal function of Htt is speculative at present, however, cloning of the normal and diseased gene revealed the mutant form of the gene contains an increased number of glutamine-encoding CAG repeats in the first exon [194]. Normal individuals have 11 to 34 repeats whereas affected individuals have 40 or more repeats [195,196]. Such an expansion in polyglutamine residues results in an atypical conformation of the mutant protein and predisposes it to form intracellular aggregates. An initial study by Ashizawa et al. [196], as well as a recent study by Rosenblatt et al. [197], provided evidence that CAG repeat number correlated with age of onset and clinical symptom severity. However, the mechanism by which the expression of this mutant protein leads to cell death remains under investigation.

39.2.4.2 Possible Mechanisms of Disease

Understanding the normal function of Htt may prove pivotal in understanding how the mutant form leads to the selective loss of γ -aminobutyric acid-containing (GABAergic) medium spiny neurons in the striatum. Recently, several lines of evidence implicate wild-type Htt in vesicular trafficking of extracellular bound proteins, and this transport process is disrupted when the mutant form of the protein is expressed in HD models [198,199]. While the physiological role of wild-type Htt is still being elucidated, studies have suggested possible mechanisms by which the mutant HD gene product causes cell death and provided a basis for developing therapeutic strategies.

One proposed mechanism involves a pathway of cellular protein degradation. The ubiquitin/proteasome pathway is the major protein degradation pathway of the cell. The proteasome, a cylindrical peptidase-containing complex that cleaves ubiquitinated proteins into their amino acid constituents, is thought to be involved in the degradation of Htt [200,201]. In HD, ubiquitinated polyglutamine

aggregates have been identified suggesting the incompletely degraded mutant form of Htt forms aggregates, leading to an apparent apoptotic cell death [202,203]. Although downstream events leading to neuronal demise remain elusive, studies have shown that mutant Htt in its soluble or aggregated form is capable of recruiting/sequestering specific transcription factors. These include factors involved in chromatin remodeling (e.g., CREB-binding protein), and thereby are believed to instigate transcriptional dysregulation within the cell (reviewed in Refs. [204,205]).

Htt has been shown to interact with Htt associated protein 1 (HAP-1) [206], Htt interacting protein 1 and 2 (HIP-1, -2) [207,208], glyceraldehydes-3-phosphate dehydrogenase (GAPDH) [209], and calmodulin [210]. HAP-1 binding to Htt is enhanced by increased glutamine repeat length [206]. This factor has been shown to be involved in vesicular trafficking of various membrane receptors, further reinforcing Htt's role in intracellular protein transport [211–213]. Unlike HAP-1, HIP-1 binding to Htt is inversely related to the polyglutamine residue number. The loss of this interaction in a HD neuron may affect the cytoskeletal architecture given HIP-1's similarity to cytoskeletal proteins [208]. HIP-2 is an ubiquitin-conjugating enzyme that may be involved in the proteasomal degradation or aggregation of mutant Htt [214]. The glycolytic enzyme, GAPDH, binds to cleaved Htt fragments *in vitro* [209]. The increased binding of GAPDH to cleaved Htt fragments may alter cellular energy production leading to membrane depolarization, increased intracellular calcium, and cell death. Furthermore, Bae et al. have demonstrated that the nuclear translocation of mutant Htt is reliant on its interaction with GAPDH and Siah1, an ubiquitin-E3-ligase, using a mouse neuroblastoma cell line [215]. Htt can form a complex with calmodulin in a Ca^{2+} -dependent manner, but the mutant form binds independent of calcium [210]. Subsequent activation of downstream targets of calmodulin, such as those activated in excitotoxic cell death, may lead to cell death.

Adding to the putative mechanisms of striatal neuron death in HD is the ability of mutant Htt to aberrantly influence mitochondrial function and energy metabolism. This hypothesis stems from what is known about mitochondrial complex II function and protein levels found altered in the striatum of postmortem HD brains [216,217]. Recently, evidence for the above hypothesis was provided by *in vitro* cell culture studies using rat primary striatal neurons. Downregulation of mitochondrial complex II expression or function induced selective striatal neuron death upon lentiviral vector-mediated expression of a mutant form of the Htt protein (Htt171–82Q), which encompasses the first 171 amino acids of the protein including an expanded polyglutamine tract [217,218]. Furthermore, Cui et al. reported that PGC-1 α mRNA levels are decreased in the caudate of postmortem brains of presymptomatic HD patients, and further demonstrated that mutant Htt can inhibit the expression of peroxisome proliferator-activated receptor gamma coactivator-1 α (PGC-1 α) in striatal neurons of HD mice

[219]. PGC-1 α is a transcriptional coactivator protein critical for proper mitochondrial processes and energy metabolism. Thus, transcriptional repression of PGC-1 α has been linked to mitochondrial dysfunction and the demise of striatal neurons.

Further understanding of the interactions of Htt with the aforementioned proteins as well as its ability to transcriptionally dysregulate endogenous genes in its mutant form will facilitate the development of targeted gene therapy. Based on our current understanding, therapies designed to block apoptosis, relieve oxidative stress, and prevent the expression and accumulation of degraded mutant Htt may help relieve or prevent symptoms in affected patients.

39.2.4.3 Potential Gene-Based Therapies for HD

Yamamoto et al. [220] demonstrated that continuous expression of mutant protein is necessary to maintain intracellular inclusions and symptoms. Thus, taking into account the monogenic nature of HD, therapies designed to decrease mutant gene expression via RNAi strategies are being extensively pursued with promising preclinical results in mouse models of HD. In this strategy, a viral vector expressing an siRNA or short hairpin RNA (shRNA) to mutant Htt is delivered to the striatum of the HD mouse. These small RNA species specifically bind to the mutant Htt mRNA and instigate degradation of the transcript via the cells RNAi machinery. Several groups have used adeno-associated viral vectors to deliver anti-Htt siRNA into the striatum of various mouse models of HD, which express different forms of the mutated human Htt protein. These studies revealed that partial repression of mutant htt protein levels in the striatum of these mice via RNAi is sufficient to ameliorate neuropathological and behavioral aberrations linked to HD [221–224]. Prior to implementing such a strategy in HD patients, it will be crucial to design and test siRNAs capable of exclusively targeting the mutant Htt mRNA, and also preclude off-target suppression of the wild-type Htt mRNA and other bystander transcripts. Alternatively, if a technology were available to reduce the glutamine repeats or replace the mutant allele with a normal allele, a permanent reversal of the disease might be accomplished. The use of chimeroplasts, target-specific RNA/DNA oligonucleotides, could possibly correct the genetic deficit, but this may not be technically feasible for such a large mutation [225–227].

A second approach takes advantage of the well-characterized neurotrophic factors, endogenous soluble proteins that regulate survival, growth, morphological plasticity or synthesis of proteins for differentiated functions of neurons [227]. The delivery of the neurotrophic factors GDNF, BDNF, or CNTF have shown neuroprotective effects when given prior to a quinolinic acid challenge in rodent and primate models of HD [228–232]. The neuroprotective effect of lentiviral vector-mediated delivery of CNTF in the quinolinic acid model for HD is illustrated in Figure 39.8 [368]. Further analysis is needed to evaluate the full potential of neurotrophic factor treatment for HD.

FIGURE 39.8 Use of a tetracycline-regulated lentiviral vector expressing ciliary neurotrophic factor (CNTF) in the quinolinic acid rat model of HD has a dose-dependent neuroprotective effect. Rats received intrastriatal injections of a tetracycline-regulated lentiviral vector expressing either CNTF (TRE-CNTF) or the reporter protein GFP (TRE-GFP). The vector-injected rats were treated with saline (“off”) or doxycycline (“on”) to regulate transgene expression. Quinolinic acid was infused into the striatum of these mice and they were subsequently sacrificed and brains analyzed by immunocytochemistry for the striatal marker DARPP-32. Representative photomicrographs showing DARPP-32-immunostained striatal (Panel A) and nigral sections (Panel B). The quinolinic acid-induced lesion is clearly identified by the loss of DARPP-32 staining in the GFP- and CNTF-off groups, whereas a significant protective effect is observed when CNTF expression is switched on. (From Regulier, E., et al., *Hum. Gene Ther.*, 13(16), 1981, 2002. © 2002 Mary Ann Liebert, Inc. With permission.)

A third approach would be to target mechanisms of apoptotic cell death and oxidative stress. Similar to neurotrophic factors, this approach may delay the progression of the disease, but does not permanently correct the genetic deficit. The antiapoptotic gene, *bcl-2*, has been shown to inhibit neuronal apoptosis both *in vitro* and *in vivo* [233–243]. Delivery of the *bcl-2* gene to affected neurons may prevent or delay cell death that occurs in HD. If oxidative free radicals contribute to cell death, the expression of gene products capable of directly or indirectly lowering or removing free radicals (e.g., SOD, catalase, glutathione reductase [GR], glutathione peroxidase [GPX], and glutathione [GSH]) might prove useful in combating neuronal loss. Recently, the previously described coactivator PGC-1 α has been shown to elicit neuroprotective effects on ROS-mediated cytotoxicity by regulating the expression of genes involved in oxidative stress responses (reviewed in Ref. [244]). Lentiviral delivery of PGC-1 α to the striatum of R6/2 transgenic HD mice leads to the protection of striatal neurons 3.5 weeks postinjection [219]. Keeping in mind that PGC-1 α protein is expressed in postmortem HD brains and also in the striatum of an established mouse model of HD, further investigation into the therapeutic potential of PGC-1 α is warranted.

Another strategy devised to prevent mutant Htt-induced cytotoxicity and potentially retarding the disease progression could be to inhibit its aggregation and thus preclude cytotoxicity in striatal neurons (reviewed in Ref. [245]). In 2004, Colby et al. demonstrated that a single-domain intracellular antibody specific for Htt was able to inhibit aggregation in a mammalian cell model of HD [246]. The application of intracellular antibodies (intrabodies) for such an endeavor

seems coherent given that scFv antibodies are currently being tested in Alzheimer’s disease models, where disruption of protein aggregation has led to reduced amyloid deposition in the brain [164].

39.2.5 STROKE

39.2.5.1 Introduction

Hypoxic injuries, such as stroke, are the genesis of substantial morbidity and mortality in neonates and older individuals. Oxygen deprivation can lead to profound effects on motor function and cognition [247], leading to severe disability and diminished quality of life. Stroke is most commonly the result of embolic obstruction that results in either reduced or complete loss of blood flow to downstream fields. Two types of cell death appear to occur following a stroke. At the ischemic core, necrosis is readily apparent and has been linked to elevated extracellular glutamate and intracellular calcium levels. Necrotic cell death involves nonspecific DNA degradation, nuclear pyknosis, diminished membrane integrity, and mitochondrial swelling. Neuronal degeneration within this area following blood vessel obstruction occurs very rapidly (minutes) following the ischemic insult, and due to this time limitation, does not represent a viable target for gene-based therapeutics. In brain areas more distal to the ischemic core, termed the penumbra, neurons undergo a more delayed form of cell death (hours to days) that exhibits dependence upon *de novo* gene expression [248–250]. This delayed neuronal death, or apoptosis, is capable of producing damage equivalent to the acute necrotic lesion observed soon after severe ischemia.

Cells undergoing apoptosis exhibit characteristic fingerprints, including chromosome condensation, internucleosomal DNA fragmentation, and membrane blebbing. A thorough understanding of the gene expression profiles and signaling events that occur in the penumbra immediately following an ischemic event is likely to yield several molecular/cellular targets that are amenable to pharmacological and gene-based therapeutics.

39.2.5.2 Possible Mechanisms of Disease

Ischemia promotes adaptive and pathologic responses in the neuronal compartment. As illustrated in Figure 39.9 extrinsic and intrinsic perturbations in the ischemic brain appear to activate neuronal ischemic sensors, which in turn promotes adaptive and pathologic gene expression [369]. One of the

ischemic sensors believed to trigger de novo gene expression during oxygen deprivation is the transcription regulator, hypoxia-inducible factor-1 α (HIF-1 α). During hypoxia, the otherwise rapidly turned-over HIF-1 α is stabilized and leads to the transcriptional activation of numerous genes including vascular endothelial growth factor (VEGF), erythropoietin (EPO), and glucose transporter 1 (GLUT-1) (reviewed in Ref. [251]). In 2005, the Barlow laboratory conditionally knocked-out HIF-1 α in the mouse brain and subjected these mice to acute hypoxic insult [252]. Their findings suggest a more complex ischemic sensory network is present during hypoxia, including the activation of HIF-1 α and its downstream targets. Surprisingly, the lack of HIF-1 α in the brains of conditional HIF-1 α ^{-/-} mice appears neuroprotective when these mice are subjected to acute hypoxic insult compared to control animals. Previous studies have proposed other ischemic sensors,

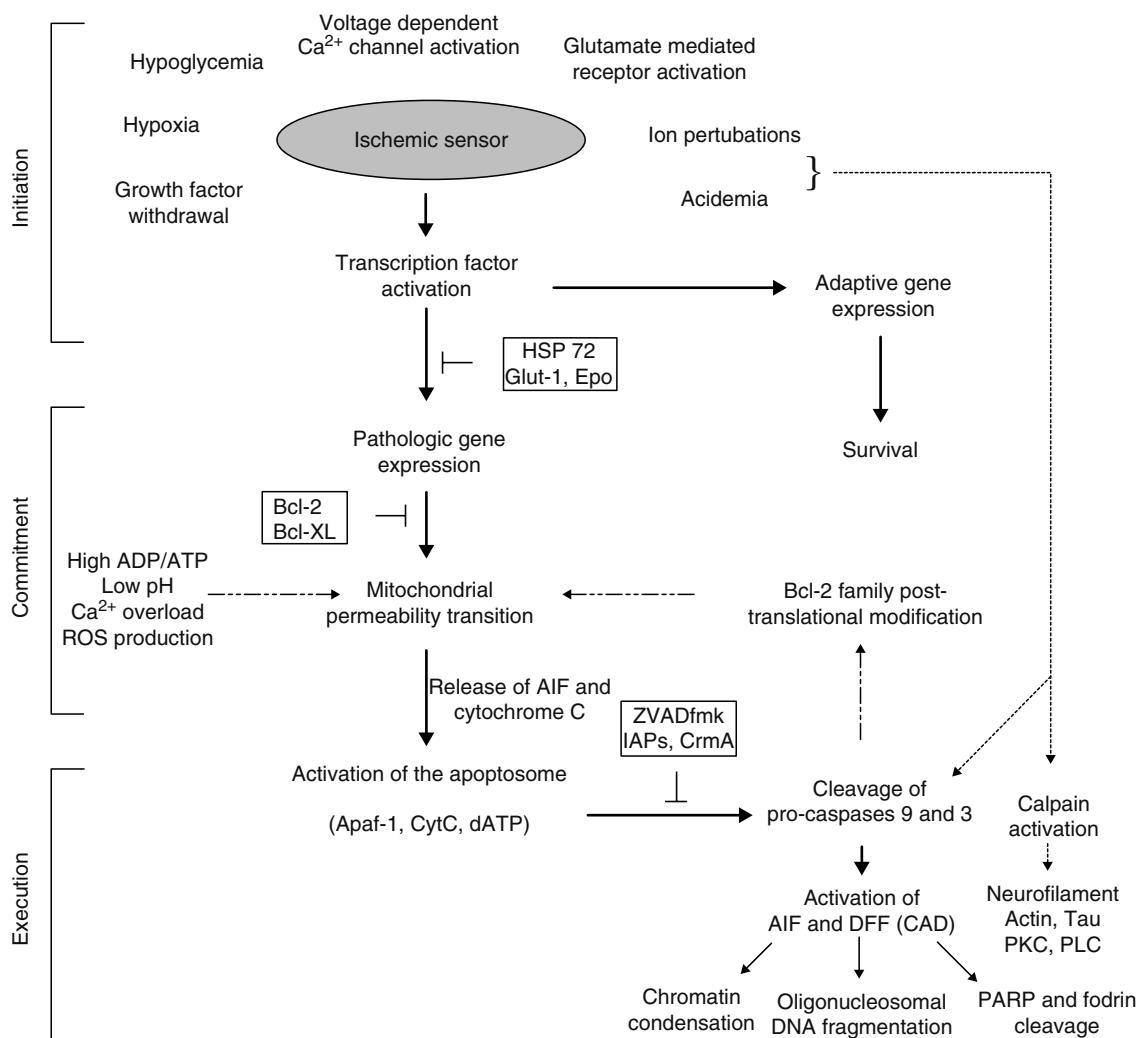

FIGURE 39.9 Ischemia promotes adaptive and pathologic responses in the neuronal compartment. Extrinsic and intrinsic perturbations in the ischemic brain activate a neuronal ischemic sensor, which in turn promotes adaptive and pathologic gene expression (solid lines). In addition, select stimuli can activate neuronal death independent of de novo gene expression (dashed lines). Specific gene products, which have demonstrated the ability to block the initiation, commitment, or execution phases of the programmed death pathway, are also included (boxed items). (From Halterman, M.W., et al., *J. Neurosci.*, 19(16), 6818, 1999. © 1999 Elsevier Science B.V. With permission.)

including HIF-2 α [253,254], play integral roles during oxygen deprivation, further highlighting the complex nature of events that occur during the pathological and adaptive response to stroke.

It is the complex interplay amongst the numerous molecular signaling cascades and time sensitivity of the disorder that makes development of gene-based approaches for stroke both an exciting and daunting task. The ischemic sensors activate a series of transcription factors that, depending upon their respective stoichiometry and subcellular localization, act to initiate either an adaptive or pathologic signaling cascade. Insights into candidate gene products that confer protection against ischemic exposure can be gleaned from prior preconditioning studies [255]. The gene products involved in adaptive processes include those that inactivate ROS, and those that participate in DNA repair and cytoplasmic calcium regulation [256,257]. Hypoxic insult, as previously described in context with HIF-1 α , stimulates the secretion of factors like EPO and VEGF, which can act via a paracrine manner to effect neuroprotection [258,259]. Other gene products, including heat shock protein 72 (HSP 72) and GLUT-1, have been identified that block the initiation of pathologic gene expression [260–263]. Such factors may provide sufficient protection during the early stages of cellular responses to ischemia in order to subvert potential downstream apoptotic signaling.

39.2.5.3 Potential Gene-Based Therapies for Stroke

Many early experimental gene therapy approaches targeted either intermediate or the late stages of the apoptotic process. The commitment to apoptosis, which is believed to involve mitochondrial permeability transition, can be averted by overexpression of a subset of Bcl-2 protein family members and a neuronal apoptosis inhibitory protein (NAIP). HSV-based vectors overexpressing Bcl-2 reduces the incidence of apoptosis and improves neuronal survival both *in vitro* and *in vivo* [239,264]. In 2003, the Steinberg laboratory provided direct evidence for the potential use of BCL-w, a novel Bcl-2 antiapoptotic family member, in protecting neurons from hypoxia-induced injury [265]. In this study, a recombinant AAV vector capable of overexpressing BCL-w was delivered to the cortex and striatum of adult rats 3 weeks prior to focal cerebral ischemia induced by MCA occlusion. The BCL-w overexpressing rats demonstrated reduced infarct volumes 24 h and 1-week following focal ischemia, as well as improved neurological function compared to control rats. Additionally, Kilic et al. demonstrated similar neuronal protection following MCAO in mice pretreated with an adenoviral vector expressing Bcl-X_L, which also belongs to the antiapoptotic Bcl family [266]. Thus, both studies exemplify the therapeutic benefit afforded by prosurvival Bcl-2 family members in the treatment of stroke. Furthermore, adenoviral vector-mediated expression of NAIP resulted in reduced levels of activated caspase-3 and diminished neuronal degeneration following transient forebrain ischemia [267,268]. Other strategies involve inhibition of cellular caspases that act during later stages of

apoptosis through the use of cell-permeable peptides to block the morphologic features of apoptosis [248]. Additionally, vector-mediated expression of anti-inflammatory molecules (i.e., interleukin-1 receptor antagonist) has been employed to minimize poststroke inflammatory responses within the brain [269–272]. However, since ischemia induces global disruptions of cellular processes upstream of mitochondrial commitment, caspase activation, and resultant inflammation, it is unclear whether these strategies can effectively interrupt the initiation of apoptosis or restore function to neurons endangered by this cellular process [273,274]. It is also important to note that many of the stroke-related gene transfer approaches performed to date have been employed prior to the onset of experimental ischemia. For gene transfer to be clinically applicable for ischemic disorders, treatments must be assessed following the ischemic event (realistically at times 1–2 h postinjury, [275])

Gene-based neuroprotective approaches that employ neurotrophic and angiogenic factors have also been extensively examined. Tsai et al. utilized AAV vectors to express GDNF in the setting of experimental stroke as an approach to minimize neuronal damage caused by transient ischemia [276]. Rats receiving AAV-GDNF immediately following bilateral common carotid artery ligation and middle cerebral artery occlusion (MCAO) exhibited significantly reduced infarct volumes as compared to animals receiving a β -galactosidase-expressing AAV control vector (see Figure 39.10) [370]. Zhang et al. performed studies using adenovirus-expressed GDNF to examine the therapeutic window following transient MCAO in rats [275]. The protective effect afforded by GDNF overexpression (i.e., reduced infarct size and inhibition of caspase-3 expression) was evident only if Ad-GDNF was administered at the time of reperfusion, but the effects of the gene transfer were minimal at 1 h postreperfusion. Additionally, Harvey et al. exploited the neurotropism and rapid expression profile of the HSV amplicon to overexpress GDNF and assess its efficacy in a focal ischemic stroke model [277]. Their findings revealed that pretreatment with HSV-GDNF, 4 days prior to MCA occlusion, afforded neuroprotection and behavioral improvements compared to rats receiving the neurotrophic vector 3 days post-MCAO. However, as previously highlighted, the viral vector of choice for therapeutic gene delivery plays a pivotal role in the efficacy of potential gene-based modalities for CNS disorders. Shirakura et al. showed that administration of negative-strand RNA virus-derived Sendai vectors carrying GDNF (SeV/GDNF), as well as other neurotrophic factor genes NGF and BDNF, at 4 or 6 h postischemic injury were capable of impeding hippocampal neuron death in gerbils [278] (see Figure 39.11). Taken together, these results underscore the importance of early postischemia interventions in minimizing neurodegeneration.

Restoration of energy stores in hypoxic neurons via overexpression of the rat GLUT-1 has been an approach that has shown promise in experimental models of ischemia and brain injury. HSV vector-mediated delivery of GLUT-1 in three models of injury (transient focal cerebral ischemia,

FIGURE 39.10 (See color insert following blank page 206.) Injection of rAAV-GDNF markedly reduces cortical infarction induced by middle cerebral arterial ligation in rats. The right middle cerebral artery and bilateral common carotid arterial were occluded for 90 min. Animals received a PBS, rAAV-lacZ (10^{10} viral particles), or rAAV-GDNF (10^{10} viral particles) unilateral infusion during arterial occlusion, were sacrificed 72 h later, and their brains were coronally sectioned (2 mm thickness) for TTC staining. White areas represent infarcted zones in the cerebral cortex. Rats receiving rAAV-GDNF exhibited a marked reduction in infarct size as compared to animals receiving the rAAV-lacZ or PBS control. (From Tsai, T.H., et al., *Exp Neurol.*, 166(2), 266, 2000. © 2000 Elsevier Science B.V. With permission.)

kainic acid, and 3-acetylpyridine) led to localized increased uptake of glucose, reduced neuron loss, blunted decline in ATP concentrations and metabolism, and decreased glutamate release and cytosolic calcium levels [262,263,279]. Approaches that more directly address the detrimental cytosolic calcium excess observed following ischemia include overexpression of calcium-binding proteins. Viral vector-mediated delivery of the calcium-binding protein calbindin D28K exhibits calcium-buffering activity and is protective in conditions of hypoglycemia and experimental stroke [280–282].

As with many neurodegenerative disorders, the augmented generation of ROS during cerebral ischemia contributes significantly to the ultimate demise of neurons within the oxygen-deprived area of the brain. Hence, transient overexpression of enzymatic antioxidant genes, SOD1 and glutathione peroxidase (GPX), via HSV-1 amplicon vectors pre- and post-transient ischemia have been shown to protect striatal neurons by inhibiting pathways leading to apoptotic cell death [283,284]. Although these studies appear promising, infarct volumes were unaffected in either study, thereby bringing into question the therapeutic mechanisms of action underlying antioxidant gene therapy.

During times of cellular stress, resident proteins can become misfolded, a process which can result in diminution of protein function and activity and potentially lead to intracellular aggregation (reviewed in Ref. [285]). Stress response factors, such as HSPs, have been shown to act as molecular chaperones to assist in protein folding and may represent another approach to support a cell under ischemic attack. Several reports of vector-mediated overexpression of HSPs (e.g., HSP72) in ischemic animal models demonstrate a neuroprotective role for these factors [286,287]. HSV amplicon-mediated delivery of HSP72 to rats 30 min after MCAO resulted in higher numbers of surviving neuron numbers as compared to animals receiving a β -galactosidase-expressing amplicon [286].

In aggregate, gene transfer applications for stroke have shown preclinical promise. For such approaches to gain merit as viable treatment options in humans, major issues need to be addressed. One consideration relates to means of vector delivery. Focal administration of viral vectors following an ischemic event will likely have minimal benefit due to the large areas of the brain that are typically affected. Convection-enhanced delivery may provide the means in which to widely distribute a given therapeutic vector, but remains largely untested in ischemic paradigms [11]. A second issue, which is not entirely unrelated to the first, concerns the window of therapeutic opportunity. As described above, a multitude of signaling events occur immediately after ischemia that determine whether the compromised neuron follows an adaptive or a pathologic set of molecular instructions. This time window is extremely limited (1–2 h poststroke), which makes the implementation of stereotactic means of gene therapeutic vector delivery nearly improbable. However, efforts have been made to prolong this opportunistic period by mild postischemic hypothermia in an experimental model of stroke [288]. Another approach being investigated to exploit this timeframe for therapy is the development of a hypoxia-inducible vector system capable of instantaneously “switching-on” neuroprotective genes during an ischemic event, thus, minimizing the extent of the hypoxic injury [289,290]. A comprehensive understanding of the molecular signals and their temporal expression profiles will likely identify targets at the earliest of times within this restricted therapeutic window. Until these gaps in disease process knowledge are filled and technical hurdles overcome, clinical gene therapy interventions for stroke will remain an impractical potential alternative to pharmacologic compound-based therapeutics.

FIGURE 39.11 (See color insert following blank page 206.) Representative photographs of pyramidal neurons in the hippocampal CA1 regions after treatment (4 and 6 h after ischemia) with SeV vector following ischemic injury. Sham-operated gerbils (A), SeV/GDNF (B,E), SeV/NGF (C,F), or SeV/GFP (D,G) were administered intraventricularly 4 h (B,C,D) or 6 h (E,F,G) after ischemic insult. The sections were stained with hematoxylin and eosin. Scale bar = 50 μ m. (From Shirakura, M., et al., *Gene Ther.*, 11(9), 784, 2004. © 2004 Nature Publishing Group. With permission.)

39.2.6 EPILEPSY

39.2.6.1 Introduction

The epilepsies constitute a group of neurologic disorders characterized clinically by various seizure syndromes and at the cellular level by hyperexcitability. The inherent cell biologic problem is that of pathologic shifting of the normally well-regulated balance between inhibition and excitation towards the latter. The etiology of acquired epilepsy is unknown although an emerging viewpoint is that early lifetime events, perhaps subclinical in nature, contribute to or trigger the development of the neural substrate underlying the hyperexcitable state (reviewed in Ref. [291]). Since the processes responsible for inducing epileptogenesis are not fully elucidated, present treatment strategies are therefore directed at controlling symptoms (seizures). The seizures are the clinical manifestations of aberrant hypersynchronization of neural networks that can remain local, spread to other locations, or involve all cortical regions at once. Neocortical or hippocampal circuits are uniformly activated during an epileptic seizure. Synaptically connected regions may be recruited in a manner to augment or attenuate the discharge. When epileptic discharges travel unimpeded through neural networks, the network functions are subverted, temporarily rendering them incapable of executing normal tasks. With increasing duration of disease, particularly in epilepsies involving the temporal lobe, the neural substrate is scarred, presumably from chronic exposure to excitatory neurotransmitters (e.g., mesial temporal sclerosis).

For those epilepsies that are unresponsive to pharmacologic therapies, the only present means of relief for some individuals is neurosurgical resection. Due to the highly complex nature of the mammalian CNS and the unknown etiology of epilepsy, the execution of complicated neurosurgery to treat this debilitating disorder is approached with extreme caution. Such medically refractory and surgically difficult cases may prove to be suitable targets for gene therapy. Gene transfer

would provide a means to locally alter synaptic transmission so as to synchronize excitatory and inhibitory signals, and in doing so, disrupt the hyperexcitable state. Of course, a number of considerations must be addressed, including the cell types to be targeted, localization of the transgene product (e.g., cell intrinsic vs. secreted), transgene expression control (e.g., constitutive vs. regulated), and effects on neighboring normal neuronal circuitry. These concerns were highlighted during an attempt to treat focal seizures by downregulating levels of the *N*-methyl-D-aspartic acid receptor subunit by AAV-mediated antisense therapy, where different promoter elements transcriptionally driving an identical antisense oligonucleotide segment surprisingly elicited opposite effects on seizure sensitivity *in vivo* [292]. However, novel approaches for treating epilepsy using gene-based means have begun to exhibit promise as illustrated below.

39.2.6.2 Potential Gene-Based Therapies for Epilepsy

The development of animal models for epilepsy has greatly enhanced the means to assess the possible etiology, and in turn, new therapies for this disorder. Extant in the literature is the observation that accumulation of *N*-acetyl-L-aspartate (NAA) in the brain leads to induction of seizure-like syndromes. NAA is found predominantly in neurons of the CNS and has served as a useful marker of neuronal injury or death in several neurodegenerative diseases. Intraventricular infusions of NAA produce absence-like seizures with signature hippocampal electroencephalograms (EEG; spike-wave-like complexes) in rats [293]. A deletion mutation in the aspartoacylase (ASPA) gene, which encodes for the enzyme responsible for metabolizing NAA into aspartate and acetate in glial cells, has been discovered in tremor rats, a model of human petit mal epilepsy [294]. The tremor rat model represents a useful *in vivo* system in which to test novel antiepilepsy gene transfer approaches [295]. Seki et al. utilized a replication-defective recombinant

adenoviral vector to deliver the rat ASPA gene to the tremor rat [296]. Injection of the ASPA-expressing vector into the brains of 7-week-old tremor rats significantly reduced the appearance of absence-like seizures as compared to rats receiving a β -galactosidase expressing control adenovirus vector. Subsequently, they delivered the ASPA-expressing recombinant adenoviral vector into an 11-week-old spontaneously epileptic rat (SER: tm/tm, zi/zi), in order to assess its efficacy in preventing tonic convulsions observed in this animal model [297]. The SER rat is a double mutant derived from the tremor rat and exhibits tonic convulsions along with absence-like seizures at 8–9 weeks of age [298,299], thus making it a compelling animal model for epilepsy. Administration of the adenoviral ASPA vector reduced the number of tonic convulsions 7 days after treatment. However, the therapeutic benefit afforded by ASPA expression via the adenoviral vector was transient in nature and failed to prolong survival times compared to control animals. This study brings into question the efficacy of first-generation adenoviral vectors in the treatment of epilepsy and warrants further investigation into the usage of other viral vectors with enhanced expression duration profiles for the delivery of ASPA in future preclinical studies.

Another animal model that can be utilized to assess novel gene-based therapies for epilepsy is the protein-L-isoaspartyl methyltransferase (PIMT)-deficient mouse [300,301]. PIMT is a ubiquitously expressed enzyme that repairs proteins that have undergone isomerization of aspartate residues or deamidation of asparagine residues. Failure to repair these spontaneously occurring protein alterations leads to mislocalization and diminished protein function [302]. In fact, PIMT-deficient mice, which are devoid of both splice variant forms of PIMT, accumulate isoaspartate (IsoAsp) within their brains. One

obvious phenotype of this deficiency is the progressive development of fatal epileptic seizures. Intraventricular delivery of both splice variants (PIMT-I and -II) via *exo-utero* means to E14.5 PIMT-deficient mice led to improved growth, diminished IsoAsp accumulation, enhanced survival times, and marked reduction in occurrence of epileptic seizures [303]. Sustained therapeutic gene expression and concomitant clinical benefit was evident at times up to 7 weeks postinjection.

In recent years, specific neuroactive peptides present in the CNS have proven to be anticonvulsant and antiepileptogenic during seizures and have been deemed promising candidates for the treatment of epilepsy as corroborated by the following preclinical accounts. In 2003, Haberman et al. constructed a rAAV vector capable of expressing the neuropeptide, galanin (GAL), which was modified for *in vivo* secretion by fusing the fibronectin (FIB) secretion signal sequence to its N-terminus [304]. GAL is posited to exert its anticonvulsive effects by inhibiting glutamate release in the hippocampus, thus reducing the hyperexcitability associated with epilepsy [305]. Delivery of the AAV-FIB-GAL vector to the inferior collicular cortex in a rat model of acute, focal seizure resulted in a significant attenuation of seizures over a 4-week period compared to animals receiving a control AAV vector expressing a secretory form of the green fluorescent protein (AAV-FIB-GFP) [304]. Furthermore, infusion of the AAV-FIB-GAL vector into the hippocampus of a rat model of temporal lobe epilepsy (TLE) resulted in neuroprotection of the otherwise compromised hilar neurons (see Figure 39.12), but was futile in suppressing limbic seizure activity induced by kainic acid administration [304]. Subsequently, delivery of the AAV-FIB-GAL vector to the piriform cortex of the TLE rat model 7 days prior to kainic acid administration resulted in a significant

FIGURE 39.12 Effects of unilateral AAV-FIB-GAL or AAV-FIB-GFP infusion on hippocampal hilar neurons 2 weeks before peripheral administration of kainic acid. (A,C) Two weeks after kainic acid administration, hilar cells appear normal in the area of AAV-FIB-GAL infusion (arrows indicate injection tract; cresyl violet stain). (B,D) Contralateral hippocampus shows significant cell loss 2 weeks after the kainic acid administration (uninjected, damaged side exhibits a deformity of the dentate gyrus; $P < 0.05$ by paired *t*-test). (E,F) Infusion of AAV-GAL into the hippocampus (E; arrow indicates injector tip) was not protective against kainic acid treatment 2 weeks later. The injected side (E) exhibits the same amount of damage as the contralateral uninjected hippocampus (F). This damage is in marked contrast to (C). (From Haberman, R.P., et al., *Nat. Med.*, 9(8), 1076, 2003. © 2003 Nature Publishing Group. With permission.)

decrease in limbic seizure activity in rats previously exposed to seizure activity, thus, making this treatment modality more clinically applicable [306].

Neuropeptide Y (NPY), is a 36 amino acid polypeptide capable of exerting anticonvulsive properties during seizures (reviewed in Refs. [307,308]). In 2004, Richichi et al. overexpressed human NPY via a rAAV vector in the hippocampus of rats prior to intrahippocampal kainic acid administration and observed a striking reduction in EEG seizures with a delay in their onset as well as disruption of kindling epileptogenesis compared to control animals receiving an empty vector [309]. These promising preliminary results warrant further preclinical investigation in more established animal models of epilepsy.

In addition to these novel gene therapeutic modalities for treating epilepsy, Kanter-Shlifke et al. recently demonstrated the seizure-suppressant activity of the glial-cell derived neurotrophic factor (GDNF) using two models of TLE [310]. In their study, intrahippocampal delivery of a GDNF-overexpressing rAAV vector did not impact epileptogenesis, but significantly attenuated generalized seizures and increased seizure induction thresholds in kindled and status epilepticus (SE) rats. Their results also suggest that GDNF overexpression induces changes in the levels of neuropeptide Y, which could potentially underlie the antiepileptic effects elicited with GDNF treatment.

In aggregate, the promising results garnered from these epilepsy gene transfer studies, along with the discovery of potential antiepileptogenic gene targets from recent microarray data obtained from a rat model of TLE [311], evoke enthusiasm for further development of gene-based therapies for those epileptic syndromes refractory to standard symptomatic treatments.

39.2.7 MOTOR NEURON DISEASE

39.2.7.1 Introduction

The motor neuron diseases are a group of disorders characterized by predominant degeneration of the motor neurons. The most commonly recognized are familial spastic paraplegia (FSP, upper motor neuron disease), spinal muscular atrophy (SMA), spinobulbar muscular atrophy (SBMA, or Kennedy's disease) (lower motor neuron diseases), and amyotrophic lateral sclerosis (ALS; combination of upper and lower motor neuron disease). These disease syndromes can range in severity from debilitating (spastic paraplegia; Kennedy's disease) to lethal (some spinal muscular atrophies; ALS).

The clinical features of these conditions are well known to neurologists, but the recognition of the molecular basis, and the possibility of molecular confirmation of diagnosis, has clarified the extent and relationship of some of these conditions. A genetic basis has now been identified for all these diseases. Different genetic mechanisms, including missense mutations (ALS), gene deletions or aberrant gene splicing (SMA), and trinucleotide repeat expansions (SBMA), are responsible for the pathological findings and clinical presentations

of these motor neuron disorders. The molecular findings are of variable value as diagnostic tests. More importantly, it is hoped that understanding the underlying molecular basis of these conditions will ultimately usher forward specifically targeted treatments.

39.2.7.2 Models of Motor Neuron Disease

A number of mouse models of lower motor neuron degeneration or neuronopathy are currently available for experimental therapeutics. These include a number of naturally occurring mutant mice: wobbler (wr), progressive motor neuronopathy (pnm), neuromuscular degeneration (nmd), wasted (wst), motor neuron degeneration (mnd and mnd2), motor neuron disease (mneu), and muscle deficient (mdf). In all of these mice, the trait is autosomal recessive reflecting a presumed loss of function of the disease gene. To date, disease genes underlying these spontaneous mutations have not been identified [312]. Within the past decade, transgenic mouse models have been created whose features closely model human motor neuron degenerative disease. These include mice with engineered abnormalities of one of the neurofilament subunits, and mice overexpressing mutant Cu/Zn SOD1 that has been shown to underlie a subset of familial ALS cases [313–317]. In the case of most of the transgenic mouse models, lower motor neuron pathology or degeneration is most likely the result of a gain-of-function related to the neurofilament or mutant SOD1. The comparable gene knockout strategies result in more subtle pathology in these mice [318,319]. The underlying mechanism of mutant SOD1-mediated neurodegeneration in ALS models is still under investigation. However, recent cell-based models of ALS propose that mutant SOD1-expressing astrocytes, one of the principal glial cell populations in the CNS, may have a detrimental effect on motor neurons in a noncell autonomous manner [320,321]. These *in vitro* studies suggest that soluble neurotoxic factors released from mouse astrocytes harboring the mutant SOD1 gene are capable of selectively reducing the life span of wild-type and mutant SOD1-expressing motor neurons derived from various transgenic mutant SOD-1 mice. The task of identifying the toxic soluble factors responsible for motor neuron death in this culture model is currently in progress. Nevertheless, activation of proapoptotic pathways, such as the Bax-dependent cascade, has been implicated in downstream events, leading to motor neuron death *in vitro* and *in vivo* [321,322]. The identification of such cellular contributors plus the pathways leading to ultimate motor neuron degeneration will facilitate the development of more efficacious gene therapeutic modalities for ALS and other motor neuron diseases.

39.2.7.3 Potential Gene-Based Therapies for Motor Neuron Disease

Although the genetic basis for certain familial motor neuron diseases has been elucidated, the complex network of downstream events that eventually lead to motor neuron demise has not been fully understood. Thus, developing gene-based therapies for motor neuron disease remains a challenge, but recent

preclinical studies have begun to show promise and offer promising new therapeutic targets for treating ALS.

Putative therapeutic approaches for motor neuron disease have been categorized based on hypothetical pathogenetic mechanisms or cell death pathways. Evidence that excess glutamate excitotoxicity can lead to motor neuron death mediated via non-NMDA receptors suggests that pharmacologic agents targeting the non-NMDA receptors might provide a promising strategy. Motor neuron death has been linked to excitotoxicity involving non-NMDA glutamate receptors, the glial glutamate transporter EAAT2 (also called GLT-1) [323–326], and related calcium-dependent pathways [327,328] in ALS and in *in vitro* models. Compared to other neurons, motor neurons possess a lower Ca^{2+} -buffering capacity due to reduced levels of calcium-binding proteins such as calbindin-D28K and parvalbumin [329] as well as a higher density of Ca^{2+} -permeable alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors [330], which renders them more susceptible to excitotoxic death. These same non-NMDA receptor-directed excitotoxic phenomena have now been implicated in mutant SOD1-mediated motor neuron death [331,332]. Related evidence supports a secondary role for voltage-gated calcium channels and downstream intracellular calcium dysregulation in motor neuron death [332]. In an *in vitro* model, expression of the cytoplasmic calcium-binding protein, calbindin-D28K, was able to rescue mouse spinal motor neurons from death downstream of mutant SOD1 expression, exogenous glutamate, or paraquat [332]. Additionally, overexpression of parvalbumin in spinal motor neurons in mutant SOD1 transgenic mice resulted in delayed onset of motor neuron degeneration and prolonged survival times compared to control mice [333]. Some beneficial effects were observed with administration of two antiglutamatergic agents, riluzole and gabapentin, to the transgenic mice [334]. Riluzole is currently the only medication for which effect on human disease has been demonstrated [335].

Accumulated neuronal damage resulting from oxidative stress over the course of decades may be a common pathogenetic mechanism shared by neurodegenerative disorders including ALS and PD. The fact that approximately 20% of all familial ALS cases are associated with gain-of-function mutations in the gene encoding the vital cellular antioxidant enzyme, SOD1, bears compelling evidence to the role of oxidative stress in motor neuron degeneration (reviewed in Ref. [336]). Oxidative damage has been documented at the molecular level in motor neuron disease [337,338]. Agents, which counteract oxidative stress, have had mixed success in preventing motor neuron degeneration in *in vitro* models [332], transgenic mice, and ALS patients themselves. Some beneficial effects in transgenic mice (either delayed onset, prolonged survival, or improved function) were observed with dietary supplementation with vitamin E [334], a modified catalase, given subcutaneously [339], and treatment with trientine and ascorbate [340]. *N*-acetyl-L-cysteine reduced lower motor neuron degeneration in wr [341,342]. Nitric oxide synthase inhibitors failed to alter disease course in the SOD1 mutant transgenic mice [343]. Recently a manganese porphyrin,

AEOL 10150, with antioxidant and free radical scavenging properties was tested in an early phase clinical trial after preclinical studies conducted in a mutant SOD1 transgenic mouse revealed therapeutic benefit of the compound when administered at symptom onset [344]. Adding to this list is the cellular energy substrate, pyruvate, which Park et al. have shown to retard disease progression in an SOD1 transgenic mouse model possibly due to its inherent antioxidant properties [345]. Collectively, these data suggest enzymes/compounds capable of reducing oxidative free radicals (as described in aforementioned neurodegenerative disorders) may be useful in treating motor neuron diseases.

Apoptosis plays a key role in development and morphogenesis. Interplay between antiapoptotic genes such as *bcl-2* and proapoptotic genes such as *bax* and *bad* may determine the activation of the enzymatic cascade of caspases leading to condensation and cleavage of nuclear DNA and the hallmark death of the cell with blebbing of the membrane and cytosolic contents. Increasing evidence gleaned from model systems suggest that motor neurons undergo apoptosis when subjected to pathological conditions related to motor neuron disease [346,347]. Thus, antiapoptotic strategies have been used in *in vitro* and transgenic mouse models to prevent motor neuron degeneration. Delayed onset of disease was observed in double transgenic (mutant SOD1 + *bcl-2* overexpression) [348] or in transgenic mice injected intraspinally with a recombinant AAV vector encoding the antiapoptotic gene *bcl-2* [349]. Furthermore, overexpression of another antiapoptotic family member, Bcl- χ L, was shown to protect cultured rat E15 motor neurons from glutamate excitotoxicity when transduced via a rAAV vector [350]. Some beneficial effects were also seen with the caspase inhibitor, zVAD-fmk [351]. Ultimately, protection against apoptosis may not be sufficient in preventing motor neuron death [352]. The contribution of apoptosis to the etiology of motor neuron death is still being debated [353].

The use of neurotrophic factors has been the most aggressively pursued approach for therapy in the past decade. Members of the NGF family, NGF itself, NT3, NT4/5-BDNF, CNTF, LIF, and GDNF, as well as other trophic factors like IGF-1 (myotrophin) and VEGF, have all been tested for their efficacy in supporting survival or regeneration of motor neurons in *in vitro* and mouse models. These factors may provide trophic support to the neuronal cell body, promote neurite elongation/sprouting, or reinnervation of the neuromuscular junction. Figure 39.13 depicts the neuroprotective effects of a VEGF-expressing lentiviral vector in a mouse model for ALS [354]. Ad vectors have been employed to introduce CNTF, BDNF, and NT-3 in rodent models of motor neuron degeneration [343,346,347]. Based on data from the earliest of these studies, CNTF, BDNF, GDNF, and myotrophin have all been employed at various stages of clinical trial evaluation in ALS patients [355,356]. In one approach, microencapsulated cells, genetically engineered to secrete CNTF, were implanted in lumbar intrathecal space [357]. Results from this study and others clinical trials have been discouraging [358,359]. Since then, alternate gene therapeutic strategies have been developed using AAV, lentiviral, and

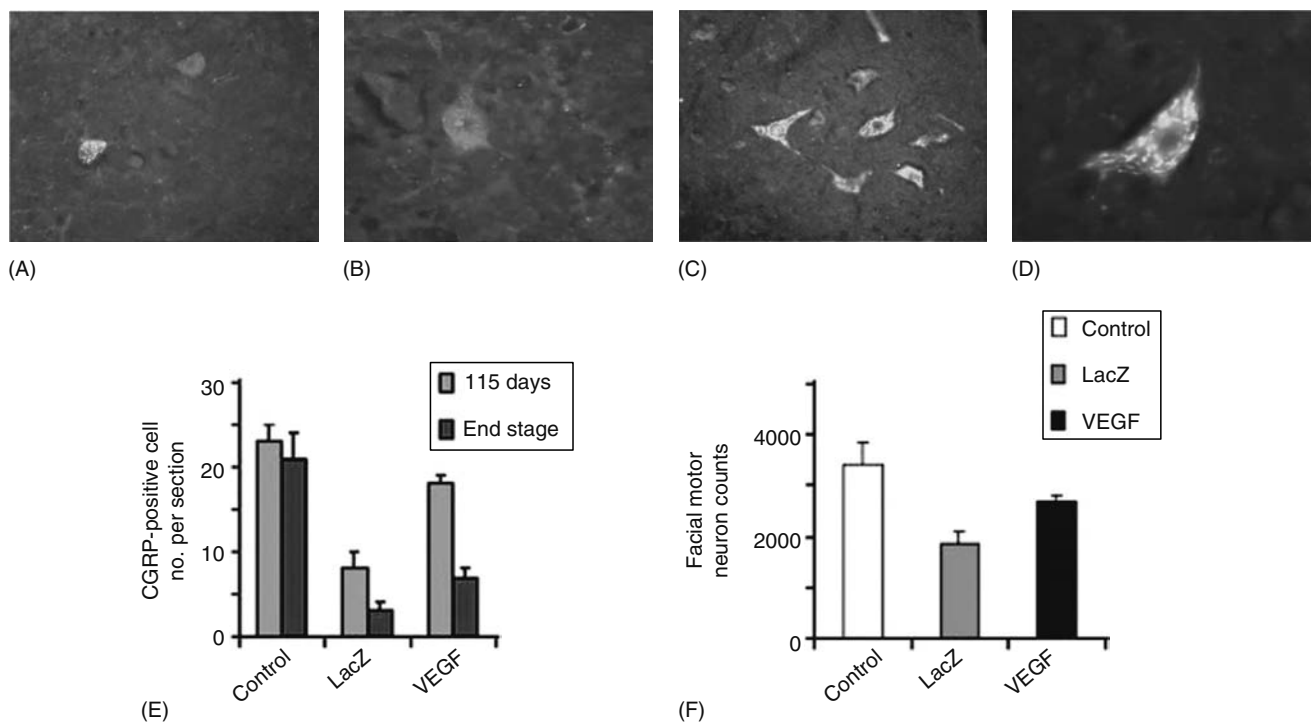

FIGURE 39.13 (See color insert following blank page 206.) VEGF gene therapy protects spinal and brainstem motor neurons in $SOD1^{G93A}$ transgenic mice. (A)–(D) Immunohistochemistry showing CGRP-positive neurons in lumbar spinal cord of EIAV-LacZ (A,B) and EIAV-VEGF injected animals (C,D). (E) Cell counts of surviving lumbar spinal cord motor neurons in control (wild-type), EIAV-LacZ, and EIAV-VEGF-treated $SOD1^{G93A}$ mice at 115 days of age (blue) and at the end stage of disease (red). (F) Quantification of facial nucleus motor neurons in animals injected with EIAV-LacZ, EIAV-VEGF, and control animals at the end stage of disease. EBV vectors, which have exhibited therapeutic benefit in mouse models of ALS. One such strategy employed intramuscular grafting of myoblasts that were genetically modified to secrete the neurotrophic factor, GDNF, using a hybrid EBV/retroviral vector. Familial ALS transgenic mice treated by this method demonstrated reduced motor neuron loss and reduced disease progression [360]. Another approach exploited the retrograde transport capability of lentiviral and AAV vectors with the intention of delivering IGF-1- and VEGF-encoding genes to motor neurons of the spinal cord following intramuscular infusion of the viral vector. Both IGF-1 and VEGF delivered via AAV and lentiviral vectors, respectively, were able to delay the onset of symptoms and prolong the life expectancy in a mutant $SOD1$ mouse model of ALS [354,361].

A strategy to combat motor neuron degeneration in familial cases of ALS caused by the aberrant $SOD1$ enzyme would be to eliminate its cellular presence by silencing the dominantly inherited, mutant $SOD1$ encoding gene. In 2005, Ralph et al. employed a lentiviral-based RNAi strategy to specifically downregulate the expression of mutant human $SOD1$ (G93A) gene in a mouse model of ALS [362]. Transgenic mice that received the h $SOD1$ -targeted shRNA vector demonstrated a significant reduction in h $SOD1$ expression, which translated into a significant delay in the onset of ALS symptoms and prolonged survival compared to mice receiving an empty

vector. Furthermore, efforts have also been made to design siRNAs that can specifically silence the mutated $SOD1$ allele, whilst permitting expression from the wild-type copy in a transgenic mouse model of ALS [363]. However, such a therapeutic approach would be limited to familial ALS patients in whom the specific mutation within the $SOD1$ allele is known.

Taken together, these studies suggest that the most effective therapies for motor neuron degeneration will include agents drawn from several of the classes described above. Further basic research addressing issues of vector, mode of delivery, and upregulation and control of expression of the therapeutic agent (such as neurotrophic factor) is crucial to the design of improved gene therapy strategies for motor neuron diseases [364–366].

39.3 FUTURE OF GENE THERAPY AND NEUROLOGICAL DISEASES

The ability to deliver and express genes *in vivo* has revolutionized the conduct of biological research and created potential new therapeutic approaches. Gene therapy offers potential advantages over traditional pharmacological therapy, a permanent correction of genetic anomaly thereby precluding the need for repetitive dosing. The past decade has seen significant strides in the development of novel gene therapeutic modalities to combat a wide spectrum of human genetic disorders. However, the challenges that present themselves are

also numerous due to the complex etiologies of most neurologic diseases and limitations in current gene delivery technology. Neurodegenerative disorders affect millions of people, account for billions of dollars in health care costs annually, and as a group of diseases are without available curative therapy. As technology improves, this will lead to a better understanding of the underlying molecular mechanisms that constitute the pathogenesis of neurodegenerative disease and will facilitate the generation of superior disease recapitulating animal models. These models will thus expedite the discovery of additional efficacious therapies, which can easily be translated into a clinical setting for treating patients. With this, the full potential of gene therapy will be realized.

40.1 INTRODUCTION

40.1.1 HISTORICAL PERSPECTIVE ON INBORN ERRORS OF METABOLISM

Inborn errors of metabolism (IEM) have played a central role in the formulation of modern genetics. The hallmark of IEM is the accumulation of a biochemical in a bodily tissue. With the development of chemical analytical techniques, it became possible to identify and measure these biochemicals and correlate them with specific diseases (Figure 40.1). Knowledge of metabolic pathways enabled enzymatic defects to be identified, which eventually led to discovery of the cognate proteins and genes.

The appreciation that inborn susceptibilities play important roles in diseases was first promulgated at the beginning of

the twentieth century by Alfred Garrod. He formulated the concept of an inherited metabolic disease on the basis of his studies of patients with alkaptonuria, albinism, cystinuria, and pentosuria. Cognizant of the laws of Mendel, he postulated that the relevant biochemical accumulates due to a metabolic block that is inherited in a recessive process.

The one gene–one enzyme principle developed by Beadle and Tatum provided the next conceptual framework for understanding IEM. This principle provides that metabolic processes are the result of specific enzymatic steps, which are under the control of a single gene. A mutation in a gene leads to deficiency of the enzyme that catalyzes the specific step. The molecular basis for a defective enzyme was provided by Pauling and Ingram's experiments on sickle-cell anemia,

FIGURE 40.1 Flow of information in elucidating the genetic basis of metabolic disorders.

while the molecular basis for a defective gene was provided by Watson and Crick and subsequent elaboration of the central dogma. This dogma defines the flow of information as proceeding from DNA to RNA to protein. The objective of gene therapy is to modulate the flow of genetic information so as to attenuate the disease state.

40.1.2 HISTORICAL PERSPECTIVE ON GENE THERAPY OF IEM

IEM have also played a pivotal role in the formulation of gene therapy [1]. In fact, many of the first human clinical trials in gene therapy were for IEM. In the late 1960s, Rogers attempted to treat three siblings with arginase deficiency by injecting them with the Shope virus on the basis of the incorrect assumption that the virus contained an arginase gene. While being ahead of his time in anticipating the development of viral vectors, the injections had no effect on the subjects' arginine levels. In the more modern era of gene therapy, the first human trials for treating a disease involved children with severe combined immunodeficiency (SCID) caused by a deficiency in adenosine deaminase (ADA).

In addition to human gene therapy trials, IEM have played an important role in the development of gene therapy tools [1]. Cell lines deficient in hypoxanthine phosphoribosyl transferase (HPRT) and grown in hypoxanthine/aminopterin/thymidine (HAT) media enabled the selection for genetically modified cells that take up the HPRT gene in conjunction with other foreign genes. Similarly, cell lines deficient in thymidine kinase (TK) can be used for gene transfer selection. Many of the initial clinical trials in the gene therapy field revolved around IEM such as ADA deficiency, familial hypercholesterolemia (FH), ornithine transcarbamylase deficiency (OTC), and Canavans disease.

With the advent of positional cloning and the human genome project, disorders are being linked to defective genes without any understanding of how metabolism has been disrupted.

The current challenge will be to identify how the defective gene leads to a disturbance in development or homeostasis. Gene transfer and expression in animals and humans will provide critical tests for hypotheses of pathogenesis.

40.2 BASIS FOR GENE THERAPY FOR IEM

40.2.1 TYPES OF IEM

One common type of IEM is caused by deficiency of an enzyme that catalyzes the conversion of one chemical to another (Figure 40.2A). Deficiency of a specific enzyme can cause disease through three separate mechanisms: (1) excessive accumulation of substrate to toxic levels, (2) deficiency of an essential product, or (3) metabolism of the substrate through alternative biochemical pathways leading to toxic secondary metabolites. Examples of such IEM include phenylketonuria (PKU) and methylmalonic aciduria.

IEM can also be caused by deficiency of protein that is involved in the transport of a metabolite (Figure 40.2B). Examples include the cystine transporter in cystinosis and the low-density lipoprotein (LDL) receptor in FH.

Other genes relevant to IEM are required for the proper formation of organelles (Figure 40.2C). Neonatal adrenoleukodystrophy and Zellweger syndrome are caused by defects in genes that are required for the proper formation of peroxisomes. Disorders affecting the biogenesis of organelles lead to the disruption of multiple enzymatic pathways and organelle functions.

40.2.2 DIFFERENT PATHOGENESIS MODELS FOR IEM

The pathogenesis of IEM can be explained by several models (Figure 40.3). One major category includes IEM in which organ dysfunction occurs by a circulating toxic metabolite (Figure 40.3A). Another major category is organ dysfunction resulting from a cell-autonomous process (Figure 40.3B). Although these concepts are useful in formulating gene therapy approaches, it should be appreciated that they are only models and that our understanding of the pathogenesis for many IEM is incomplete. In fact, gene therapy trials may provide decisive information concerning the mechanism by which the metabolic defect leads to the diseased state.

40.2.3 CIRCULATING TOXIC METABOLITE

In this class of disorder, a metabolite accumulates in one tissue as a result of an enzymatic deficiency (Figure 40.3A). This leads to increased metabolite levels in the blood and toxicity in other tissues. The prototype for this type of disorder is PKU in which deficiency of hepatic phenylalanine hydroxylase (PAH) leads to increased blood levels of phenylalanine and toxic effects to the developing brain. FH is another IEM that fits this model. Deficiency of the LDL receptor (LDLR) in the liver leads to increased levels of LDL and subsequent damage to the coronary arteries.

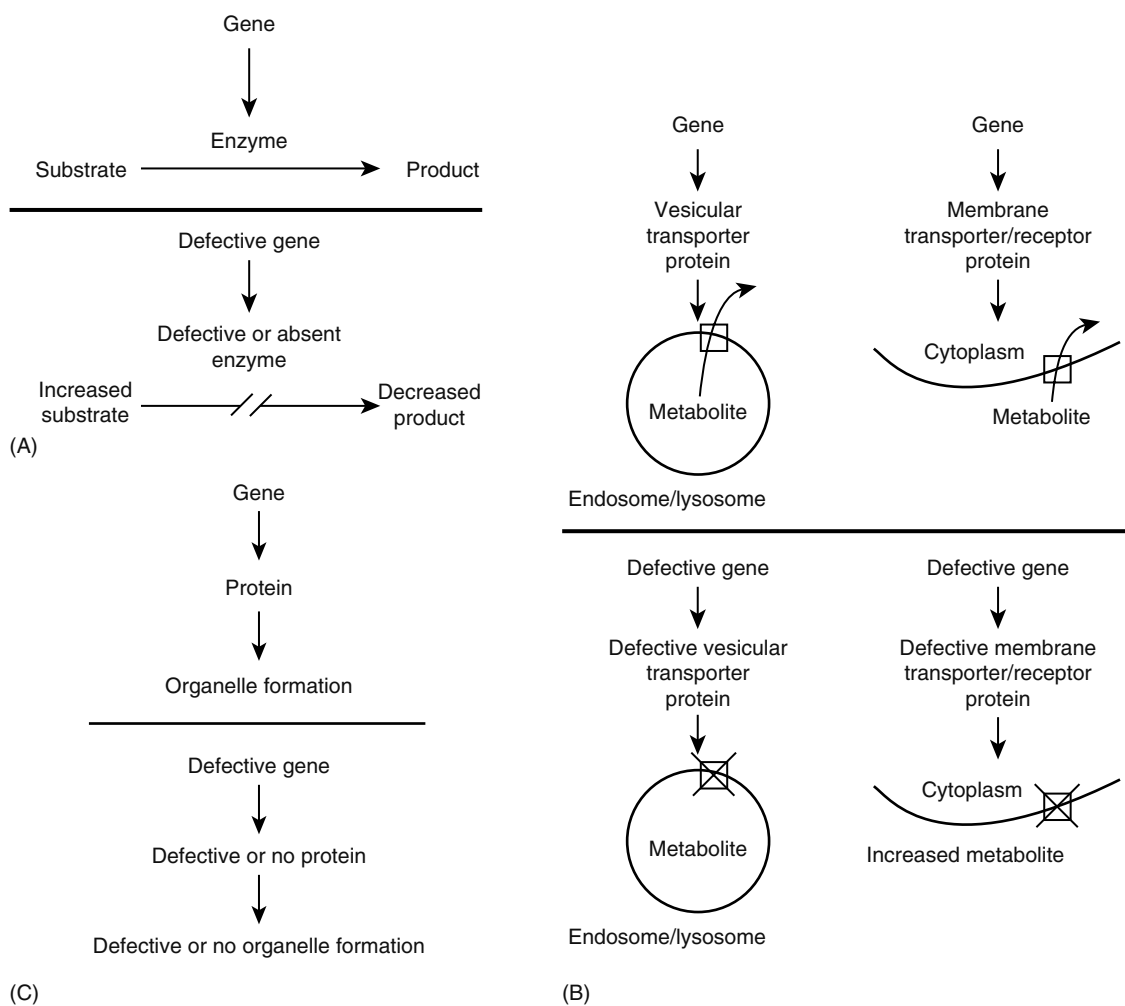

FIGURE 40.2 Types of normal functions that are disrupted in IEMs: (A) defects in enzymatic activity, (B) defects in the uptake or transport of metabolites, and (C) defects in the formation of organelles.

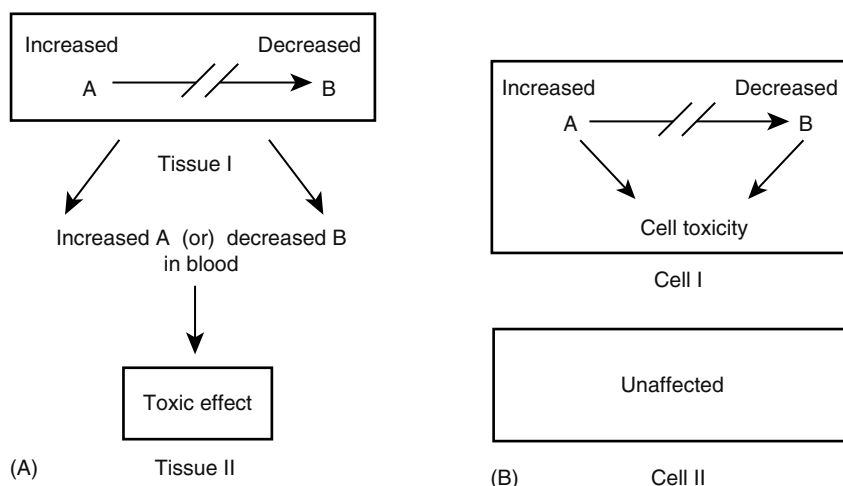

FIGURE 40.3 Two models by which IEM leads to cellular toxicity: (A) circulating toxic metabolite and (B) cell autonomous toxicity.

A corollary of this model is intraorgan toxicity from a metabolite that accumulates in an extracellular space within the affected tissue. It is particularly applicable to the central nervous system (CNS). Some IEM associated with neurological dysfunction may be caused by a toxic metabolite that accumulates within the brain and circulates in the cerebral spinal fluid (CSF). Gene therapy could then be predicated on providing gene expression in any cell within the brain as long as the expressed enzyme could lower levels of the toxic metabolite in the CNS. The CSF could provide the conduit for such exchange.

A metabolic defect in one tissue could also harm another tissue by decreasing the circulating level of a metabolite. For example, a defect in gluconeogenesis that occurs in the liver and muscle (e.g., glycogen storage disorder) can cause hypoglycemia and damage to the brain.

40.2.4 CELL AUTONOMOUS TOXICITY

In other IEM, the metabolic defect only leads to toxicity to the cell that has the metabolic deficiency (Figure 40.3B). Cellular toxicity results from either increased or decreased levels of a metabolite within the affected cell. For these disorders, gene therapy would be effective only if the normal gene is targeted to the dysfunctional cell.

40.2.5 METHOD OF GENE CORRECTION

A variety of parameters of expression are important determinants of the ability of gene therapy to treat specific disorders. Some generalizations can be made concerning the expression requirements for IEM (Table 40.1). Most IEM are recessive conditions and addition of a single gene copy is sufficient to correct the disease phenotype. In effect, gene addition converts the patient to a biochemical state analogous to that of a carrier. For those patients with single-point mutations, targeted gene correction using gene conversion or homologous recombination is a possible therapy, but gene correction is not necessary if a functional gene can be added. The obvious therapeutic gene to be added in IEM is the human gene that is defective in the disease state, but it is conceivable that a therapeutic effect could be achieved using another gene. For example,

a gene from another species could metabolize a toxic metabolite by a different mechanism.

40.2.6 REQUIREMENTS FOR EXPRESSION PERSISTENCE

For most IEM, gene expression does not have to be regulated and can be constant. Most genes involved in IEM are considered “housekeeping” genes. In contrast, in diabetes mellitus, insulin expression has to be regulated in response to blood glucose levels.

Given that IEM are chronic conditions, persistent expression is needed. It would be best if gene correction and therefore a “cure” could be done with one or few administrations. If expression cannot be persistent after one gene dose, then repetitive administrations are required. Repetitive administrations can be problematic for some vectors such as adenoviral and adenoassociated vectors that induce neutralizing antibodies. Loss of expression from vectors can be a result of removal of the foreign DNA, promoter suppression, or rejection of the foreign gene product.

Immune effects can arise even if the gene product is intracellular because all parts of proteins are presented to the immune system via the MHC I complex. The important issue is whether, in the disease state, the patient expresses any residual native protein and is immunologically tolerant to the normal gene product. One measure of this is whether tissues from the patient exhibit crossreactive material (CRM), protein that crossreacts with antibodies against the native protein. This is best determined by performing immunoblot (Western blot) analysis. Even if protein is not present, native protein could have been produced but be unstable. Expression of the foreign gene in such a patient may not induce an immune effect because the protein is not recognized as foreign. Further experience is necessary to determine whether the immune system will prevent stable expression of the normal gene in patients with IEM.

40.2.7 REQUIREMENTS FOR EXPRESSION LEVELS

The level of expression is a critical determinant for the success of a gene therapy. For most IEM, foreign gene expression only has to be greater than 5% of normal levels in order to

TABLE 40.1
Generalizations Concerning Expression Requirements
for Gene Therapy of IEM

Expression Parameter	Requirement
Method of modification	Gene addition is sufficient
Therapeutic gene	Normal gene that is defective in patient
Duration	Persistent
Regulation	Not needed
Levels	>5% of normal levels
Target tissues	Liver, CNS, blood cells, muscle, heterologous expression possible in some disorders

attenuate the majority of the diseased state. This is based on clinical experience in which the percent of residual enzyme activity is correlated with the phenotype. In many IEM, people with more than 5% of normal enzymatic activity are free of symptoms. If enzymatic activity is between 1% and 5%, their clinical course is less severe than patients with 0% of enzymatic activity.

Although the total enzymatic activity is one measure, the percent of cells expressing the foreign gene may also be important. Overexpression in a few cells may not lead to a therapeutic effect if the expressed enzyme alone cannot completely produce the metabolic conversion. The protein deficient in the patient may be part of an enzymatic complex so that overexpression of one component would not necessarily lead to higher activity of the complete complex. Similarly, other enzymatic steps, cofactors, or transport of metabolites may limit the ability of the cell to perform the required metabolic conversion at a rate higher than the normal level. If so, the therapeutic gene has to be expressed in more than 5% of the target cells.

40.2.8 TARGET TISSUES

Details of the pathogenesis for the IEM need to be understood, and the target tissue has to be tailored for each disorder. For IEM that fit the “circulating toxic metabolite” model, the therapeutic gene does not necessarily have to be targeted to the tissue that normally expresses the affected gene (Figure 40.4). Although correction of the deficient enzymatic activity in the affected organ would be most straightforward, expression within a heterologous tissue (different from that which normally expresses the enzyme) could clear the circulating toxic metabolite and attenuate the disease state. For this approach to be effective, the enzyme must be functional within the heterologous tissue. Restrictions on enzymatic function can include requirements for protein subunits, cofactors, substrate, and clearance of product. Given the ability for several gene transfer systems (e.g., plasmid DNA, adenoviral

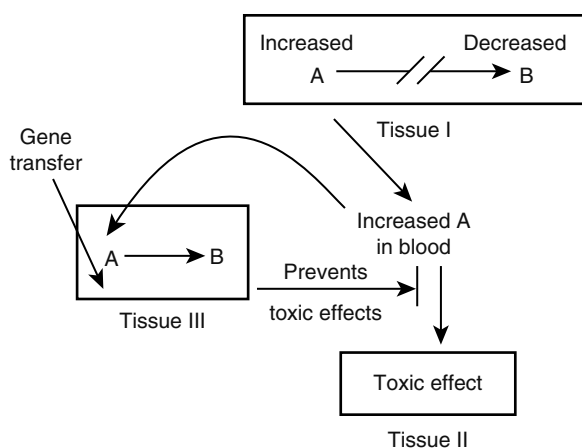

FIGURE 40.4 Heterologous tissue expression of a therapeutic gene to treat an IEM in which a circulating toxic metabolite causes the diseased state.

vectors, and AAV vectors) to express foreign genes stably in muscle, it will be a useful tissue for many heterologous gene therapy approaches. Blood cells derived from genetically modified stem cells are another candidate tissue for heterologous gene expression if the problems associated with stable foreign expression are solved.

For IEM that fit the “cell autonomous” model, expression within the affected cell is generally required. The exception is for the lysosomal storage disorders in which the enzyme can be transferred from one cell to another.

For IEM that affect the brain, “global” gene expression throughout the brain may be required. Alternatively, specific neurological symptoms could be treated by targeting specific regions of the brain. For example, in Lesch–Nyhan syndrome, choreoathetoid movements could be treated by targeting the basal ganglia.

40.2.9 MITOCHONDRIAL DISORDERS OF OXIDATIVE PHOSPHORYLATION

Several IEM are caused by defective oxidative phosphorylation within the respiratory chain complex of mitochondria. A unique feature of mitochondria is that 13 of the more than 80 respiratory chain subunits are encoded within the mitochondrial genome. The mitochondria also contain 22 transfer RNA (tRNA) and two ribosomal RNA that enable protein synthesis within the mitochondria. The remaining 70 or so respiratory chain subunits are encoded within the nuclear genome. These proteins are produced within the cytoplasm and contain an amino terminus that targets their entry into the mitochondria by interacting with a number of chaperone and transport proteins.

For disorders caused by mutations in the nuclear encoded respiratory chain genes, the gene therapy approaches described above are germane. However, disorders caused by mutations in the mitochondrial genome offer additional challenges for gene therapy. One approach would be to express the deficient subunit within the nucleus, regardless of its native mitochondrial origin. The subunit could be modified to contain an amino leader sequence to enable entry into the mitochondria.

The other approach of genetically modifying the mitochondrial genome is at an early conceptual stage. Toward this end, a peptide mitochondria-targeting sequence has been covalently attached to oligonucleotide to enable mitochondrial entry. The oligonucleotide could correct a point mutation by some type of gene conversion or recombination process. Point mutations occur in mitochondrial disorders such as Leber hereditary optic atrophy (LHON), myoclonic epilepsy and ragged-red fiber disease (MERRF), and mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS). An alternative treatment approach would be the addition of functional tRNA genes to patients with mitochondrial disorders such as MERRF or MELAS that are caused by tRNA mutations. The treatment of mitochondrial DNA deletion diseases would require the delivery of larger DNA sequences (>5 kb), which would be more challenging. Deletions occur in

disorders such as Kearns–Sayre syndrome. Another option would be to deliver normal mitochondria *in toto*.

Different mitochondria can proliferate in a tissue at different rates. This may explain why inborn and somatic (acquired) mitochondrial defects often present in later life. Any genetic modification of mitochondria must enable the corrected mitochondria to have a proliferation advantage over the abnormal mitochondria in order to achieve a permanent cure. A final challenge for mitochondrial disorders is that they often involve the nervous system, which is less accessible than other organs to therapeutic endeavors.

40.2.10 NEWBORN AND PRENATAL SCREENING

Gene therapy for IEM will have a significant impact on newborn screening programs and vice versa. Screening for IEM at birth enables gene therapy to be initiated prior to the onset of symptoms and any irreversible tissue damage and thereby increases the value of the gene therapy. Irreversible brain damage occurs in many IEM when a neonatal metabolic crisis is not prevented. For example, the extent of perinatal hyperammonemia in a urea cycle defect, OTC, has been directly correlated with intelligence in later life.

One criterion for the initiation of newborn screening for a particular disorder is whether an effective treatment exists. The development of effective gene therapy for a disorder could satisfy this criterion. Another criterion is the availability of a reliable, inexpensive laboratory method for disease detection.

Currently, most states in the United States and many other nations are screening for PKU and galactosemia. Screening for maple syrup urine disease or homocystinemia is less common. Tandem mass spectroscopy procedures are being developed for analyzing blood spots in amino acids and organic acids conjugated to carnitine (acylcarnitines) in order to detect many of the disorders in amino acid and fat metabolism and organic acidurias. Such comprehensive newborn screening programs developed in conjunction with new gene therapies are having a major impact on the morbidity and mortality of IEM.

Many IEM can be reliably diagnosed in the prenatal period. As intrauterine gene therapy approaches are developed, IEM will be good candidates for such approaches. One potential

advantage of prenatal approaches may be a decreased chance of an immune recognition of the therapeutic gene product.

40.3 GENE THERAPY OF SPECIFIC DISORDERS

A comprehensive review of the tremendous progress in the gene therapy for IEM is beyond the scope of this chapter. In fact, gene therapy studies have been conducted in almost every type of IEM. Instead, specific IEM were chosen either because they illustrate the above principles or for their important historical role.

40.3.1 AMINOACIDOPATHIES

The aminoacidopathies are a heterogeneous group of recessively inherited enzyme deficiencies that are associated with the accumulation of specific amino acids in blood and other tissues. The best known and most studied aminoacidopathy is PKU (Table 40.2) caused by deficiency of the liver enzyme PAH (Figure 40.5). PAH deficiency prevents the hydroxylation of phenylalanine to tyrosine and leads to excessive accumulation of phenylalanine in the body. If PKU is left untreated in an infant, poor brain and physical growth, seizures, and mental retardation will result from increased levels of the circulating toxic metabolite phenylalanine. Other examples of aminoacidopathies include tyrosinemia, maple syrup urine disease, homocystinuria, and ornithine transcarbamylase (OTC) deficiency (Table 40.2). Each of these enzyme deficiencies leads to the accumulation of a different specific substrate and causes a different symptom complex.

Contemporary therapy for these diseases is based on an understanding of the pathogenesis involved in each case, and the design of any gene therapy protocol must also be grounded upon a rational understanding of the specific disease pathophysiology. For example, high levels of phenylalanine in PKU are toxic to the developing brain and reducing blood phenylalanine levels are critical to successful treatment of PKU. However, some symptoms of PKU may be caused by deficiencies of specific neurotransmitters, such as dopamine, that are synthesized from tyrosine. In tyrosinemia 1 due to fumarylacetoacetate hydrolase (FAH) deficiency, elevated blood

TABLE 40.2
Summary of Select Aminoacidopathies

Disease	Deficient Enzyme	Elevated Blood Amino Acids	Animal Model
PKU	PAH	Phenylalanine	<i>Pal^{em2}</i> mouse
Tyrosinemia type I	FAH	Tyrosine	FAH knockout mouse
OTC deficiency	OTC	Glutamine; elevated blood ammonia	Sparse fur (<i>spf</i>) mouse
Maple syrup urine disease (MSUD)	Branched-chain keto acid dehydrogenase	Leucine, valine, isoleucine	Hereford inbred calf MSUD
Homocystinuria	Cystathionine β -synthase	Homocystine	None

FIGURE 40.5 Pathogenesis of PKU.

tyrosine levels do not appear to be directly toxic, but accumulation of the toxic substrate fumarylacetoacetic acid and its conversion to an equally toxic secondary metabolite succinylacetone causes apoptosis in FAH-deficient hepatocytes. So, for PKU, any therapy that lowers blood phenylalanine and restores tyrosine levels will correct the disease phenotype. In tyrosinemia, clearance of tyrosine from blood is less important but FAH activity must be restored within individual hepatocytes to prevent the accumulation of toxic metabolites within the cell. These considerations must play a role in the design of any gene therapy protocol.

In many aminoacidopathies, the deficient enzyme is normally either exclusively or primarily expressed in liver; liver is the obvious target for gene transfer in these diseases [2]. However, for select disorders, circulating toxic metabolites may be effectively removed from the body by enzyme expressed in a tissue other than liver. The concept of expressing in an alternative tissue a protein that is normally restricted to a specific organ is known as heterologous gene therapy. As an example, PAH expression in skeletal muscle, if supplied with the necessary cofactors, might effectively clear phenylalanine from the circulation of a person with PKU. Gene targeting to the liver may not be essential for some aminoacidopathies. For other diseases, specific pathophysiological features limit the effectiveness of a heterologous gene therapy approach. In OTC deficiency, the substrate for OTC, carbamyl phosphate, is produced only locally in the liver and does not appear in the circulation. As we have already seen, hepatocellular damage in tyrosinemia type 1 can only be prevented if FAH activity is restored in hepatocytes. If possible, disease-specific pathophysiological features and the effectiveness of any gene therapy approach should be demonstrated in an animal model of the disease, if one is available, prior to application of the method in humans. Table 40.2 lists animal models available for the study of some aminoacidopathies.

Gene transfer experiments to treat PKU illustrate the difficulties and complexities of gene therapy for aminoacidopathies and other liver diseases [3]. The availability of a mouse

model, the *Pah^{enu2}* mouse, that accurately portrays human PAH deficiency has allowed significant advances in PKU gene therapy research. Experimental work with this animal model has demonstrated that PAH activity must be restored in at least 5% of hepatocytes before a substantial reduction in blood phenylalanine is achieved and early gene therapy attempts were limited by the inability to stably transduce sufficient numbers of hepatocytes [4]. The feasibility of hepatocyte-directed gene transfer was demonstrated using a recombinant Moloney murine leukemia virus vector to correct PAH deficiency in cultured hepatocytes from the animal model. However, portal venous infusion of cultured hepatocytes treated *ex vivo* with a β -galactosidase reporter gene-containing retroviral vector yielded only 1% β -galactosidase-expressing cells in the liver of a dog, a transduction frequency that would be insufficient to prevent hyperphenylalaninemia in PKU. As discussed below, a human clinical trial of this approach in subjects with FH yielded a similar transduction frequency and incomplete phenotypic correction [5]. This approach has, however, been employed successfully in the treatment of murine tyrosinemia type I [6]. In this mouse model, enzymatically corrected hepatocytes have a survival advantage over enzyme-deficient cells in the host; although they initially constitute only a very small fraction of the liver, retrovirus-treated enzyme-expressing hepatocytes gradually repopulate the entire liver. Recombinant retroviral-mediated gene therapy may be useful for disorders that require correction of only 1% to 2% of the liver to effect a phenotypic change or in situations where corrected cells have a competitive advantage over the native hepatocytes.

Higher transduction frequencies can be achieved using recombinant adenovirus vectors injected directly into the liver circulation. A recombinant adenovirus containing the PAH cDNA has been infused into the portal circulation of PKU mice [7]. In this experiment, hepatic PAH activity was reconstituted to 5% to 20% of control levels. Complete normalization of plasma phenylalanine levels occurred in animals with hepatic PAH activity equivalent to at least 10% of that in control animals. However, the effect had disappeared by 3 weeks following the treatment, and no hepatic PAH activity was detected following a second treatment with the adenoviral vector. The stability of expression from adenoviral vectors administered *in vivo* is limited by the immune response of the host against the vector or the reporter gene product. In experimental trials of adenovirus-mediated, liver-directed gene therapy employing a variety of different therapeutic genes to treat several different animal models, gene expression has been stable for 7 to 10 days and then has decreased to undetectable levels over the next few weeks. Preexisting immunity and vigorous inflammatory responses against adenovirus in humans further limit the applicability of this vector. In a clinical trial that administered a recombinant adenovirus containing the human OTC cDNA via the hepatic artery to humans with partial OTC deficiency, an overwhelming systemic inflammatory response and fatal hepatic failure occurred following infusion of the vector into a single subject [8].

Recombinant adeno-associated virus (rAAV) vectors have recently enjoyed widespread application in preclinical studies of gene therapy for IEM. AAV is a nonpathogenic single-stranded DNA parvovirus that is capable of stable integration without active cell division. Recombinant AAV vectors are capable of infecting multiple different cell types but pseudotyping with capsid proteins from different AAV serotypes can substantially alter tissue tropism. In comparison to adenovirus vectors, rAAV vector administration to animals has not triggered a vigorous inflammatory reaction. Unlike wild-type AAV, rAAV vector genomes remain predominantly episomal within the target cell; integration of the rAAV genome into the host genome occurs only rarely. Yet, in the absence of rapid target cell turnover and loss of episomal genomes, rAAV administration can lead to long-term sustained therapeutic gene expression. Sustained and complete correction of hyperphenylalaninemia in *Pah^{enu2}* mice following injection of PAH-expressing rAAV2/8 vector has been accomplished [9,10]. Concerns about tumorigenesis, hepatotoxicity, and immune complications require further study before an AAV-based clinical trial is initiated for PKU. Success with a naked plasmid DNA approach has also been achieved in the mouse model [11].

40.3.2 ORGANIC ACIDURIAS

Propionic aciduria and methylmalonic aciduria are two organic acidurias that have been well studied and are excellent candidates for gene therapy (Figure 40.6). In severe cases, patients present in the neonatal period with coma, metabolic ketoacidosis, and hyperammonemia. With vigorous medical support, they can survive this initial metabolic crisis, but they then must adhere to a strict diet restricted in protein intake. Despite dietary therapy, they continue to have metabolic crises that can be life-threatening. Given the inadequacy of dietary therapy, a gene therapy approach is needed.

Both disorders are caused by enzyme deficiencies in the metabolism of three-carbon species that are generated from the catabolism of amino acids and other metabolites (Figure 40.6). Methylmalonic aciduria is caused by a deficiency of methylmalonyl-CoA mutase activity that is a result of a defect either in the apoenzyme or in the active form of vitamin B₁₂. Patients with the latter defect often respond well to treatment with large amounts of vitamin B₁₂ and are therefore in less need of gene therapy.

The prominent target tissue for both disorders is presumed to be the liver. Hepatorenal transplantation has been successfully employed in a patient with a severe form of methylmalonic aciduria. Nonetheless, the major pathology associated with these organic acidurias is due to circulating toxic metabolites. The associated enzymes are normally expressed in many tissues including leukocytes, muscle, and fibroblasts. Therefore, these heterologous tissues should be explored in gene therapy preclinical studies. Unfortunately, animal models for these disorders do not exist at the present time.

Five percent of normal enzymatic activity in either propionic aciduria or methylmalonic aciduria is associated with a benign clinical course, indicating that this level of expression in a gene therapy should be sufficient to realize a large clinical benefit. This level of expression may have to be distributed over approximately 5% of the cells because overexpression of the relevant genes may not lead to a proportional increase in metabolic flux through the three-carbon pathway. For example, in propionic aciduria, the propionyl-CoA carboxylase has two different subunits, α and β . In patients with a defect in the β -subunit, overexpression would require gene transfer with both subunits. However, in patients with a defect in the α -subunit, overexpression of the α subunit may be sufficient because the β -subunit is produced in a fivefold excess over that of the α -subunit.

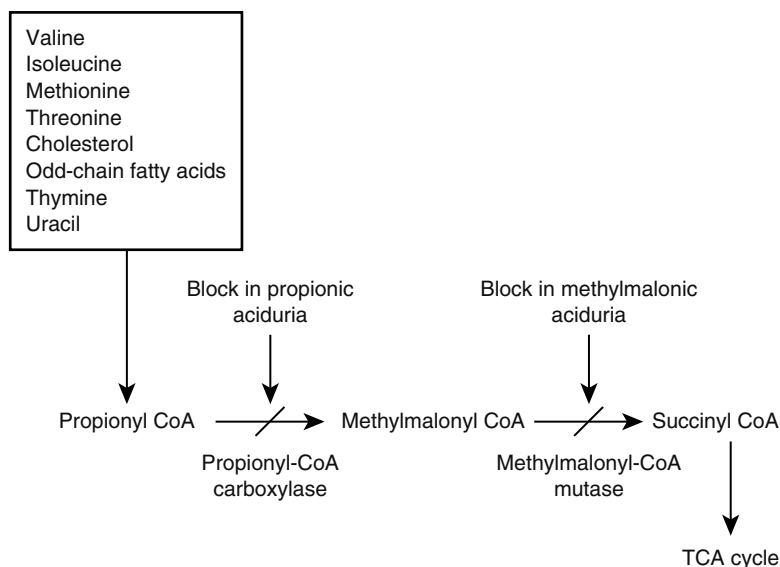

FIGURE 40.6 Enzymatic deficiencies in methylmalonic aciduria or propionic aciduria. TCA, tricarboxylic acid cycle.

40.3.3 LYSOSOMAL STORAGE DISEASES

The common feature of lysosomal storage diseases is the inappropriate accumulation of normal cellular components within lysosomes. This storage of material is visible in cells by light microscopy as very large lysosomes that displace a large part of the cytoplasm. This class of disorders is caused by deficiency of specific lysosomal enzymes that are required for the degradation and recycling of glycoproteins and other cellular components. Without a specific degradative enzyme, the substrate for the reaction accumulates and cannot be removed from the lysosome. The clinical phenotype of each disease is dependent on the tissue type most affected by storage and by the accumulation rate. Physical findings that are suggestive of lysosomal storage include enlargement of the liver and spleen, anemia, and thrombocytopenia due to replacement of normal bone marrow by stored material, destruction of bone, and for those enzymatic deficiencies that cause lysosomal storage in neurons, severe developmental regression, seizures, and other neurological symptoms. Not all of these problems are present in all lysosomal storage diseases; each different enzymatic deficiency presents with a specific phenotypic complex.

The challenges of gene therapy for lysosomal storage diseases are illustrated by the results of contemporary treatment with enzyme replacement therapy (ERT) or bone marrow transplantation. A major challenge to treating a lysosomal storage disease with gene therapy (in contrast to treatment of a liver enzymopathy) is the necessity of reversing lysosomal storage in multiple separate tissues. No currently available gene transfer technique is capable of delivering DNA to multiple target tissues efficiently. However, many lines of evidence demonstrate that lysosomal enzyme proteins can be produced in isolated tissues or even purified *ex vivo* and effectively delivered to most target tissues. For example, glucocerebrosidase, the enzyme deficient in Gaucher's disease can be produced *in vitro* using standard recombinant techniques, chemically modified to facilitate lysosomal targeting, and delivered to affected organs by simple intravenous infusion. This therapy if repeated periodically dramatically reduces liver and spleen size, corrects anemia and thrombocytopenia, and possibly prevents bone deterioration, all major debilitating features of Gaucher's disease. So, at least for gene therapy of Gaucher's disease, the enzyme would not need to be locally produced in all affected tissues. The enzyme could potentially be produced in a single target tissue, secreted into the circulation, and taken up by other diseased tissues. The major limitation of this approach is the difficulty of engineering a secreted form of the enzyme that would be efficiently taken up by other cells and incorporated into lysosomes.

Alternatively, the enzyme could be transferred from the site of production to diseased tissues via circulating blood cells. Seminal experiments demonstrated that functional lysosomal enzymes may be transferred directly from a normal cell to an enzyme-deficient cell in tissue culture. Bone marrow transplantation in the treatment of lysosomal storage diseases exploits this phenomenon. Replacement of enzyme-deficient

host bone marrow with enzyme-sufficient donor bone marrow yields a population of circulating blood cells of the reticuloendothelial lineage that infiltrates tissues and transfers lysosomal enzyme to the native cells. Bone marrow transplantation has been employed successfully in Gaucher's disease and in select other storage diseases that do not exhibit brain involvement. Apparently either insufficient numbers of corrected cells penetrate the CNS or insufficient enzyme is transferred to neurons to successfully ameliorate the neurological phenotype of many lysosomal storage disorders. Presumably, difficulties with correcting enzyme deficiency in the brain will also be a major obstacle to successful gene therapy.

Gene therapy for lysosomal storage diseases has to date focused on gene transfer into bone marrow stem cells for the purpose of supplying enzyme via circulating reticuloendothelial cells [12]. Enzymatic correction of Gaucher's bone marrow cells in culture has been accomplished with recombinant retroviral vectors. Similar experiments using other lysosomal enzymes in both cultured bone marrow and fibroblasts have been successful. Persistent production of enzyme in circulating blood cells has been demonstrated in rodents. Phenotypic improvement following retroviral-mediated gene transfer into bone marrow has been shown in *gus^{mps}/gus^{mps}* mice, a β -glucuronidase-deficient mouse model of human mucopolysaccharidosis type VII. As expected, enzymatic correction of bone marrow resulted in amelioration of the somatic symptoms but did not arrest progressive neurological deterioration in this model. However, lysosomal storage in the brain did decrease in mice that had received intracerebral β -glucuronidase-expressing fibroblast implants. Clinical trials of retroviral-mediated bone marrow stem cell-directed gene therapy are under way in humans with Gaucher's disease and in patients with Hunter's syndrome (mucopolysaccharidosis type II) who have little CNS involvement.

40.3.4 LESCH-NYHAN SYNDROME

This X-linked syndrome is caused by a deficiency in HPRT, an enzyme required for salvaging purines (Figure 40.7). It is characterized clinically by increased blood and urine uric acid, mental retardation, choreoathetoid movements, and, most extraordinarily, self-mutilation. It is not understood how a deficiency in HPRT leads to these remarkable neurological sequelae. A genetic mouse model completely lacking HPRT activity does not exhibit any neurological dysfunction except when stressed with amphetamine administration or inhibition of adenine phosphoribosyl transferase (APRT) with 9-ethyladenine. The choreoathetoid movement disorder, however, is postulated to be due to dysfunction within the basal ganglion secondary to disturbed dopamine metabolism.

Although the hyperuric acidemia and its sequela can be controlled with allopurinol, the absence of treatment for the neurological symptoms has prompted the search for gene therapy approaches. Historically, Lesch-Nyhan syndrome has played an important role in the development of gene therapy. One of the first demonstrations of the ability of retroviral

FIGURE 40.7 Enzymatic deficiency in Lesch–Nyhan syndrome.

vectors to correct a genetic mutation was done using the human HPRT gene. The first animal experiment in which a foreign gene was expressed in the brain was done by intracerebrally transplanting fibroblasts genetically modified to express the human HPRT [13]. Although HPRT is expressed in all cells, its high levels in the basal ganglia suggest that this area of the brain should be targeted for gene transfer. Prevention of the mental retardation may require more global expression within the brain.

The amount of normal gene expression required to effect relief can be extrapolated from clinical experience. Although it was previously believed that the severity of the syndrome was not correlated with residual enzymatic activity, it is now realized that its severity does correlate with the amount of HPRT activity in whole cells. Patients with 1.6% to 8% of normal activity had choreoathetosis but not mental retardation or self-mutilation.

In summary, this syndrome is an example of a genetic disorder in which therapy is lacking even when so much is known about its genetic and molecular basis. The development of effective gene transfer methods into the brain may not only provide a therapy but will be quite revealing about its pathogenesis.

40.3.5 GLYCOGEN STORAGE DISEASES

Glycogen storage diseases (GSD) are generally associated with hypoglycemia, hepatomegaly, skeletal and cardiac myopathy depending upon the specific enzymatic defect. Clinical problems arise from deficiency of product, glucose, in GSD type I and III or from lysosomal accumulation of the substrate, glycogen, in GSD type II. For those disorders such as GSD

type I (deficiency in glucose-6-phosphatase) and III (deficiency in glycogen debrancher enzyme) that are associated with hypoglycemia, the mainstay of therapy has been continuous gastric feedings or cornstarch therapy. But this has not prevented late stage liver tumors and renal disease, prompting the search for more definitive therapies such as gene therapy [14]. AAV vectors have been used to correct the metabolic disturbances (hypoglycemia and hypercholesterolemia) present in genetic mouse and dog models of GSD type I and prolonged survival.

GSD type II is caused by deficiency in the lysosomal acid alpha-glucosidase (GAA) enzyme. The infantile form of GSD II (Pompe disease) presents in infancy with generalized muscle weakness and hypertrophic cardiomyopathy, leading to cardiorespiratory failure and death. The juvenile and adult forms of Pompe do not exhibit cardiomyopathy but still have progressive skeletal muscle weakness and eventual respiratory failure. ERT is showing promise in both the infantile and late-onset forms but requires frequent infusions of large amounts of the enzyme, thus sparking interest in gene therapy approaches. Both adenoviral and AAV vectors have corrected the metabolic defect in a GAA-knock-out model for Pompe disease. Humoral antibodies against the GAA enzyme is problematic with both ERT and gene therapy approaches. In the mouse model, this problem has been avoided by the use of an AAV 2/8 vector expressing GAA from a liver-specific promoter.

40.3.6 FAMILIAL HYPERCHOLESTEROLEMIA

Gene therapy has the potential to significantly improve the clinical status of patients with FH, which is caused by a defect in the LDLR (Figure 40.8). Deficiency in this receptor leads to reduced clearance of LDL by the liver and higher blood levels of LDL. In addition, affected individuals synthesize more cholesterol because the inhibitory effect of LDL on cholesterol synthesis is lost. This inhibition results from decreased HMG CoA reductase activity, the rate-limiting step in cholesterol synthesis.

FIGURE 40.8 Pathogenesis of familial hypercholesterolemia. Chol, cholesterol; HMG, 3-hydroxymethylglutaryl; LDLR, low-density lipoprotein receptor.

Heterozygotes with LDLR deficiency occur at a frequency of 1:500 (as common as insulin-dependent diabetes mellitus), making it one of the most common genetic disorders in the United States, Europe, and Japan. Such patients have a two-fold elevation in plasma cholesterol levels (300–600 mg/dL) and may develop coronary artery disease by the fourth decade of life. Three percent to 6% of survivors of myocardial infarctions are heterozygotes for FH.

Homozygotes with LDLR deficiency occur much more infrequently (one in a million), but have much higher cholesterol levels (600–1000 mg/dL) and invariably die from coronary artery disease in their twenties. The severity of the sequelae is attenuated in the homozygote by a few percent residual LDLR activity. Deaths were much less frequent in those homozygotes who had at least 10% of normal LDLR activity. This indicates that clinical benefit could be achieved by a gene therapy in which only a small percentage of LDLR activity is restored. Furthermore, the severity of this disorder increases the benefit-to-risk ratio of clinical trials and thereby facilitates them. A gene therapy protocol can be first tested in the homozygotes (aided by Orphan Drug Status) and then extended to the more common heterozygotes.

Liver transplantation in children has proven that correction of the LDLR defect in the liver can normalize cholesterol levels. For this reason, gene therapy techniques for FH have been directed at the hepatocyte. Based on preclinical studies in mouse and rabbit LDLR-deficient models, *ex vivo* gene therapy in five homozygous FH patients using retrovirus-mediated LDLR gene transfer was performed. This technically challenging protocol yielded a highly variable metabolic response with some improvement in only one of the patients [5]. This study indicates that important modifications must be made to the *ex vivo* gene transfer method before gene therapy can be used as a general therapeutic procedure for such patients [15].

Given the borderline results of the human clinical trial, efforts were initiated with adenoviral vectors carrying the LDLR gene. *In vivo* adenovirus-mediated transfer of the LDLR was shown to be highly effective in reversing the hypercholesterolemia in LDLR knockout mice and WHHL rabbits [16]. The important limitation of adenoviral-mediated gene transfer remains the transient expression *in vivo* after infection of somatic cells with recombinant adenovirus. Nonetheless, these studies demonstrate the proof-of-principle for the gene therapy of FH by the transfer of the normal LDLR gene and highlight the inadequacies of current gene transfer methods.

Current therapy for hypercholesterolemia (not limited to homozygous FH) includes the use of HMG-CoA reductase inhibitors, which work by secondarily inducing expression of the LDLR, thereby lowering plasma LDL levels. These agents not only lower serum cholesterol, but also lower all-cause mortality by at least 30% in men and women who have coronary disease and total cholesterol levels of 215 to 300 mg/dL. However, 2% of patients suffer liver toxicity and 0.2% develop muscle disease requiring cessation of drug administration. These drugs have to be taken once or twice every day for

extended periods of time and compliance is often difficult. A gene therapeutic agent that is administered less than every month (even by intravenous injection) would offer substantial benefit to the patient.

At high efficiencies of liver gene transfer, LDLR gene transfer into the liver could be used to prevent coronary artery disease in the general population. Taking into account all types of hypercholesterolemias, the third National Health and Nutrition Examination Survey (NHANES III) concluded that lipid-lowering therapy was required for 29% of Americans over 20 years of age [17]. The Cholesterol and Recurrent Events study showed that patients with coronary artery disease but having “normal” LDL cholesterol levels benefited from treatment with a single statin therapy [18]. The positive correlation between LDL levels and coronary artery disease is a continuum. In addition, overexpression of the normal LDLR in the liver of transgenic mice (four to five times that of the endogenous receptor) prevented diet-induced hypercholesterolemia, suggesting that unregulated overexpression of the LDLR by liver gene therapy would be therapeutic in humans with hypercholesterolemia of various causes [19].

Many individuals develop coronary artery disease from other causes not amenable to statin therapy but that are potentially treatable by gene therapy. Liver gene therapy using the apoB mRNA editing enzyme (ApoBc 1) or the very low density lipoproteins (VLDL) receptor genes could modify LDL cholesterol levels. Other lipoprotein factors besides LDL cholesterol levels influence the onset of coronary artery disease and are amenable to modulation by liver gene transfer. Additional expression of apoA-I in the liver by foreign gene transfer could raise high-density lipoprotein levels and prevent atherosclerosis, as has been demonstrated in mouse and rabbit models. Hypertension, a predisposing factor for coronary artery disease, could be treated by delivering the kalikrein gene to the liver.

Another approach is to block the expression of specific genes using antisense or siRNA molecules. Antisense against apoB has been reported to lower cholesterol levels in people. However, blockage of apoB may lead to steatosis. Other anti-hypercholesterolemic targets for gene knockdown include PCSK9 and acetylCoA-cholesterol transferase, which appear to lower blood cholesterol levels without causing steatosis. It is likely that the siRNA approaches will succeed antisense approaches given siRNA's greater potency and efficacy.

40.3.7 CRIGLER–NAJJAR HYPERBILIRUBINEMIA

Crigler–Najjar syndrome is caused by genetic mutations in the UGT1A gene that encodes UDP-glucuronosyltransferase 1. Deficiency in this enzyme causes unconjugated hyperbilirubinemia (jaundice) that can lead to bilirubin encephalopathy (kernicterus). Current therapy consists of phototherapy or liver transplantation [20].

Bilirubin is produced from the reticuloendothelial cells (macrophages) when they take up aged erythrocytes and degrade the heme moiety within hemoglobin. This unconjugated bilirubin is released into the circulation and taken up by hepatocytes where it is converted by UDP-glucuronosyltransferase

into the conjugated form for secretion into the bile duct. Accordingly, adenoviral, AAV, lentiviral, and naked plasmid DNA approaches have been used to express the enzyme in hepatocytes and correct the hyperbilirubinemia present in the Gunn rat model for Crigler–Najjar syndrome [21–23]. A heterologous expression approach has been to express the enzyme in muscle [24]. The idea is that muscle can take up the unconjugated bilirubin, convert it to the conjugated form, and release the conjugated bilirubin into the circulation where it is either excreted in the urine or taken up by hepatocytes for secretion into the bile.

40.4 SUMMARY

The foundation for treating many IEM by gene therapy has been established. It is clear that the expression of the cognate gene can correct the metabolic disturbance and the disease state in most IEM. As in other types of disorders, clinical success has been thwarted by inefficiencies in the gene delivery and expression systems. As new vectors and expression systems are developed and improved over the next few years, it is anticipated that clinical efficacy will be demonstrated for an increasing number of IEM.

41.1 INTRODUCTION

Controlling HIV infection continues to be a major challenge both in underdeveloped and developed nations despite the fact that the currently employed drug cocktails have markedly changed the profile of progression to acquired immunodeficiency syndrome (AIDS) in HIV-infected individuals. Despite the successes, highly active antiretroviral therapy (HAART) treatment is not without significant problems and drawbacks [2–9]. Because of pharmacokinetic differences between individuals, there are multiple drug-related toxicities leading to nonadherence problems. There is a need for personalized dosing regimens and combinations and continued therapeutic monitoring of the drugs themselves. They continue to be drug failures for those on HAART as a consequence of viral resistance and other complications due to a lifelong regimen of chemotherapy [10,11]. Temporary interruption of HAART therapy is common; however, in marked contrast to earlier thinking, a recent study shows that compared to continuous antiretroviral therapy, episodic HAART leads to an increased risk of liver cirrhosis, myocardial infarction, renal failure, and stroke with no concomitant increase in quality of life [12]. The increase in side effects due to long-term conventional treatment is due in part to the improved lifespan brought on by the very success of antiretroviral therapies. In addition, treatment guidelines traditionally have not recommended initiating therapy in early stages of infection despite the risks

associated with loss of immunological function, increased likelihood of transmission, and the development of a larger pool of viral subspecies that serve as a reservoir for potential resistance. However, there has also been a recent shift toward starting retroviral therapy earlier before CD4 counts drop below $200 \times 10^6/l$ [1,13]. As a possible means of circumventing some of the problems associated with HAART, a number of investigators are focusing their attention on gene therapy either as a stand alone approach or as an adjuvant to pharmacological drug regimens.

We will focus on the progress in developing RNA-based anti-HIV gene therapeutics for long-term applications, with particular attention to molecular targets and their mechanisms of action within the context of the special challenges posed by HIV. An important consideration is the issue of viral versus cellular targets. RNA antivirals can be designed with high specificity and HIV-1 products are the preferred target; however, many viral RNAs are highly abundant and viral escape is a major problem that can only be partially ameliorated by targeting highly conserved sequences. Cellular targets are far less prone to mutational escape and are often in lower abundance, but the side effects of downregulating cellular targets for the long-term are unknown. We evaluate RNA gene therapies in the light of the emerging consensus that combinatorial gene therapeutics has the greatest likelihood of success analogous to HAART therapy.

41.2 RNA INTERFERENCE AS A POWERFUL MECHANISM FOR TARGETED INHIBITION OF GENE EXPRESSION

RNAi is a regulatory mechanism of most eukaryotic cells that use small double-stranded RNA (dsRNA) molecules as triggers to direct homology-dependent control of gene activity [14]. Known as small interfering RNAs (siRNA) these ~21–22bp long dsRNA molecules have characteristic two-nucleotide 3' overhangs that allow them to be recognized by the enzymatic machinery of RNAi that eventually leads to homology-dependent degradation of the target mRNA. In mammalian cells, siRNAs are produced from cleavage of longer dsRNA precursors by the RNaseIII endonuclease Dicer [15]. Dicer is complexed with two RNA-binding proteins, the TAR-RNA-binding protein (TRBP) and protein kinase R-activating protein (PACT), which are involved in the hand off of siRNAs to the RNA-induced silencing complex (RISC) [16]. The core components of RISC are the Argonaute (Ago) family members. In humans, there are eight members of this family but only Ago-2 possesses an active catalytic domain for cleavage activity [17,18]. While siRNAs loaded into RISC are double-stranded, Ago-2 cleaves and releases the “passenger” strand, leading to an activated form of RISC with a single-stranded “guide” RNA molecule that directs the specificity of the target recognition by intermolecular base pairing [19]. Rules that govern selectivity of strand loading into RISC are based upon differential thermodynamic stabilities of the ends of the siRNAs [20,21]. The less thermodynamically stable end is favored for binding to the PIWI domain of Ago-2.

An important arm of RNAi involves the microRNAs (miRNAs). These are endogenous duplexes that regulate gene expression posttranscriptionally by complexing with RISC and binding to the 3' untranslated regions (UTRs) of target sequences via short stretches of homology termed the “seed sequences” [22,23]. The primary mechanism of action of miRNAs is translational repression although this can be accompanied by message degradation [24].

The miRNA duplexes possess incomplete Watson–Crick base pairing and the antisense strand cannot be chosen by cleavage of the passenger strand as for siRNAs, therefore the antisense strand must be chosen by an alternative mechanism [25–27]. miRNAs are endogenous substrates for the RNAi machinery. They are initially expressed as long primary transcripts (pri-miRNAs), which are processed within the nucleus into 60–70 bp hairpins by the microprocessor complex, which consists of Drosha–DiGeorge syndrome critical region gene 8 protein (DGCR) [28,29]. The pre-miRNAs are further processed in the cytoplasm by Dicer and one of the two strands is loaded into RISC, presumably via interaction with PACT [16]. Importantly, it is possible to exploit this native gene silencing pathway for regulation of gene(s) of choice. If the siRNA effector is delivered to the cell it will “activate” RISC, resulting in potent and specific silencing of the targeted mRNA. Because of the potency and selectivity of RNAi, it has become the methodology of choice for silencing specific gene expression in mammalian cells.

Control of disease-associated genes makes RNAi an attractive choice for future therapeutics. Basically every human disease caused by activity from one or a few genes should be amenable for RNAi-based intervention. This list includes cancer, autoimmune diseases, dominant genetic disorders, and viral infections. RNAi can be triggered by two different pathways: (1) an RNA-based approach where synthetic effector siRNAs are delivered by various carriers to target cells as preformed 21 base duplexes; or (2) via DNA-based strategies in which the siRNA effectors are produced by intracellular processing of longer RNA hairpin transcripts (reviewed in Refs. [28,29]). The latter approach is primarily based on nuclear synthesis of short hairpin RNAs (shRNAs) that are transported to the cytoplasm via the miRNA export pathway and are processed into siRNAs by Dicer. While direct use of synthetic siRNA effectors is simple and usually results in potent gene silencing, the effect is transient. In a clinical setting, this would usually mean repeated treatments would have to be administered and these are large and costly drugs. In the case of HIV infection, this would be a lifelong treatment. DNA-based RNAi drugs on the other hand have the potential of being stably introduced when used in a gene therapy setting allowing in principle, a single treatment of viral vector delivered shRNA genes.

41.3 RNAi AND HIV THERAPEUTICS

HIV was the first infectious agent targeted by RNAi perhaps because the life cycle and pattern of gene expression of HIV is well understood. Synthetic siRNAs and expressed shRNAs have been used to target virtually all of the HIV-encoded RNAs in cell lines, including *tat*, *rev*, *gag*, *pol*, *nef*, *vif*, *env*, *vpr*, and the LTR [30–34]. Subsequent work showed a host of other viruses, including HBV, HCV, poliovirus, RSV, and others were targetable by RNAi (recently reviewed in Ref. [35]).

Despite the early successes of RNAi-mediated inhibition of HIV-encoded RNAs in cell lines, targeting the virus directly represents a substantial challenge for clinical applications because the high viral mutation rate will lead to mutants that can escape being targeted [36–39] although a clever recent strategy takes advantage of escape mutants in critical genes by targeting the mutants directly [40]. An alternative approach to avoid this problem is to target cellular transcripts that encode functions required for HIV-1 entry and replication. To this end, cellular cofactors such as NF kappa beta, the HIV receptor CD4, and the coreceptors CCR5 and CXCR4 have all been downregulated with the result of blocking viral replication or entry [32,33,41–43]. The macrophage-tropic CCR5 coreceptor holds particular promise as a target. This receptor is not essential for normal immune function and individuals homozygous for a 32 bp deletion in this gene are resistant to HIV infection whereas individuals who are heterozygous for this deletion have delayed progression to AIDS [44–46]. CXCR4 is essential for hematopoietic stem cell homing to marrow and subsequent T cell differentiation [47–49]; targeting this receptor is therefore not a good choice for anti-HIV

therapy nor is targeting the essential CD4 receptor. A possible exception is in dendritic cells where the DC-SIGN receptor can be targeted by siRNAs to prevent infection [50]. Targeting only the CCR5 coreceptor may also present problems since HIV-1 switches to CXCR4 tropism during the course of AIDS, sometimes creating a more virulent infection [51]. Thus, there are drawbacks in solely targeting cellular HIV cofactors and viral targets will need to be included in any successful strategy using RNAi. It should be pointed out that it may be someday be possible to use RNAi to prevent viral transmission by employing siRNAs as a microbicides [52].

Viral targets should be sequences that are highly conserved throughout the various clades to ensure efficacy against all viral strains and to minimize emergence of viral mutants resistant to RNAi. Multiplexing si/shRNAs by simultaneously targeting several sites in the virus is an option that should be fully explored and carefully examined for efficacy, inhibition of viral mutants, and potential toxicity. Since the shRNA pathway impinges on the endogenous miRNA pathway, there is ample opportunity for off-target effects and competition with miRNAs for loading into RISC [53,54]. An additional

potential concern is the putative inhibition of RNAi via HIV Tat and TAR. HIV-1 Tat has been demonstrated to bind and inhibit Dicer [55]. It should be pointed out that most investigators do not see inhibition of RNAi when targeting HIV though. TAR also binds TRBP, which is a Dicer cofactor and is a component of RISC [56]. Moreover, unlike other components of RISC, TRBP is made in limited amounts in the cell and hence binding to the TAR RNA could sequester TRBP from interacting with RISC and perhaps limit the effectiveness of an RNAi-based therapy. Binding of TRBP by TAR may also be a factor in the observed changes in miRNA profiles in HIV-infected cells [57].

An alternative approach to relying solely upon RNAi as an anti-HIV approach is mixing a single shRNA with other antiviral genes to provide a potent combinatorial approach (Figure 41.1). This has been successfully accomplished by coexpressing an anti *tat/rev* shRNA, a nucleolar localizing TAR decoy and an anti-CCR5 ribozyme in a single vector backbone [58]. A somewhat different combination used an shRNA with a dominant-negative Rev M10 protein in a coexpression system [59]. Perhaps other, more potent combinations

FIGURE 41.1 Expression and function of anti-HIV RNAs. The RNAs are expressed from Pol II or III promoters from viral vectors. Expressed hairpins are exported to the nucleus via the Exportin 5-Ran GTP carrier. In the cytoplasm, the RNaseIII enzyme Dicer processes the hairpins into siRNAs. One of the strands is chosen as the guide and enters the RISC where it serves to guide RISC for cleavage and functional destruction of targeted RNAs. The ribozymes are either exported to the cytoplasm via mRNA export pathways or are retained in the nucleus, as the RNase P guide sequence. The ribozymes either cleave the target autonomously or use RNase P to assist in the cleavage mechanism. The aptamers or decoys bind and sequester proteins that they are designed to interact with. This can take place either in the nucleus or cytoplasm.

of shRNAs with mixtures of non-shRNA antivirals will be developed in the near future for testing in preclinical settings.

41.3.1 T-CELLS, STEM CELLS, AND VIRAL VECTORS

Delivery of siRNAs or shRNAs to HIV-1 infected cells is also a challenging problem. The target cells are primarily T-lymphocytes, monocytes, dendritic cells, and macrophages. Since synthetic siRNAs will not persist for long periods in cells, they would have to be delivered repetitively for years to effectively treat the infection. Systemic delivery of siRNAs to T-lymphocytes is probably not feasible. Therefore, a potential method is to isolate T-cells from patients, followed by transduction, expansion of the transduced cells, and reinfusion. In an ongoing clinical trial, T-lymphocytes from HIV-infected individuals are transduced *ex vivo* with a lentiviral vector encoding an anti-HIV antisense RNA [60,61]. The transduced cells are subsequently expanded and reinfused into patients. This type of therapeutic approach could also be applicable to vectors harboring genes that encode siRNAs. A different approach is to transduce isolated hematopoietic progenitor or stem cells with vectors harboring the therapeutic genes. This approach has the advantage that following maturation and differentiation of these cells, all the hematopoietic lineages capable of being infected by the virus are transduced and protected. Hematopoietic stem cells are mobilized from the patients and transduced *ex vivo* prior to reinfusion. Two clinical trials where retroviral vectors expressing ribozymes were transduced into mobilized, autologous hematopoietic stem cells have demonstrated the feasibility of this approach [62,63]. Since RNAi is more potent than ribozyme or antisense approaches, movement of this technology to a human clinical trial for HIV treatment is expected to take place in the near future.

RNAi for the treatment of HIV-1 infection was first demonstrated in 2002. In just four years, there have been over 100 publications testing various siRNAs and shRNAs against different strains of the virus. Viral vector-mediated delivery to hematopoietic cells, including stem cells, is a feasible approach for shRNA gene delivery. Clearly, the barriers that initially confronted therapeutic applications of RNAi for HIV infection are rapidly being broken down, and one can expect to see this powerful cellular process applied clinically to HIV-1-infected patients within the year.

41.4 MULTITARGETING RNAi APPROACHES TO INHIBIT HIV REPLICATION

HIV-inhibitory RNAi therapeutics continues to be investigated because effective siRNAs mediate very potent target knockdown; both the limitations and strengths of using this approach are becoming clearer. Although RNAi can inhibit HIV-1 replication effectively in the initial stages of infection, a single base change in nearly any position within the target sequence may be sufficient to create siRNA/shRNA-resistant viruses after only a few days in culture, even in highly conserved

target sequences [36,38,39]. In addition, mutations outside the RNAi target sequence can allow viral escape to occur by evolving alternative RNA secondary structures [37]. Simultaneous targeting of both wild-type virus and RNAi-escape mutant variants by two or more shRNAs was ineffective in one study, presumably due to competition between shRNAs directed against the wild-type and major escape variant targets [66].

However, using multiple shRNAs to target separate conserved sites in HIV, akin to the HAART approach, is more promising, as it prevents crossresistance between different RNAi-effectors or between RNAi-effectors and conventional pharmaceuticals. Multiple RNAi-effectors would thus have the advantage of limiting escape and targeting a range of sequences as is found in different viral genotypes or quasispecies [64,65]. Viruses, which escape the antiviral effects of RNAi, can be reinhibited by targeting different sequences [66] and thus a multiple inhibitory approach should aim to target distinct genomic regions of HIV-1 or, alternatively, target host-derived factors, which contribute to viral replication.

A variety of approaches are being explored to express multiple siRNAs [67]. The target sequence of a typical siRNA is 21 nucleotides. Long hairpin RNAs (lhRNAs) greater than 50bp in length can be expressed in cells and create multiple siRNAs via Dicer-mediated processing [68–70]. Expressed lhRNAs have been shown to be effective in cell culture against targets for HCV [71] and HIV [72–74] and *in vivo* for targets against HBV [69]. However, processing and knockdown efficacy of these substrates is asymmetric, being greatest at the base of the hairpin and tapering-off across the full length of the duplex [69]. A 50bp U6 lhRNA against a conserved HIV-1 *int* region suppressed HIV replication in a variant resistant to a shorter shRNA in the same target [72]. A replication-competent *nef*-deleted HIV-1 variant with a 300bp lhRNA targeted to *nef* showed significant inhibition of HIV-1 *in trans*, although intriguingly through a non-RNAi-mediated mechanism [73].

Another approach is the use of polycistronic shRNAs, where several hairpins are expressed as a single transcript. Unlike the lhRNAs, which typically target adjacent sequences, different short hairpins (usually 19 to 29-nt in length) in the primary transcript can be directed against widely separated targets. The individual units can be either simple hairpins or modeled on miRNAs, and potentially processed individually for better control of their individual activity.

Finally, multiple shRNAs may be expressed from individual promoters, typically the U6 and H1 polymerase III promoters. Recent studies show that it is possible to saturate the RNAi pathway by overexpressing shRNAs [53,54], resulting in cellular toxicity, particularly with the U6 promoter [53]. We recently described the use of tRNA^{Lys3}-shRNA chimeric cassettes that mediate graded shRNA knockdown, which may be valuable in multiplexing strategies [90], particularly if the principles can be extended to other tRNA isoforms. Use of lower multiplicities of infection when introducing multiplexed shRNAs in lentiviral backbones can

alleviate toxicity; in one study, three separate shRNAs targeted to regions within *pol* and *gag* were capable of inhibiting HIV-1 with the addition of each shRNA-expressing cassette providing an additive inhibitory effect [75].

41.5 IMMUNOSTIMULATION BY RNAi

One general concern regarding the use of RNA-based gene therapy approaches remains the potential to induce unwanted immunostimulation. The intracellular presence of duplexed RNA often elicits components of the innate immune system and specifically the cytoplasmic receptors dsRNA-dependent protein kinase (PKR) and retinoic-acid-inducible gene-1 (RIG-I), leading to a type 1 interferon (IFN) response (reviewed in Ref. [76]). Over 300 IFN-stimulated genes (ISGs) are activated by increased circulating levels of cytokines IFN- α and β [77]. In particular, the activation of 2'-5'-oligoadenylate synthetases (2-5-OAS) leads to apoptosis via the nonspecific degradation of cellular mRNAs by activated RNase L (reviewed in Refs. [76,78]). Exogenously introduced RNAs (ssRNAs and dsRNAs) are also capable of interacting with different endosomal Toll-like receptors (TLRs), leading to a signaling cascade, which elicits the IFN pathway. However, we have recently shown that endogenously (nuclear) expressed shRNAs evade detection by TLRs, RIG-I, and PKR when integrated in CD34 + progenitor hematopoietic stem cells [79]. The expression of lhRNAs (>30 bp) also appears to be well-tolerated and does not induce ISGs, whether transiently expressed in cells [68,70,74] or *in vivo* when injected in mice by hydrodynamic tail-vein injection [69]. These results suggest that expressed dsRNAs may mimic nuclear-derived natural RNAi precursors and augurs well for future gene therapy clinical trials.

41.6 LENTIVIRAL VECTOR TRIPLE HIV THERAPEUTIC MOVES TOWARD THE CLINIC

We have previously described a triple combination lentiviral construct comprised of a U6-driven TAR-RNA decoy appended upon a U16 snoRNA for nucleolar localization, a U6-promoted shRNA targeted to both *tat* and *rev* open reading frames, and a VA1 promoted, chimeric anti-CCR5 *trans*-cleaving hammerhead ribozyme [80]. The triple construct efficiently transduced human progenitor CD34 + cells and demonstrated improved suppression of HIV-1 over 42 days when compared to a single anti-*tat/rev* shRNA or double combinations of shRNA/ribozyme or decoy [80]. These three expression cassettes utilize a broad spectrum of the alternatives available in RNA therapeutics, demonstrating the potential power of this approach.

41.7 EXPANDING THE REPERTOIRE OF HIV TARGETS

Viral proteins and cellular partners involved in the early events in the emergence of HIV from latency to active replication have been a focus of drug development, since the problems

associated with both emergence of viral resistance and perturbation of cellular metabolism as well as viral knockdown vastly increase after the onset of active HIV replication. The Tat-TAR interaction has received special attention due to its central role in the HIV transcriptional transactivation, but cellular cofactors such as NF- κ B are also targets of drug development [81]. Not surprisingly, drugs against cellular cofactors have high toxicity, but are still being pursued as options in the event of failure of traditional chemotherapy. Other recently identified cofactors in activation of HIV transcription include the Werner's syndrome helicase [82] and p90 ribosomal S6 kinase 2 (RSK2) [83].

There has also been a great deal of interest regarding the TAR-RNA-binding protein (TRBP) and its effects on HIV replication. Initially identified as an activator of HIV transcription, its subsequent recognition as a partner of the RNAi enzyme Dicer [84] led to the suggestion that TAR subverts the RNAi pathway during HIV infection by sequestering TRBP [85]. However, HIV infection does not cause general downregulation of endogenous miRNAs; in fact, some are upregulated [86]. The effects of siRNA knockdown of TRBP indicate that the activation activities of TRBP predominate in HIV infection at several points during replication [87], consistent with observations that low endogenous expression of TRBP is directly linked to low HIV replication as in astrocytes [88,89].

41.8 PROSPECTS

The successful use of RNA mediators of anti-HIV activity in human hematopoietic cells has now been validated by many different investigators. With the development of genetically modified viral vectors that are capable of transducing hematopoietic cells with therapeutic RNA-encoding constructs, there will be more proof-of-concept studies in animal models within the next couple of years. Ongoing clinical trials using anti-HIV ribozymes and antisense RNAs have demonstrated the safety of hematopoietic-based gene therapies. The next step is to prove efficacy of these RNA-based inhibitors. Once efficacious use of antiviral RNAs in a gene therapy setting has been demonstrated, this will open the door for expanded clinical applications.

While a cure for AIDS does not appear to be immanent, the success of HAART therapy presents the very real possibility of maintaining HIV as a chronic condition. While many hurdles need to be overcome, the hope is that gene therapy will provide an added option when pharmacological drugs fail and perhaps an adjuvant to current therapies that promote longer and better quality of life.

42.1 INTRODUCTION

Greater understanding about the skin's molecular biology and about the genetics of many skin and systemic disorders has led to significant progress in corrective gene therapy through cutaneous gene transfer. This progress has only been possible due to advances in the areas of vector design and efficiency of delivery, immune modulation, regulation of targeted gene replacement, correction and expression, and the development of appropriate animal models. The skin has a unique and complex structure and it presents remarkable advantages as a tissue for developing

innovative gene therapy strategies. The skin is a readily accessible organ, which facilitates gene delivery, subsequent monitoring of transgene expression, and excision of small or large areas if required [1]. Epidermal keratinocytes and dermal fibroblasts can be readily expanded in culture. In addition, keratinocytes have high proliferative potential and inherent biological characteristics that allow them to synthesize mature proteins from a vast array of transgenes [2]. This rapid progress has made the skin a reasonable target to develop and test a variety of gene therapy approaches to both cutaneous and systemic diseases.

42.2 SKIN

42.2.1 STRUCTURE, FUNCTION, AND DEVELOPMENT

The skin is the most superficial and the largest organ in the body. Its functions are essential for the homeostatic balance of the organism. The skin provides protection against UV light, mechanical, thermal, and chemical insults, and also prevents excessive dehydration due to its relative water impermeability [3]. It also acts as a physical barrier against microorganisms and is involved in the coordination of multiple immune responses [4,5]. The skin is the major organ involved in sensory perception. For instance, it possesses tactile, pressure, pain, and temperature receptors [6,7]. In humans and in many other mammals, the skin is essential in thermoregulatory responses [5,8,9]. For example, heat conservation is aided by the presence of hair and adipose tissue in the hypodermis, and heat loss is increased by the evaporation of water through the skin's surface and by increasing the blood flux through the rich capillary plexus of the dermis [8]. The skin also plays a definite role in the body's metabolism as an important store of energy in the form of triglycerides and in the synthesis of vitamin D [5]. The skin presents regional variations with regard to thickness, coloration, and presence of adnexa. For

instance, the skin is thicker, presents lower levels of coloration, and has no hair follicles in the palms and soles. However, the basic structure of the skin is maintained in all body areas. The external part of the skin, the epidermis, is formed by a stratified squamous epithelium, which is composed of keratinocytes in majority. Other cell types such as melanocytes, Langerhans cells, and Merkel cells are also found in this layer (Figure 42.1). The epidermis is divided into two major compartments: the basal (proliferative) and suprabasal (differentiation) compartments. The suprabasal compartment is further divided into different layers based upon microscopic characteristics: the spinous layer, the granular layer, and the cornified layer (Figure 42.1). The basal keratinocytes are attached to the basement membrane (BM) through specialized multi-protein junctional complexes called hemidesmosomes [10].

Early in development, the epidermis develops from the surface ectoderm, which is one cell layer thick and expresses keratin 18 (K18) up until its commitment to stratification [11]. The surface ectoderm shortly becomes a two-layer structure composed of an outer layer that differentiates into the periderm, which is a temporary structure, and an inner layer (basal layer), which gives rise to all the cells of the epidermis [11,12]. Once

FIGURE 42.1 Schematic representation of the epidermis. The epidermis is a stratified epithelium consisting of basal, spinous, granular, and stratum corneum layers. The basal layer contains the stem cells and adheres to the BM via hemidesmosomes. K5, K14, and integrins are expressed by basal cells and their expression is downregulated as the cells detach from the BM and move upward to the suprabasal compartment where K1 and K10 become highly expressed. As the differentiating keratinocytes move toward the epidermal surface, the expression of other markers, such as filaggrin and loricrin, is detected. Other cell types such as melanocytes, Langerhans cells, and Merkel cells are also found in this layer.

the cells of the surface ectoderm commit to stratification, keratin 5 (K5) and keratin 14 (K14) are induced and K18 is downregulated starting at embryonic day (E) 9.5 [13]. The periderm is thought to provide protection to the developing embryo against amniotic fluid pending the formation of the epidermal barrier [14]. At E13.5, an intermediate layer starts developing between the basal layer and the periderm [15,16]. Further epidermal development takes place as the periderm is lost and the basal layer divides to produce an outer population of cells that will form the spinous layer, which in turn differentiates to form the granular and cornified layers [17]. The spinous cells are first seen at E15.5 and express keratin 1 (K1) and keratin 10 (K10) [17]. Between E16.5 and 17.5, loricrin and filaggrin begin to be expressed concomitant with the formation of the granular layer and stratum corneum [17]. The periderm is entirely lost and epidermal stratification is complete on E18.5 [18].

The expression of keratins, integrins, and involucrin is also regulated during keratinocyte differentiation in the mature epidermis. K5, K14, and integrins are expressed by basal cells and their expression is downregulated as the cells detach from the BM and move upward to the suprabasal compartment where K1 and K10 become highly expressed [13,19,20]. Subsequently, as keratinocytes migrate toward the epidermal surface, the expression of other markers, such as filaggrin and loricrin, is detected [17,19,21,22] (Figure 42.1). Most of the cellular organelles are degraded in the stratum granulosum. Terminally differentiated cells then undergo programmed cell death and these dead keratinocytes form the stratum corneum.

The dermis, a thick layer of fibroelastic dense connective tissue, which supports and nourishes the epidermis, is composed of numerous blood and lymphatic vessels, sensory elements, and different cell types such as fibroblasts, macrophages, and lymphocytes. The hypodermis (subcutaneous layer or

subcutis) is localized under the dermis and contains adipose tissue and blood vessels. The adnexal structures such as sweat glands, sebaceous glands, and hair follicles are structures of ectodermal origin that form by invagination of the epidermal epithelium into the dermis, and sometimes the hypodermis.

42.2.2 EPIDERMAL STEM CELLS: SKIN RENEWAL, REGENERATION, AND REPAIR

The epidermis, a tissue in constant turnover, is sustained by permanent mitotic divisions in the basal compartment where stem cells reside [23]. The cells in the basal layer undergo a series of maturational changes, and at some point, a given number move upward to the postmitotic suprabasal compartment where they undergo terminal differentiation. The basal layer is composed of a heterogeneous population of cells that can be classified according to their capacity for sustained growth into three subpopulations: (a) the holoclones or stem cells, which have the greatest reproductive capacity, (b) the paraclones or differentiated cells with a short replicative lifespan and limited growth capacity, and (c) the intermediate meroclones, which are the transitional stage between the holoclones and the paraclones [24].

Numerous studies provide strong evidence for the existence of stem cells in the upper outer root sheath (the hair follicle bulge region; bulge stem cells) in the basal layer of the interfollicular epidermis (interfollicular stem cells), and, potentially, a third stem cell population in the sebaceous gland (Figure 42.2). These stem cell populations are heterogeneous. Under normal homeostatic conditions, the bulge and interfollicular stem cells represent two distinct populations, but when the epidermis is damaged, it can be completely regenerated by bulge stem cells [25,26]. In addition, interfollicular stem cells

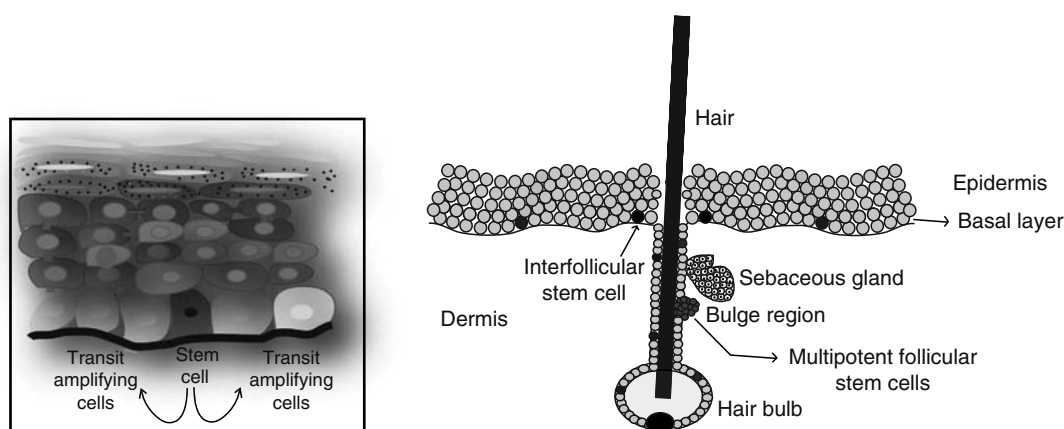

FIGURE 42.2 Schematic representation of the skin. The skin is composed of epidermis, dermis, and adnexal structures (sebaceous glands and hair follicles). The dermis supports and nourishes the epidermis and is composed of blood and lymphatic vessels, sensory elements, and different cell types such as fibroblasts, macrophages, and lymphocytes. The adnexal structures such as sweat glands, sebaceous glands, and hair follicles are structures of ectodermal origin that form by invagination of the epidermal epithelium into the dermis. The epidermal stem cells are found in the bulge region of the hair follicles, in the basal layer of the interfollicular epidermis, and a potentially (under debate) in the sebaceous glands. The interfollicular stem cells give rise to transient amplifying cells, which in turn generate the cells that undergo terminal differentiation and form the suprabasal layers (inset).

can be induced to form hair follicles and sebaceous glands when in contact with dermal papilla cells [27,28]. The presence of an intrinsic stem cell population in the sebaceous gland is still under much debate; it is possible that the sebaceous gland is maintained by bulge stem cells.

42.3 CUTANEOUS GENE TRANSFER

42.3.1 STRATEGIES

Multiple *ex vivo* and *in vivo* approaches are currently used with various degrees of success for gene delivery to the skin. In the *ex vivo* approach, the skin cells from the host are isolated and harvested after removal by biopsy. The cells are then grown *in vitro* where therapeutic gene transfer is performed. Finally, the altered cells are grafted back into the host (Figure 42.3A). This method offers some advantages because primary keratinocytes, including human, are receptive to gene modification, readily expanded in tissue culture under

selective conditions, and easily grafted back into host [29–33]. However, the *ex vivo* approach is disadvantageous because of its labor intensity and potential scarring.

The *in vivo* approach consists of gene transfer through direct administration of genes by different modalities such as topical application, direct intradermal injection, particle-mediated gene transfer or liposome technology (Figure 42.3B). The genetic material maybe delivered in the form of naked DNA or packaged in vectors of viral or nonviral origins. This approach is favored over the *ex vivo* approach as the need for cell culture and surgery are bypassed making it technically, clinically, and economically advantageous [29]. In spite of these advantages, the direct *in vivo* approach is still limited by the low levels of transduction frequency for stem cells, leading to transient expression of the transferred gene.

One of the main strategies for genetic therapy is to achieve the overexpression of the correct protein after delivery and incorporation of the wild-type gene. However, most dominant disorders cannot be treated by simply overexpressing the correct

FIGURE 42.3 *Ex vivo* and *in vivo* approaches for cutaneous gene transfer. (A) In the *ex vivo* approach, the host skin cells are isolated and harvested after being removed by biopsy. The cells are grown *in vitro* where they can be genetically altered, selected, and expanded before being grafted back into the host. (B) In the *in vivo* approach, genetic transfer is accomplished by administration of genetic material to the cells in situ. This could be done by different modalities, such as naked DNA or in vectors of nonviral or viral origins. There is no need for cell culture and surgery; therefore, it is technically, clinically, and economically advantageous.

protein; thus, it is imperative to correct the mutant allele or to decrease or completely silence its expression. New gene therapy strategies have recently emerged in such cases. For example, RNA–DNA oligonucleotides have been used for targeted single-base gene correction through homologous recombination and mismatch DNA repair in skin cells [34–37]. Antisense DNA oligonucleotides (AS-ODNs), which are short-length synthetic DNA molecules that hybridize with specific mRNA sequences and silence gene expression, have been successfully used in cutaneous gene transfer studies [38–41]. Ribozymes, RNA molecules possessing a self-catalytic enzymatic function [42], have been used to cleave mutant target RNA and to repair mutant RNA through splicing [43–45]. Furthermore, ribozymes have been used to downregulate gene expression in the skin [46]. Small interfering RNAs (siRNAs) are short double-stranded RNA molecules capable of binding and inducing the degradation of specific mRNAs [47–49]. The first studies demonstrating the effective application of siRNA technology in the skin to suppress gene expression have been published [50,51]. However, the potential use of siRNAs in clinical applications for cutaneous gene therapy remains to be fully explored. In addition, the spliceosome, the site where introns are removed to produce mature RNA species through a process known as splicing, has been postulated as a target in efforts to achieve gene correction in the skin [52]. Splicing may take place by using alternative splicing sites when standard splice sites are mutated. In these cases, RNA–DNA oligonucleotides or ribozymes might be used to correct these mutations or AS-ODNs may be employed to induce suppression of alternative splice site usage. Recently, a related cellular mechanism known as trans-splicing whereby an intron of a pre-RNA interacts with an intron of another pre-RNA, enhancing the recombination of splice sites between two conventional pre-RNAs, has been exploited for gene correction [53–55]. This strategy is referred as spliceosome-mediated RNA transplicing (SMaRT) and it has been used in keratinocytes derived from generalized atrophic benign epidermolysis bullosa (GABEB) patients to correct the type XVII collagen (COL17A1) gene [56].

42.3.2 GENE TRANSFER SYSTEMS

The first step in effective gene therapy is to transfer the corrective genetic material to target tissue with high efficiency. The skin can be specifically targeted by either *in vivo* or *ex vivo* strategies. A variety of systems with successful application in skin gene transfer have been developed and they can be classified into two large categories: viral and nonviral.

42.3.2.1 Viral Gene Transfer Vectors

Currently, viruses provide the most efficient means for delivering genes to target cells. Replication-defective viral vectors are created by removal of viral genes. The gene of interest is inserted and the viral proteins required for cell entry and gene delivery are provided either by packaging cells lines or by other vectors. There are six main factors to consider in a viral system for efficient gene transfer: ability for high titer generation, cargo-carrying capacity, capacity to transduce dividing or nondividing cells, integration properties, vector antigenicity, the ease with which clinical-grade vectors can be prepared free of replication-competent virus, and the length of time of gene expression required [57]. Some disadvantages should also be considered when working with viral vectors. Since the expression of the delivered genes depends heavily on the integration site, it is important to understand that all the integrative viral vectors have the limitation of their lack of true site-specific integration. Furthermore, downregulation of the introduced genes by epigenetic mechanisms represents another significant obstacle. To overcome these obstacles, several strategies have been developed including the use of insulator elements and the bacterial tetracycline regulatory system [58–60]. Several classes of virus have been employed for gene delivery to skin cells and the choice of vector depends on the specific application (Table 42.1). Viral vectors are efficient for gene transfer in cell culture as part of the *ex vivo* approach and they have also yielded positive outcomes when administered topically or by direct injection during the *in vivo* approach [33,57,61–71].

TABLE 42.1

Viral Vectors Used in Cutaneous Gene Transfer

Vector	Advantages	Disadvantages
Retroviruses	Transduce almost all dividing mammalian cells; high transduction efficiency; long-term expression of transgene	Random integration into host genome; insertional mutagenesis known to cause target cell transformation; inability to transduce nondividing cells; only genes <6 Kb can be packaged
Lentiviruses	Transduce dividing and nondividing cells; high transduction efficiency; long-term expression of transgene	Random integration into host genome; virus is pathogenic; large-scale production is relatively costly and time-consuming; safety concerns in generating replication-competent viruses
Adenoviruses	Low risk of serious side effects; high cargo capacity; high titer easily obtained; no insertion into host genome; transduce dividing and nondividing cells	Highly antigenic; elicit cellular and humoral immune responses; most people already exposed to virus; transient expression of transgene; does not integrate into host genome; host range depends on serotype
Adenoassociated viruses	High safety profile; not associated with any known pathology in humans; transduce almost all mammalian cell types; transduce dividing and non-dividing cells	Low cargo capacity; transduction efficiency usually low; insert into host genome; induce antibody response; host range depends on serotype; difficult to produce in large quantities

42.3.2.1.1 Retroviruses

These are the most widely used viruses for gene delivery. They are capable of delivering genes to nearly any dividing mammalian cell type and integrate their genomes onto host cell chromosomes [72]. With the introduction of pantropic envelope proteins, “pseudotyped” retroviruses have been used to stably deliver genes to a much broader host range, including insect cells and nonmammalian eukaryotes [73]. Retroviral vectors can accommodate up to 6 Kb of foreign DNA and high-titer virus production is easily obtained [57]. Their transduction capacity is restricted to nonproliferating cells, therefore, their use in skin gene therapy has been limited to *ex vivo* approaches [29,57,65–67]. In addition, insertional mutagenesis has been reported to cause target cell transformation in humans [74–76]. Nonetheless, a recent landmark study has demonstrated the effective use of a retroviral vector for the gene therapy of junctional epidermolysis bullosa (JEB) in a patient [33]. The investigators isolated epidermal stem cells from a patient and transduced them with a retroviral vector carrying the LAMB3 cDNA encoding the laminin $\beta 3$ subunit of laminin 5, a component of the BM. The corrected stem cells were expanded into epidermal grafts, which were transplanted into the patient, leading to functional correction of the phenotype *in vivo*. Of importance, the authors report no evidence of selection of specific integration events or clonal expansion.

42.3.2.1.2 Lentiviruses

One of the most important advances in retroviral vector applications is the use of lentiviruses. Lentiviruses have the unique capacity to infect nondividing as well as dividing cells [77]. This is of particular importance for gene therapy approaches in which target cells are nondividing or slow-dividing such as epidermal basal cells (including stem cells) or nervous tissue cells [67,70,71,78]. In fact, *in vivo* approaches have been successful in these tissues where stable, long-term production of proteins has been observed for genes delivered by lentiviral vectors [67,70,71,78,79]. Of significance, a lentiviral vector was employed to restore expression of the type VII collagen protein in keratinocytes and fibroblasts from dystrophic epidermolysis bullosa (DEB) patients using an *ex vivo* approach [80] and in a human DEB composite skin equivalent grafted onto immunodeficient mice by an *in vivo* approach [81]. These experiments provide proof-of-concept that gene correction in the skin is feasible using lentiviral vectors.

42.3.2.1.3 Adenoviruses

These vectors have been widely used for skin gene transfer. Most of these vectors have been rendered replication-deficient by deletion of their E1A and E1B essential genes [82,83]. The development of “gutless” adenoviral vectors, in which more viral genes are stripped, has increased their cargo capacity and minimized the toxicity of viral products to target cells [84]. Adenovirus vectors can carry up to 35 kb of foreign DNA and the viral particles can be produced at high titers. They can infect a wide variety of cell types and both replicating and nonreplicating cells. In addition, safety

precedents already exist because adenovirus-based vaccines have been used in patients without any major side effect [85]. Adenoviral transgene expression has been detected in all cell types of both dermis and epidermis when injected subcutaneously [29,57,61,63,64]. However, adenoviruses are highly antigenic and because they do not integrate into the host genome, only transient expression of the delivered gene is achieved most of the time. Therefore, adenoviral vectors are not ideal for sustained expression in a regenerating tissue such as the epidermis, making their use to correct inherited skin diseases limited. Nonetheless, it has been reported that recombinant adenovirus vectors carrying the xeroderma pigmentosum (XP) A (XPA) and XPC genes achieved long-term expression and long-term restoration of biological activity (up to 2 months) in XPA and XPC immortalized and primary fibroblast cell lines [86]. Adenoviral vectors have been successfully used in applications such as DNA vaccination [87], anticancer therapy [88], and promotion of wound healing [89–91].

42.3.2.1.4 Adeno-Associated Viruses

Adeno-associated viruses (AAVs) are nonpathogenic viruses that were once considered poor vectors due to their limiting packaging size (about 4.0kb). However, the requirement for a helper virus (adenovirus or herpesvirus) for productive infection makes them one of the safest viral vectors [92]. Currently, recombinant AAVs have a high safety profile because 96% of the AAV genome has been removed. AAVs can transduce a great variety of human cell types, both *in vitro* and *in vivo* [93]. AAVs can exist in both integrated and nonintegrated forms and are able to transduce replicating and nonreplicating cells [57,94]. AAVs do not induce a cytotoxic T cell response and long-term expression of the transgene is possible, but they are able to induce an antibody response and the transfection efficiencies are usually low [95]. In addition, they are difficult to produce in large quantities. Nonetheless, cutaneous gene transfer with long-term expression using these vectors has been reported [68,69].

42.3.2.2 Nonviral Gene Transfer Vectors

Although viral vectors are quite efficient for gene delivery, safety concerns have led to the development of other means for genetic transfer, the nonviral vectors. The use of nonviral vectors avoids some of the problems that occur with viral vectors, such as endogenous virus recombination, potential oncogenicity, and induction of an immune response [96]. However, low gene transfer rates and only transient expression are typically achieved in most of the cases. Nonviral reagents can be used to increase the stability and the efficient delivery and uptake of genetic material into skin cells. Overall, nonviral vector techniques for gene transfer can be classified into two groups: delivery by a chemical/biochemical vector and delivery of genetic material by physical methods [96,97].

42.3.2.2.1 Chemical or Biochemical Nonviral Vectors

The advantages of chemical or biochemical nonviral vectors include their lack of immunogenicity, absence of a theoretical

Nonviral Vectors Used in Cutaneous Gene Transfer

Vector	Advantages	Disadvantages
Cationic polymers/proteins and cationic lipids	Lack of immunogenicity; no theoretical size limit for cargo capacity; can be used with naked DNA, RNA–DNA oligonucleotides, ribozymes or other genetic materials; low cost	Gene transfer less efficient than viral vectors; short-lived therapeutic gene expression; long-term selection usually needed
“Naked” DNA	Low immunogenicity; low biosafety risk	Low efficiency of gene transfer; short-term transgene expression
Φ 31 bacteriophage integrase and engineered transposases	Precise integration of large DNA molecules into host genome; low biosafety risk; more efficient for stable gene transfer than plasmid-based systems; no theoretical size limit for cargo capacity	Further development needed for clinical applications

size limit for the therapeutic gene, use of one transfer agent for any desired gene, and the consequently ease of production, applicability, and low cost (Table 42.2). The two main nonviral vectors include cationic polymers or proteins (such as dendrimers, polylysine, DEAE-dextran, protamine, or polyethyleneimine) and liposomes [96–100]. These vectors are versatile and have been successfully applied in cutaneous gene transfer. Polymer and liposome formulations have been shown to be efficient vehicles for transdermal delivery of genes following topical application [101,102]. In the epidermis, ribozyme technology has been recently shown to be effective in downregulating gene expression using either an ethylene glycol-based vehicle or a liposome vector delivery system [46]. In a recent study, cationized gelatin microspheres were used to deliver a plasmid expressing an siRNA directed against vascular endothelial growth factor (VEGF) to squamous cell carcinoma (SCC) tumors *in vivo* [50]. The authors showed that this strategy is effective in decreasing vascularity and tumor growth. In another study, efficient lipid-mediated transfection of malignant melanoma (MM) cells *in vitro* of the microphthalmia-associated transcription factor (MITF)-specific siRNA was reported [51]. MITF is essential in the survival of MM cells and its downregulation by the MITF-specific siRNA induced apoptosis of these cells.

In addition, other means of gene delivery for cutaneous gene transfer have been developed in recent years. An engineered transposase, named Sleeping Beauty, originally isolated from fish binds to the inverted repeats of salmonoid transposons in a substrate-specific manner and mediates the precise cut-and-paste transposition in fish, as well as in mouse and human cells [103]. This is an active transposon system that can be used for the introduction of a therapeutic gene or construct. In fact, it has been used to drive the integration of the LAMB3 cDNA into holoclones from JEB patients [104]. These cells regenerated human skin with corrected levels of laminin 5 protein expression, hemidesmosome formation, and blistering. Additionally, the Φ C31 bacteriophage integrase, which is a site-specific recombinase that stably integrates large DNA molecules containing an attB phage attachment-site sequence into genomic “pseudo-attP sites” [105], has been recently used in studies targeting epidermal progenitor cells [106]. By implementing a Φ 31 integrase-based gene transfer

system, Ortiz-Urda et al. were able to stably transfer the type VII collagen alpha-1 (COL7A1) cDNA into the genome of primary epidermal progenitor cells of recessive dystrophic epidermolysis bullosa (RDEB) patients and to achieve phenotypic correction in skin regenerated using these cells. Clearly, these two systems are advantageous because they lack the biosafety risks of viral vectors, they are more efficient than the stable transfer achieved with plasmid-based systems, and they allow for the stable integration of large DNA sequences into chromosomal DNA.

42.3.2.2.2 Physical Methods

In recent years, many physical techniques for *in vivo* cutaneous gene transfer have been developed (Table 42.3). Cutaneous gene transfer by topical application has been reported [46,101,102, 107,108]. This strategy has many advantages particularly for the treatment of large surface areas, but its efficiency is low and transgene expression is usually temporary. Direct intradermal injection of naked DNA has been shown to be an efficient mechanism for gene delivery to the skin. Using this technique, gene expression has been detected in both epidermal and dermal cells [2,67,109–112]. The advantages of this method are its simplicity and safety, but it is relatively inefficient and the coverage area tends to be small [2,96]. Therefore, additional physical methods in combination with other approaches have been tested in order to improve the efficiency of *in vivo* gene transfer. For example, topical application of antisense oligonucleotides and of DNA complexed with liposomes is effective in targeting the epidermal cells [113–115]. The use of epidermal enzymes, depilatory creams, or the stripping of the skin with tape to induce structural disruption of the stratum corneum can potentially increase the uptake of liposomal particles or oligonucleotides [29]. Electroporation, which is the use of electrical pulse fields to increase cell permeabilization [116], has been determined to increase gene uptake and transgene expression following injection of naked DNA in numerous tissues including the skin [71,117–122]. Puncture-mediated gene transfer, a method in which a device with a constantly high-frequency oscillating bundle of fine metal needles, leads to DNA transfer, and subsequent detection of reporter genes in skin cells [123]. Particle-mediated gene transfer or “gene gun” is also an effective method

TABLE 42.3
Physical Methods for Cutaneous Gene Transfer

Technique	Advantages	Disadvantages
Topical application	Practical; simple application of multiple treatments; advantageous for treatment of large surface areas	Low efficiency of gene transfer; transgene expression usually short-term
Direct intradermal injection	Simple; targets epidermal and dermal cells; safe	Low efficiency of gene transfer; small coverage area per application
Particle-mediated gene transfer (gene gun)	Targets both nonadherent cells and tissues; simple; practical; allows high expression of transferred genes	Short-term transgene expression; low transfection efficiency; deposits foreign material (gold microparticles) in tissue
Electroporation	Circumvents the use of viral vectors; high expression of transgene; long-term transgene expression may be achieved; area of gene transfer clearly delineated; protocols are easily optimized; recent technological developments have occurred	High risk of voltage-induced cellular injury; can induce tissue ischemia; may induce calcium-mediated protease activation leading to tissue damage; efficiency of transgene transfer needs to be optimized; limited effective range between electrodes
Puncture-mediated gene transfer (microseeding)	Does not deposit other foreign material on tissue; simple; practical; no labor-intensive preparation of genetic material required	Requires further optimization to be useful in clinical trials
Ultrasound	Noninvasive, can penetrate soft tissue; practical; large coverage area	Low transgene delivery efficiency; current value for cutaneous gene transfer is minimal
Hydrodynamic injection	Simple; reproducible; good for highly perfused tissues	Low transgene delivery efficiency; current value for cutaneous gene transfer is minimal

to deliver genetic material to skin cells, producing high transgene expression. In this method, small DNA-coated particles are accelerated into tissues and are capable of penetrating the cell by virtue of their small size; once inside the cell, the DNA dissociates and its expression ensues [96,124,125]. The major limitation of the gene gun technique is the degree of penetration into tissues, but it has been demonstrated that epidermal and dermal penetration is sufficient to induce high levels of transgene expression in the targeted areas [126–129]. In addition, other techniques such as ultrasound and hydrodynamic injection are being developed, but their current value for gene transfer to the skin is minimal [96,130,131].

42.4 CUTANEOUS GENE THERAPY

Many skin diseases are characterized by single gene mutations, either dominant or recessive and therefore can be corrected by destruction of the mutant gene product or by introduction of a wild-type gene product. In addition, taking advantage of the potent antigen-presenting dendritic cells in the epidermis (Langerhans cells) and dermis, the skin can be used as a route of immunization against tumor-associated or infection-associated antigens. Furthermore, the skin can be used as a delivery system to produce and secrete a variety of polypeptides, such as enzymes, growth factors, and cytokines, into the systemic circulation in order to aid in wound healing or to treat certain systemic diseases.

42.4.1 CUTANEOUS GENE THERAPY FOR INHERITED SKIN DISEASES

42.4.1.1 Characterization of Diseased Genes

The genetic basis of a number of inherited skin diseases has been elucidated in recent years. These include genetic lesions

leading to skin blistering, abnormal cutaneous cornification, and predisposition for cancer. In the epidermis, mutations in the genes expressed in the basal keratinocytes usually lead to skin fragility and blistering. Examples include K5 and K14 mutations in epidermolysis bullosa (EB) simplex (EBS) [132,133], mutation in genes encoding the BM-component laminin 5 (LAM5) in a subset of JEB [134,135], and mutations in the COL7A1 gene in DEB [136,137].

Mutations in genes expressed in the suprabasal keratinocytes lead to abnormal epidermal terminal differentiation and are often manifested as keratinization disorders known as ichthyoses, characterized by thickened and scaly skin [19]. Examples include transglutaminase 1 (TGM1) mutations in lamellar ichthyosis (LI) [138] and K1 and K10 mutations in epidermolytic hyperkeratosis (EHK) [139–141]. Genetic defects in genes expressed in the skin have also been linked to cancer predisposition, as in the cases of patched (PTC) mutations in basal cell nevus syndrome [142,143] and mutations in XP genes in XP [144].

42.4.1.2 Need to Correct Stem Cells and Other Considerations for Gene Therapy of Dominant and Recessive Inherited Skin Diseases

The structure of the epidermis is maintained by division of cells in the proliferative basal layer, which replaces cells in the outer layer that are sloughed into the environment. Only the stem cells persist for the lifetime of the epidermis [145]. Thus, in a renewing tissue, such as the epidermis, any permanent gene therapy approach must target the stem cell population.

Understanding of the molecular basis of disease pathogenesis provides the cornerstone in designing rational gene therapy strategies. Previous attempts to develop gene therapy for inherited skin disorders have focused mostly on recessive disorders. In

recessive disorders, where mutations in both alleles are required to elicit the mutant phenotype, the introduction of one normal allele into epidermal stem cells would mimic the heterozygous “carrier state,” and result in a corrected phenotype. Therefore, correction of recessive phenotypes, in principle, requires the correct expression of the wild-type gene product where it was previously absent or defective. Significant progress has been made in gene therapy for recessively inherited skin diseases in model systems. Furthermore, a recent study reports successful gene therapy on a patient with JEB [33]. Although these studies demonstrate the feasibility of genetically correcting these disorders, one concern is whether the corrected keratinocytes will be rejected when returned to patients. Since the missing protein was never synthesized by the patient, it may elicit an immune response. This potential problem is not a concern when considering dominantly inherited skin disorders because patients express normal protein from the wild-type allele. However, correction of dominant-negative phenotypes presents more of a challenge. In general, correction or suppression of the mutant gene or disruption of the dominant-negative gene product has to be achieved before the normal functions of the wild-type gene product can be restored.

42.4.1.3 Establishment of Disease Models

Besides facilitating the elucidation of the pathogenesis of a particular skin disease, an appropriate model has to be established to test possible gene therapy strategies before they are applied to patients. Therefore, it is desirable to utilize a pre-clinical animal model to determine the efficacy and safety of these approaches. Such a model can be either a human tissue/animal chimeric model or an entirely animal model.

For recessive diseases, the pathologic phenotypes develop only when both alleles are mutated or deleted from the genome. Although mutant cells retaining disease characteristics from patients can be used to test therapeutic approaches *in vitro* or grafted onto an animal [146], such material is often limited. The development of mouse embryonic stem (ES) cell techniques and the use of homologous recombination made it possible to obtain virtually unlimited material if a mouse model could be generated for a specific disease. The ES cell techniques and homologous recombination allow manipulation of the mouse genome in a finely controlled manner, where mutations can be made in a particular gene to observe the consequence of its alteration during development and differentiation. Mouse models for several recessive skin diseases have been made by making a null mutation in epidermal genes, such as TGM1 gene in LI [147] and type VII collagen (COL7A1) gene in RDEB [148]. These mouse models not only provided much information on the mechanisms of disease, but also became invaluable model systems to test gene therapy approaches for these diseases.

For dominant diseases caused by haploinsufficiency, as in the case of striate palmoplantar keratoderma [149,150], introduction of a second wild-type allele for desmoplakin (DSP) may eliminate the disease phenotype, as in the case for recessive diseases. For diseases caused by a dominant-negative mutation, traditional transgenic mouse models were very

informative in helping us understand the disease mechanisms. In this approach, a mutated transgene is introduced into the mouse genome and when it is expressed at a high enough level to compete with gene products from both wild-type alleles, a phenotype is observed. Mouse models were made in this manner for EBS [151] and EHK [152]. However, such mouse models cannot be used to test gene therapy approaches. First, because both wild-type alleles are present, the mutant gene product has to compete with wild-type product from both alleles. Second, the transgene is integrated into the genome randomly; therefore its expression level and consequently the severity of the phenotype are affected by the surrounding sequences. Thus the ratio of wild-type to mutant gene product, a crucial factor in judging the success of the therapy, remains variable in these models. Therefore, there is a need for more refined animal models with inducible and reversible transgene expression that can be controlled both spatially and temporally. In our laboratory, we took advantage of the mouse ES cell techniques and homologous recombination and generated mouse models for dominant skin diseases with these characteristics. “Hot spot” mutations in the 1A region of the rod domain in K14 and K10 have been linked to EBS and EHK, respectively [153,154]. Using a knock-in/replacement strategy, we replaced a wild-type K14 or K10 allele with a mutant allele containing a “hot spot” mutation [155,156]. Heterozygous mutant mice developed phenotypes similar to EBS and EHK, respectively, as expected for the dominant mutations. These mouse models mimic the diseases at both the genetic and phenotypic level and are ideal systems to test gene therapy approaches for EBS and EHK.

42.4.1.4 Recent Progress in Gene Therapy for Inherited Skin Disorders

42.4.1.4.1 EB Simplex

EB in general is a group of hereditary mechanobullous disorders with at least 11 distinct forms, seven of which are dominantly inherited. The main clinical feature is the skin fragility and blister formation even after mild mechanical trauma. The presentation of EB can vary from a relatively mild to a severe condition that could be fatal. EB is classified according to the level of blister formation in EB, JED, and DEB. In EBS, the blister formation occurs within the epidermis. In JEB, blister formation is seen at the lamina lucida within the BM zone and in DEB, the blistering is present below the lamina densa at the level of the papillary dermis.

The estimated incidence of EBS is 10 per 1 million births in the United States [157,158] with a considerable perinatal mortality due to electrolyte imbalance, marked protein loss, and sepsis. Blistering occurs within the epidermis and is due to lysis of basal keratinocytes, which show clumps of keratin-intermediate filament proteins upon ultrastructural examination. The majority of EBS cases are due to dominant keratin mutations. EBS was linked to the type I keratin gene cluster on chromosome 17 [132] and the type II keratin gene cluster on chromosome 12 [159]. Mutations have been identified in the basally expressed keratins K5 and K14, and are mostly found in the conserved parts of the rod domain of the protein

[153,154]. The more severe forms of EBS are caused by point mutations located at the beginning and end of the rod domain, whereas milder forms have been associated with mutations in less conserved regions either within or outside the rod domain [154]. EBS is classified according to its clinical presentation [160]. The most severe form of EBS, EB herpetiformis or Dowling-Meara (EBS-DM) presents at birth with generalized blistering [161]. Blisters occur characteristically in groups on the trunk and extremities, including palms and soles and usually heal without scarring. The development of hyperkeratoses often starts later in childhood. Interfamilial phenotypic variations are not uncommon, and have also been described among members of the same family. Approximately 70% of the reported mutations in EBS-DM occur at the same mutational "hot spot," codon 125, which encodes an arginine and is located at the beginning of the rod domain of K14.

On ultrastructural examination, EBS-DM cells have perinuclear aggregates of keratin filaments in the basal cells instead of keratin bundles throughout the cytoplasm in normal basal cells [158,162,163]. Because K14 is only expressed in the basal keratinocytes, the suprabasal cells appear normal and undergo normal terminal differentiation. EBS-Koebner (EBS-K) and EBS Weber-Cockayne (EBS-WC) forms have milder presentations. In EBS-K, the blisters are also generalized but less severe and in EBS-WC, the blisters are present mainly on the hands and feet [164].

Two mouse models were previously developed, including a transgenic model [151] and a K14 null model [165]. Although both models helped us understand the disease mechanisms, and the K14 null model also provided important insight into K15 functions, neither model mimics EBS-DM at the genetic level and therefore cannot be used to test gene therapy approaches for the disease. We recently developed a mouse model for EBS-DM, where a wild-type K14 allele was replaced with a mutant allele in the mouse germline [156]. The presence of a neomycin-resistance cassette in an intron-affected expression from the mutant K14 allele and the heterozygotes had subclinical phenotypes. But homozygous pups developed extensive blisters and died shortly after birth. When the neoselection cassette was removed by Cre-mediated excision, the resulting heterozygous pups developed large blisters, as was expected for this dominant mutation. This is the first mouse model that mimics EBS-DM at both the genetic and phenotypic levels. Unfortunately, the pups died because of severe blistering. To overcome such problems, we recently developed a transgenic mouse model that allows the focal deletion of a genomic sequence via Cre-mediated excision. A transgenic mouse line carries a Cre recombinase fused to a truncated progesterone receptor, driven by a K14 promoter (K14-CrePR1) [166]. These mice were crossed with mice heterozygous for the mutant K14 allele with the neocassette flanked by loxP sites (mtK14neo), and heterozygous mutant mice carrying the transgene were obtained. On topical treatment with an antiprogesterin, the neocassette can be deleted in focal areas by activated Cre. We expected that in such areas, the mutant K14 expression would be comparable with that of the wild-type K14, causing blistering in the skin. We were indeed able to

induce blisters using this system and the mice remained viable [156]. This transgenic mouse model is ideally suited to test gene therapy approaches for EBS-DM. In this mouse model, the mutant K14 allele can be focally activated in epidermal stem cells and following topical administration of an inducer, blisters develop in treated areas. However, after a few weeks, blisters heal and never reappear. Some skin disorders are characterized by a mosaic pattern, with alternating stripes of affected and unaffected skin that follow the lines of Blaschko, a term given to the pattern assumed by different inherited and acquired skin diseases on the human skin and mucosae. These lines likely represent the distribution of a clone of genetically altered cells. These nonrandom patterns are believed to be caused by postzygotic mutations that occur during embryogenesis. Interestingly, a mosaic form of EBS has never been reported. It has been suggested that basal stem cells carrying a postzygotic mutation in K5 or K14 would have a selective disadvantage and be rapidly displaced by wild-type basal stem cells, which can move laterally. Using laser capture microdissection (LCM), we have shown that the induced blisters healed by migration of surrounding nonphenotypic stem cells into the wound bed. We also demonstrated that EBS keratinocytes have a diminished capacity to repopulate graft sites compared to normal keratinocytes and that EBS stem cells have a selective disadvantage over normal stem cells in a graft environment (our unpublished data). Thus, our model predicts that if EBS stem cells could be corrected, they will have a selective growth advantage when introduced into areas prone to blistering. This observation provides an explanation for the lack of mosaic forms of EBS-DM. In addition, it has important implications for gene therapy since it suggests that defective EBS stem cells will be replaced by nondefective stem cells. Another unexpected observation from this mouse model was the discovery that mice expressing the mutant K14 allele at levels approximately 50% of wild-type K14 do not exhibit a skin phenotype. Previously, it had been assumed that gene therapy approaches for dominant disorders like EBS must aim to either correct the mutant allele or completely inhibit its expression. Our model predicts that the EBS phenotype may be eliminated by overexpression of the normal K14 allele or partial suppression of the mutant K14 allele, thus increasing the ratio of wild-type to mutant protein. Technically, it is much easier to design gene therapy strategies that would achieve a partial suppression of a mutant-dominant allele rather than a complete correction or suppression. Therefore, we designed gene therapy strategies aimed to correct the EBS-DM phenotype by altering the ratio of wild-type to mutant K14 by either increasing the expression of wild-type K14 or by decreasing the expression of the mutant allele. We developed lentiviral vectors carrying the wild-type K14 gene and others encoding siRNA constructs that specifically cleave the mutant K14 transcripts. We demonstrated that they effectively transduce keratinocytes with long-term transgene expression in tissue culture and *in vivo*. We have been able to correct the EBS phenotype by showing that corrected EBS keratinocytes form a normal epidermis when grafted onto nude mice (unpublished results).

42.4.1.4.2 Junctional Epidermolysis Bullosa

This disease is a subtype of EB characterized by blister formation at the level of the lamina lucida within the BM zone. There are two major forms of JEB, the Herlitz variant or EB letalis, and GABEB [167]. Both forms are transmitted in an autosomal recessive manner and both have onset at birth and are associated with marked skin fragility and generalized blister formation. While scarring and milia formation are usually absent in both forms of JEB, skin atrophy is a characteristic finding in GABEB patients who also tend to have marked dystrophic or absent nails, palmoplantar hyperkeratosis, and may have significant scarring alopecia of the scalp [167]. A characteristic feature of Herlitz disease is the development of large, non-healing areas of granulation tissue; common sites include the perioral and perinasal areas, trunk, and nape of the neck. In addition, extracutaneous involvement may occur in both forms of JEB. In Herlitz disease, findings may include oral blisters and erosions, dysplastic teeth, marked growth retardation, and severe anemia. In contrast, patients with GABEB have milder mucosal involvement (oral cavity, conjunctiva, and esophagus) and early loss of permanent teeth, but neither growth retardation nor anemia [167]. Unlike DEB, musculoskeletal abnormalities are absent in both forms of JEB. The dissociation of the dermal-epidermal junction occurs beneath the basal cell layer, but above the lamina densa in this disease. On examination by electron microscopy, JEB is caused by dissolution of the lamina lucida. Mutations in a number of genes encoding vital structural proteins, including laminin 5 components $\alpha 3$ (LAMA3), $\beta 3$ (LAMB3), $\gamma 2$ (LAMC2), [134,135], BP180 (type XVII collagen or BPAG2) [168], integrin $\beta 4$ (ITGB4) [169], and plectin (PLEC1) [170] have been identified in JEB.

Several somatic gene therapy approaches have been tested to correct the JEB phenotype. In one study, keratinocytes from a patient with Herlitz JEB with a mutation in laminin 5 $\beta 3$ were transduced with a LAMB3 transgene. The transduced keratinocytes synthesized $\beta 3$ peptide that assembled with endogenous $\alpha 3$ and $\gamma 2$ forming biologically active laminin 5, which was secreted, processed, and deposited into the extracellular matrix. Reexpression of laminin 5 induced cell spreading, nucleation of semidesmosomal-like structures, and enhanced adhesion to culture substrate [171]. Organotypic cultures with the transduced keratinocytes reconstituted epidermis closely adhering to the mesenchyme and presenting mature hemidesmosomes, bridging the cytoplasmic intermediate filaments of the basal cells to the anchoring filaments of the BM [171]. A mouse line with targeted disruption of LAMA3 was created a few years ago [172]. Although the mutation in homozygous pups caused neonatal lethality, cells isolated from these pups were used successfully to test therapeutic approaches *in vitro*. In a study carried out to restore BP180 function in cultured JEB patient keratinocytes and skin grafts through gene transduction [173], the transduced cells had normalization of their adhesion parameter. Of significance, a revertant mosaicism was reported in a patient with GABEB, representing a “natural gene therapy” [174].

The reversion of the affected genotype to carrier (heterozygote in a recessive disease) genotype in about 50% of the keratinocytes was sufficient for the normal functioning of the skin. Recent studies were successful in restoring and sustaining expression of LAMB3 in human JEB skin and led to the correction of the JEB phenotype *in vitro* and *in vivo*, respectively [175,176]. In addition, the engineered transposase Sleeping Beauty has been used to integrate the LAMB3 cDNA into holoclones from JEB patients [104]. The corrected cells regenerated human skin with normalized levels of laminin 5 protein expression, hemidesmosome formation, and blistering. In a recent landmark study [33], the researchers employed epidermal stem cells from the palms of the patient, which had a few unaffected areas, transduced them with a retroviral viral vector expressing LAMB3 cDNA, and used them to prepare genetically corrected cultured epidermal grafts. The grafts were then placed onto surgically prepared regions of the patient's legs. They report that after 8 days, there was complete epidermal regeneration on both legs and a normal adherent epidermis was maintained throughout the 1-year follow-up. The grafted skin did not have blisters, inflammation, or infections and there was absence of an immune response. A risk for reintroducing a therapeutic wild-type protein into patients with a recessive disease is that immunologic responses may be elicited. Extra caution has to be taken to decrease such possibility. However, in this case, the patient was a double heterozygote carrier of a null allele and a single-point mutation in the LAMB3 gene. This is a study of paramount importance because it demonstrates for the first time that gene therapy can cure a disease of solid tissue in patients.

42.4.1.4.3 Dystrophic Epidermolysis Bullosa

DEB is a group of blistering skin disorders with either autosomal-dominant or autosomal-recessive inheritance characterized by tissue separation, which occurs below the dermal-epidermal BM at the level of the anchoring fibrils due to mutations in the COL7A1 gene. A series of successful genetic corrective studies have been performed for DEB. In one study, the expression of type VII collagen was normalized in keratinocytes from recessive DEB patients [177]. Also, the expression of the type VII collagen protein in keratinocytes and fibroblasts from DEB patients using a lentiviral vector was restored in an *ex vivo* approach [80]. The corrected keratinocytes had long-term transgene expression and displayed normal morphology, normal behavior (i.e., motility, attachment and proliferative potential), and were capable of regenerate normal skin *in vivo*. The $\Phi C31$ integrase-based gene transfer system was used by Ortiz-Urda et al. to stably transfer the COL7A1 cDNA into the genome of primary epidermal progenitor cells from four unrelated RDEB patients [106]. Collagen VII was correctly localized at the BM and phenotypic correction was achieved in skin regenerated using these cells. In another study by the same group, intradermal injection of genetically engineered RDEB fibroblasts overexpressing type VII collagen into reconstituted RDEB skin stably restored type VII collagen expression *in vivo* [178]. The type VII collagen protein was properly localized and the RDEB phenotype, including subepidermal blistering and

anchoring fibril defects, was corrected. Also, intradermal injection of a lentiviral vector expressing human COL7A1 cDNA into athymic hairless mice and into a human DEB composite skin equivalent grafted onto immunodeficient mice was performed [81]. The vector transduced dermal cells, which expressed the protein. The collagen VII incorporated into the BM zone at the dermal-epidermal junction and remained stable for at least 3 months after a single intradermal injection. The lentivirus did not target keratinocytes; fibroblasts and endothelial cells were the target cells for the *in vivo* lentiviral vector transduction. Furthermore, the investigators showed that intradermal injection of the COL7A1 lentivector into the RDEB skin equivalents corrects the subepidermal blistering and restores the anchoring fibrils to a similar pattern seen in skin regenerated from normal controls.

42.4.1.4.4 Epidermolytic Hyperkeratosis

This disease is inherited in an autosomal-dominant mode, with an incidence of 1 in 200,000 to 300,000 newborns [158]. Up to 50% of the reported cases arise sporadically. Affected children present at birth with erythroderma, blistering, and peeling. Erythroderma and blistering diminish during the first year of life, and hyperkeratoses develop, predominantly over the flexural areas of the extremities. On histopathological examination, findings consist of hyperkeratosis and parakeratosis, lysis of the suprabasal keratinocytes, and perinuclear vacuolar degeneration. The basal keratinocytes appear normal but exhibit hyperproliferation [161]. The transit time for keratinocytes to move from the basal layer to the stratum corneum is remarkably shortened and takes only 4 days in EHK patients instead of the normal 4 weeks [179]. Mutations to K1 and K10 have been linked to EHK and a mutational “hot spot” at Arg 156 in K10 has been identified in most severe cases of EHK [141,180]. Three mouse models were previously generated, including two transgenic models [152,181] and K10 null model [182]. However, because they do not mimic EHK at the genetic level, none can be used as a model system to test gene therapy for this disease.

In our laboratory, we recently generated a mouse model that mimics EHK at both the genetic and phenotypic levels by replacing a wild-type K10 allele with one that has a point mutation at Arg 156 [155]. We have started strategies aimed at the correction of the EHK phenotype by altering the ratio of wild-type to mutant K10 by increasing expression of wild-type K10. To do this, we have collected epidermal stem cells from heterozygous mutant mice and transduced them with lentiviral vectors to overexpress the wild-type K10 allele. In addition, we are attempting to correct the EHK phenotype by suppressing the expression of the mutant K10 allele by transducing EHK cells with a viral vector expressing an siRNA construct specifically designed to cleave the mutant K10 transcripts. As opposed to EBS, in which a correction of the mutation in the basal keratins translates into a growth advantage, corrected and mutant stem cells in EHK will proliferate at similar rates because the mutant K10 is not expressed in stem cells, but only in the progeny of stem cells after they have differentiated and moved into the suprabasal layers.

There is no selection against epidermal stem cells with K10 mutations and these stem cells continue to give rise to defective differentiated progeny. It has recently been demonstrated that topical selection with colchicine can be used to select, *in vivo*, for human keratinocyte stem cells transduced with the multidrug resistance (MDR) gene [183]. Therefore, to efficiently amplify the corrected cell population, the MDR gene is included as a selection marker in our targeting strategy to ablate defective epidermal stem cells and allow their replacement with corrected stem cells, which then repopulate the epidermis.

42.4.1.4.5 Lamellar Ichthyosis

The autosomal-recessive ichthyoses are a clinically heterogeneous family of diseases characterized by abnormal cornification and comprise LI and congenital ichthyosiform erythroderma [184]. In LI, patients are born encased in a “collodian” membrane that is later shed and followed by development of large, thick scales and varying degrees of erythema. Palmar and plantar hyperkeratoses are often present.

Defects in the gene encoding keratinocyte TGM1 were identified in a number of patients with LI [138,185]. TGM1 is normally expressed in differentiated keratinocytes and catalyzes crosslinking of cornified envelope precursor molecules, such as involucrin, loricrin, and small proline-rich proteins [186,187]. With loss of TGM1 function in the formation of insoluble cornified envelope, the barrier function of the outer epidermis is disrupted [19,188]. Therefore restoration of the TGM1 enzymatic activity represents a possible strategy for correcting the LI disorder. A high-efficiency retroviral vector containing a wild-type TGM1 gene was used to transduce mutant keratinocytes from LI patients [30]. More than 98% of the primary cells expressed wild-type TGM1, as measured by the proportion of keratinocytes positive for the transferred gene compared with the total number of cells determined by propidium iodide counterstaining [30]. TGM1 enzymatic activity was restored to normal levels and was targeted to the membrane fraction. In addition, transduced keratinocytes also demonstrated restored involucrin crosslinking and normal cornification [30]. When these transduced keratinocytes were grafted to immunodeficient mice, the regenerated skin displayed restored TGM1 protein expression *in vivo* and was normalized at the levels of histology, clinical surface appearance, and barrier function [31]. However, TGM1 expression in the human skin graft was lost after 1 month because of silencing of the vector [32].

Besides transplantation of genetically modified cells, another way to deliver genes to the skin is through direct administration to the intact tissue. Choate and Khavari [189] regenerated skin from LI patients on nude mice to examine the corrective impact of direct injection of naked plasmid DNA. Regenerated LI skin received repeated *in vivo* injections with a TGM1 expression plasmid and restoration of TGM1 expression at the correct tissue location in the suprabasal epidermis was observed. However, unlike LI skin regenerated from keratinocytes first transduced *in vitro* with a

retrovirus carrying TGM1 prior to grafting, directly injected LI skin displayed a nonuniform TGM1 expression pattern [189]. In addition, direct injection failed to correct the central histologic and functional abnormalities of LI. These results show that partial restoration of gene expression can be achieved through direct injection of naked DNA into human skin disease area, but underscore the need for new advances to achieve efficient and sustained plasmid-based gene delivery to the skin.

42.4.1.4.6 *X-linked Ichthyosis*

X-linked ichthyosis (XLI) is caused by a deficiency in steroid sulfatase (STS), which leads to the accumulation of cholesterol sulfate and results in abnormal scaling skin [190]. XLI is inherited in a pseudoautosomal mode, escaping X-inactivation in both humans and mice. Transduction using a retroviral vector expressing the STS gene led to restoration of protein expression as well as enzymatic activity [191]. In the same study, it was shown that transduced keratinocytes from XLI patients regenerated epidermis histologically indistinguishable from that formed by keratinocytes from healthy patients after grafting onto immunodeficient mice. In addition, the transduced XLI epidermis presented a return of barrier function parameters to normal.

42.4.1.4.7 *Harlequin Ichthyosis*

Harlequin ichthyosis (HI) is a genetic disorder with a devastating phenotype characterized by ectropion, eclabium, flattened ears, and thick scales in the whole body [184]. This disease is characterized by a high perinatal mortality rate associated with severe dehydration and infections due to the disruption of the skin barrier. Mutations in the adenosine-triphosphate-binding cassette A12 (ABCA12) gene were initially reported to be associated with an LI type 2 [192]. Just recently, two different groups found that mutations causing truncation or deletion of highly conserved regions of ABCA12 result in loss of the skin lipid barrier and cause HI [193,194]. ABCA12 is a lipid transporter present in keratinocytes. Its function is important in lamellar granule formation and lipid transport on the keratinocyte surface [193]. Recovery of lamellar granule-mediated lipid secretion has been demonstrated in cultured HI keratinocytes after corrective gene transfer of the ABCA12 gene [193].

42.4.1.4.8 *Xeroderma Pigmentosum*

XP is a group of autosomal-recessive disorders associated with defects in a number of DNA repair genes and are characterized by inadequacies in DNA repair after ultraviolet injury [144,195]. XP genes, which are involved in a specific mechanism of DNA repair called nucleotide excision repair (NER), fall into seven complementation groups (XPA to XPG) and all have been cloned [196]. XP affects both the basal and supra-basal compartments of the epidermis, including melanocytes. Thus, XP patients have increased susceptibility to epidermal neoplasms, such as basal cell carcinomas (BCC), SCC, and MM [197]. Treatment of this condition consists of avoidance to UV-light exposure, photoprotection, and surveillance and surgical resection of skin tumors when those arise. Since

every cell that is unable to repair the UV-induced DNA damage should be considered a potentially tumoral cell, any treatment to be curative, must target every cell in the epidermis including every stem cell and melanocytes. Although initial promising attempts to correct the genetic defects in this condition were performed [198–201], it became clear that XP represents a challenging condition for cutaneous targeted gene therapy because high-efficiency targeting of melanocytes remains to be developed. However, recent studies outline improved gene transfer efficiency of XP genes to different skin cells and show amelioration or correction of XP phenotypes. In one study, a functional XPC gene was introduced into primary keratinocytes of XPC patients [202]. Reexpression of the normal XPC protein corrected DNA repair capacity, UV-cell survival, and clonal transition capacity. Also, the XPC-corrected cells were able to participate in skin reconstitution *in vitro*. Marchetto et al. [203] used a recombinant adenovirus to deliver the human XPA cDNA to mouse embryo fibroblasts of Xpa-mice, which showed recovery of their defective DNA repair ability after transduction. The authors also demonstrated that subcutaneous injection of the XPA-carrying adenovirus was able to target basal keratinocytes and prevent tumor development after UV radiation in the treated mice. In another study, Marchetto et al. [204] tested the efficiency of lentiviral vectors carrying the XPA, XPC, and XPD genes to transduce XP fibroblasts. These vectors were efficient in transducing the XP fibroblasts *in vitro*. Furthermore, transduced cells showed correction of the XP cellular phenotypes such as normal UV survival and unscheduled DNA synthesis after UV radiation. Results from these recent studies suggest that significant progress in the area of XP gene therapy will be seen in the near future.

42.4.1.4.9 *Other Diseases*

In addition to the dominant-negative mutations in keratins that cause various blistering diseases and hyperkeratoses, several other diseases are inherited in a dominant mode through haploinsufficiency, such as palmoplantar keratoderma that results from DSP mutations [149,150]. Gene therapy strategies could involve introduction of a wild-type allele and host immunologic reactions will not be a concern in these cases.

42.4.2 CUTANEOUS GENE THERAPY FOR MELANOMA AND SCC

The incidence of MM has been on the rise in the last years. SCC is a common malignancy of the epidermal keratinocytes. Due to the advantages that make the skin an amenable tissue for gene transfer, MM and SCC are frequently used as models for tumor-specific gene therapy. Different strategies have been applied for both conditions. In general, gene therapy efforts for MM have centered on genetically modifying host cells by transferring tumor suicide genes, genes that increase tumor rejection responses, or genes whose action interferes with signaling cascades involved in tumor development and growth [205]. The same principles apply to SCC gene therapy efforts. For instance, adenoviral-mediated transfer of the herpes

simplex thymidine kinase “suicide” gene (tk) by direct intratumoral injection, followed by ganciclovir administration, was used to treat human MM established in nude mice [206]. In a different study using the B16 melanoma model, a synergistic effect was observed when combination therapy by adenovirus-mediated transfer of tk and interleukin 2 (IL2) or tk and granulocyte-macrophage colony stimulating factor (GM-CSF) was used [207]. Similar approaches have been employed in studies with SCC models [208,209]. Besides gene transfer mediated by adenoviral vectors, an *in vivo* liposomal-mediated approach with tk and IL-2, and a transgenic model constitutively expressing a costimulatory molecule have been performed for treatment of SCC [29]. In another study, the tk gene was cloned into an amplicon vector that was used effectively for its *in vivo* delivery on human MM xenografts [210]. Recently, a number of molecules have been targeted in gene therapy studies for MM and SCC. For example, VEGF is a key molecule in angiogenesis, which is an important process for tumor growth [211]. In one study, a vector expressing siRNA directed against VEGF was delivered by means of cationized gelatin microspheres to SCC tumors established by a xenograft model in mice [50]. The authors demonstrated that downregulation of VEGF induced a reduction in vascularity and tumor. Other studies demonstrated that administration of siRNA against the S phase kinase-interacting protein 2 (Skp2) gene, which encodes a protein overexpressed in MM and oral SCC, inhibited the cell growth of tumor cells *in vitro* and also suppressed tumor proliferation *in vivo* [212,213]. The Y-box binding (YB-1) protein was found to be upregulated in MM metastases [214]. Stable downregulation of YB-1 using siRNA in metastatic MM cells resulted in a reduced rate of proliferation, increased rate of apoptosis, and reduced the migration and invasion of MM cells. In addition, MM cells with a decreased YB-1 were more sensitive to chemotherapeutic agents [215]. MITF is essential in the survival of MM cells and its gene has been shown to be amplified in 20% of MM [216]. Nakai et al. [51] reported the downregulation of MITF on MM cells using an siRNA with a concomitant induction of apoptosis *in vitro*. Furthermore, the siRNA was delivered by electroporation into MM tumors established in mice by subcutaneous injection of B16 cells. The authors showed that the tumor cells transfected with the MITF-siRNA underwent apoptosis *in vivo* and that this strategy was effective in reducing tumor outgrowth.

42.4.3 CUTANEOUS GENE THERAPY FOR WOUND HEALING

The process of wound healing involves three stages: inflammatory reaction, formation of granulation tissue, and tissue remodeling [217]. All these events are known to be regulated by different cytokines and growth factors. Gene transfer techniques are intended to treat wound healing abnormalities or to enhance the wound healing rate. Genetic therapy for wound healing is eased because the epidermal barrier is defective, transgene expression for a short period is usually sufficient, and in most cases, the treated area is localized [218]. However,

the presence of inflammatory exudates, deposited proteins, and necrotic tissue may prevent the transfer of genetic material [218]. One strategy is to use genetically modified cells (such as keratinocytes or fibroblasts) and graft them to deliver a desired protein (e.g., growth factors) to the wound bed. For example, Eming et al. [219,220] introduced the genes encoding platelet-derived growth factor (PDGF) and insulin-like growth factor (IGF) isoforms into keratinocytes and grafted them on mice. The modified keratinocytes were shown to induce the formation of granulation tissue and to increase the proliferation of the modified cells, respectively. Similar approaches have been undertaken using dermal fibroblasts with successful results [221–225].

Multiple studies have investigated gene therapy for wound healing using *in vivo* approaches. Multiple groups have tested different modalities of gene transfer to skin wounds such as topical application, the gene gun approach, and the use of genetically modified cultured skin substitutes with promising results [126,226]. Tyrone et al. [227] successfully treated ischemic dermal ulcers in rabbits by topical application of PDGF-A or B DNA plasmids embedded within a collagen lattice. They showed a substantial increment in the formation of new granulation tissue, epithelialization, and wound closure after treatment. Subcutaneous injection of a liposomal IGF-1 cDNA construct was shown to effectively promote re-epithelialization of burn wounds by decreasing prolonged local inflammation through modulation of the expression of pro- and anti-inflammatory cytokines [228]. Intradermal injection of an AVV vector expressing human VEGF-A to full-thickness excisional wounds in rats was found to induce new vessel formation and enhance wound healing rate [229]. Similar results were obtained by Romano Di et al. using topical application of an adenovirus vector to deliver VEGF on excisional wounds of streptozotocin-induced diabetic mice [230]. In other studies, liposomal keratinocyte growth factor (KFG) cDNA delivery to acute wounds in rats enhanced wound healing by increasing cell proliferation, re-epithelialization, and neovascularization, by reducing cell apoptosis, and by activating mesenchymal cells through the induction of IGF-1 expression [231,232]. Nitric oxide production at adequate levels is essential for adequate wound healing and is driven by the activity of nitric oxide synthase (NOS). Gene transfer by topical application of an adenovirus carrying the inducible NOS (iNOS) gene was shown to reverse the wound healing defects in iNOS-deficient mice [233]. Gene transfer studies of the human hepatocyte growth factor (HGF) have shown that it promotes re-epithelialization and neovascularization in the early phase of wound healing [234] and that it enhances wound healing and inhibits overscarring [235]. In addition to growth factor genes, gene transfer studies of proinflammatory cytokines [236], a protease inhibitor [237], and a transcription factor [238] have been reported to be effective in wound healing promotion. Furthermore, it has been proposed that signal transduction molecules such as Smads can be used to promote wound healing or to treat wound healing abnormalities [239].

42.4.4 CUTANEOUS IMMUNOMODULATION IN CANCER GENE THERAPY

Gene transfer is an effective approach to induce and enhance immune responses. Injection of naked DNA encoding antigenic epitopes can induce strong specific humoral immune responses [240]. The advantages of immunomodulation by genetic vaccination are evident; for example, it does not require isolation and purification of proteins and it circumvents the use of live or attenuated viral vaccines. The skin is rich in antigen-presenting cells that can initiate and control specific immune responses. In addition, cutaneous transfer of plasmid DNA or mRNA allows the delivery of not only genetic material encoding antigenic epitopes, but also the delivery of immunomodulators [241,242]. DNA vaccination has been used to induce immune responses as an strategy in antitumoral immunotherapy [243,244]. In a clinical trial conducted by Thurner et al., dendritic cells were isolated, propagated *ex vivo*, and pulsed with a Mage-3A1 tumor peptide. Subsequently, the cells were injected subcutaneously and intradermally to advanced MM patients; regression of some metastases was seen in 6 of 11 patients, and expansion of specific cytotoxic T cells was seen in 8 of 11 patients [245]. Sun et al. [243] demonstrated tumor regression and increased survival in mice-bearing subcutaneously implanted tumors after skin gene transfer of the antitumoral cytokines IL-2, IL-6, and interferon gamma (IFNG). Regression of established primary and metastatic murine tumors was documented after cutaneous gene gun delivery of a plasmid carrying the mouse IL-12 [246]. In the same study, the researchers were able to demonstrate that a tumor-specific immunological response had been induced in the treated mice. Recent clinical trials have shown that intralesional injection of an adenovirus carrying the IFNG cDNA is an effective therapy for cutaneous lymphomas [244,247]. In addition, a similar approach with IL-2 is also effective in patients with solid tumors including melanoma [244]. It is known that adenoviral vectors are capable of inducing an innate immune response and an interferon-mediated response as well. For example, Urosevic et al. [248] performed gene profiling of lymphomas before and after intralesional IFNG transfer using an adenoviral vector. They show that the IFN response is induced by the adenoviral vector itself and that it potentiates the response induced by the IFNG transgene. Furthermore, the authors suggest that this potentiation may have significant therapeutic value.

42.4.5 CUTANEOUS GENE THERAPY FOR SYSTEMIC DISEASES: SKIN AS A BIOREACTOR

Epidermal keratinocytes secrete a variety of proteins such as collagen VII, laminin, proteinases, proteinase inhibitors, growth factors, and cytokines [249]. Studies using cultured human keratinocytes, grafted onto athymic mice and rats, demonstrated that keratinocytes secrete proteins that reach the systemic circulation. One of the first studies of the secretory function of keratinocytes was carried out by Taichman

and colleagues [250]. They first monitored secretion of human apolipoprotein E (HuAPOE) in cultured human keratinocytes [250]. The protein was identified as APOE on the basis of molecular weight, isoform pattern, and immunoreactivity. When they grafted human keratinocytes onto athymic mice and rats, human APOE was detected in the systemic circulation of graft-bearing animals as long as the graft remained on the animals [251]. Within 24 h of graft removal, human APOE was not detected in the plasma, indicating that human APOE in the plasma resulted from continuous production of the protein by grafted human keratinocytes. These results showed that proteins as large as APOE (299 amino acids) can transverse the epidermal–dermal barrier and achieve systemic circulation.

Once it was established that keratinocyte-secreted proteins could reach the systemic circulation, genetically modified keratinocytes or fibroblasts were used to test whether they could deliver transgene products into the bloodstream. Subsequent experiments using both *in vivo* and *ex vivo* approaches have been successful in delivering different polypeptides, such as growth hormone (GH), erythropoietin (EPO), factors VIII and IX, leptin, phenylalanine hydroxylase (PAH), IL-10, GM-CSF, and others to the circulation. In our laboratory, we have further enhanced the usefulness of the skin as a bioreactor by developing a bigenic gene-switch system that allows focal induction of transgene expression via topical administration of an inducer [252]. Therefore, due of its capacity to deliver various polypeptides into the systemic circulation, its accessibility and abundant vascularization, added to the refinement of gene transfer systems (e.g., the gene-switch system), the skin is a very attractive tissue for test gene therapy studies for systemic conditions that respond to delivery of polypeptides into the circulation.

42.4.5.1 Progress in Cutaneous Gene Therapy of Specific Systemic Diseases

42.4.5.1.1 Hemophilia A

This is an X-linked inherited disease caused by deficiency of factor VIII and has an incidence of 1 in 5000 male live births [253]. This condition occurs in mild, moderate, and severe forms, reflecting the mutational heterogeneity seen in the factor VIII gene, and symptoms vary from excessive bleeding only after trauma or surgery to frequent episodes of spontaneous or excessive bleeding after minor trauma, particularly into joints and muscles [253,254]. In one study, factor VIII deficient-transgenic mice expressing human factor VIII under the control of the involucrin promoter were generated [255]. Plasma factor VIII activity and correction of the phenotype were seen in this mouse model. In the same study, skin explants from these transgenic mice were grafted into factor VIII double knockouts, which showed plasma factor VIII activity of 4% to 20% normal and had improved whole blood clotting [255]. Recently, a successful clinical trial with hemophilia A patients was performed [256]. Dermal fibroblasts from six patients were grown in culture, transfected with the factor VIII cDNA, and administered by laparoscopic injection

in the omentum. Factor VIII plasma levels were significantly increased in four patients; a reduction in bleeding and the need for supplementation with growth factor VIII was seen.

42.4.5.1.2 *Leptin Deficiency*

Leptin, a 16 kDa protein hormone, is involved in the regulation of body weight in mammals [257,258]. It is secreted primarily by adipocytes and it has been shown to regulate food intake and neuroendocrine function through its action in the hypothalamus (Friedman and Halaas, 1998). In accordance with the phenotype seen in the ob/ob mice [259], it has been determined that congenital leptin deficiency is associated with early-onset obesity in humans [260]. Leptin replacement therapy has provided encouraging results in clinical studies [261]; however, the need for repetitive dosing has prompted an alternative approach using gene therapy to correct this condition. In a recent study, a cutaneous gene therapy approach for leptin deficiency was successful in correcting the mouse ob/ob phenotype [262]. Here, immunodeficient ob/ob mice grafted with skin implants from mice overexpressing leptin reached body weight equivalent to that of wild-type animals. In addition, immunosuppressed ob/ob mice that were transplanted with skin grafts made of human keratinocytes transduced with a leptin cDNA-carrying retroviral vector showed weight reduction concomitant with a decrease in blood glucose and food intake [262].

42.4.5.1.3 *Anemia Due to EPO Deficiency*

EPO is a kidney-produced glycoprotein that regulates red cell production. It binds to its receptor found in erythroid progenitor cells, activating a signaling pathway that leads to the increase of survival of these cells by inhibiting apoptosis, accelerating the release of reticulocytes from the bone marrow [263]. In 1987, recombinant human Epo (rHuEPO) was approved in the United States for the treatment of anemia of end-stage renal disease [263]. In addition, its therapeutic use has been extended to other conditions, such as anemia associated with Zidovudine treatment of patients with AIDS, anemia secondary to chemotherapy in the treatment of cancer, anemia of pregnancy, anemia of prematurity, myelodysplastic syndrome, and bone marrow transplantation [263]. Descamps et al. [264] transduced HeLa keratinocytes with an AAV vector containing the EPO gene and implanted them in nude mice. They observed a long-term increase in hematocrit, which correlated with the size of the induced tumor. This study provided proof-of-principle for the treatment of anemia using this approach. In another study, a lentiviral vector encoding HuEPO was delivered by single intracutaneous injection into human skin grafts on immunodeficient mice [70]. The investigators demonstrated that HuEPO was present in serum and its levels increased in a dose-dependent fashion. In addition, the hematocrit improved within 1 month after lentiviral injection and remained stable for almost 1 year. Siprashvili and Khavari [265] developed a lentiviral vector in which the expression of EPO can be controlled by topical administration of steroid

ligands. Also, in this system, the proviral insert can be excised by applying a topical inducer of a Cre recombinase. The investigators injected the lentivirus into human skin regenerated on immunodeficient mice and were able to control EPO and hematocrit levels over time. A clinical trial was performed in patients with chronic renal failure by *ex vivo* transduction of patient-derived dermal cores with an adenovirus containing the EPO gene [266]. EPO expression and reticulocyte counts were increased for 14 days. The researchers reported an increase in CD8 cytotoxic T cells, which could be the cause of the subsequent decrease in EPO expression. It is possible that this or a similar strategy can have increased efficiency if a different gene transfer technique is used.

42.4.5.1.4 *GH Deficiency*

Original experiments demonstrating the release of exogenous GH by transduced keratinocytes into the circulation were performed by Morgan et al. [267]. Using the recently developed bigenic gene-switch mouse model, we showed that after a single induction, high levels of human GH (huGH) were released from keratinocytes into the circulation [252]. The serum levels of huGH were dependent on the amount of inducer applied and repeated induction resulted in increased weight gain by transgenic versus control mice. Furthermore, physiological levels of huGH were detected in the serum of nude mice after topical induction of small transgenic skin grafts. These results clearly demonstrate the feasibility of using the gene-switch system to regulate the delivery of GH into the circulation for the treatment of GH deficiency. Bellini et al. [268] transduced primary human keratinocytes with the huGH gene and grafted them into immunodeficient dwarf mice (lit/scid). The graft-bearing mice had increased levels of the hormone that was associated with weight increase.

42.4.5.1.5 *Contact Hypersensitivity*

Contact hypersensitivity (CHS) responses are regulated by T cells, which release cytokines and attract other inflammatory cells after reacting with antigen. IL-10 has been known to be a key regulatory cytokine in both inflammatory and immune responses. Studies have demonstrated that IL-10 is involved in the regulation of the hypersensitivity response because recombinant IL-10 (rIL-10) prevented the elicitation of CHS in previously sensitized mice [269]. Meng et al. [270] injected a DNA plasmid containing human IL-10 into the dorsal skin of hairless rats. They detected local expression of mRNA and protein in a dose-dependent manner. They also showed the production and release of IL-10 into the circulation by transduced keratinocytes. Furthermore, they quantified a reduced response to challenge in distant areas from the injection site of previously sensitized animals.

42.4.5.1.6 *Other Conditions*

Additional studies testing the skin as a bioreactor approach and been performed. For example, two forms of APOE, both the endogenous HuAPOE and a recombinant form from a transfected vector, were detected in the serum of athymic

mice-bearing grafts of modified human keratinocytes [250,271]. When human keratinocytes in culture were transduced with a retroviral vector carrying the factor IX gene, they secreted active form of the protein into the medium [272]. When they were grafted onto nude mice, small quantities of factor IX were detected in the bloodstream. In addition, other gene therapy studies for hemophilia B have been performed [273–275]. A recent study achieved the production of insulin from human keratinocytes and tissue-engineered skin substitutes as the initial steps for developing a potential strategy to treat diabetes [276]. Other examples include the genetic transfer of adenosine deaminase (ADA) gene to keratinocytes from ADA-deficient patients [277] and of ornithine-delta aminotransferase (OAT) in keratinocytes from patients with gyrate atrophy [278].

42.5 FUTURE PERSPECTIVES

The general idea in gene therapy is to introduce wild-type gene products or to destroy mutant gene products (including the mutant gene itself). However, the patient-specific nature of some diseases may impose a tremendous challenge that must be addressed on a case-by-case basis. During the last decade, we have seen the development of highly efficient gene transfer systems and the creation of better animal models for human disease. It has become clear that the skin has multiple advantages as a target organ for the development of gene therapy strategies. This is true not only for inherited skin diseases, but for systemic conditions as well. With the recent identification and characterization of the genetic basis and molecular biology of a significant number of diseases, we are today in an exceptional position to design successful gene therapy approaches for them. Clearly, to apply these advances in human clinical trials, more efficient gene transfer methods with increased and prolonged levels of expression, high safety profile, low cost, and ease of administration must be developed. The recent landmark study by Mavilio et al. [33] reports the effective gene therapy treatment of a patient suffering from JEB, demonstrating for the first time that gene therapy can cure a disease of solid tissue in patients. Recent advances in disease model systems, epidermal stem cell techniques, and gene delivery technology highlight the promise of successful gene therapy using cutaneous gene transfer approaches. Even though significant challenges lie ahead, the future in this field is bright.

43.1 GENE THERAPY FOR EARLY ONSET BLINDNESS

43.1.1 BACKGROUND: GENE THERAPY FOR EARLY ONSET BLINDNESS

In recent years, mutations in a large number of different genes have been implicated in the pathophysiology of retinal degenerative diseases [1]. Among these are mutations, which lead to particularly severe early onset blinding diseases. With the recent development of methods for *in vivo* retinal gene delivery (reviewed in Refs. [2–4], it has become possible to evaluate efficacy of gene therapy in animal models for these blinding diseases. We selected a canine model to study the efficacy of gene therapy for a particularly debilitating disease, Leber congenital amaurosis (LCA). LCA is a disease that is usually diagnosed in infancy as it severely handicaps its subjects, leaving them with severely impaired visual function and abnormal ocular movements (nystagmus). This is a disease that affects all ethnic groups and results in blindness in approximately 10,000 individuals in the United States (www.blindness.org). There are at least nine different genes, which, when mutated, can lead to LCA [1,5,6]. One of these, *RPE65*, is named for the evolutionarily conserved retinal pigment epithelium (RPE)-specific 65 kDa protein which it encodes

[7,8] and accounts for approximately 7%–16% of these cases [8–10]. Mutations in *RPE65* can also lead to other severe and early onset blinding diseases including retinitis pigmentosa (RP) and cone-rod dystrophy [1,8,10–13].

43.1.2 CANINE MODEL FOR LCA: A UNIQUE RESOURCE

An advantage of selecting the *RPE65* gene defect for study is the availability of a large animal model for the LCA disease: the *RPE65* mutant dog. This animal, first described by Narfstrom et al. [14], suffers from an autosomal recessive inheritance of a retinal disease with severe visual deficits but a relatively slow degenerative component [15]. The canine *RPE65* gene defect is a homozygous 4 bp deletion [15,16]. The deletion results in a frame shift, leading to a premature stop codon. This eliminates more than two-thirds of the wild-type polypeptide. Histopathology in homozygotes shows prominent RPE inclusions and slightly abnormal rod photoreceptor morphology present within the first year of life [17]. There is also a lack of immunohistochemically detectable *RPE65* protein [15]. As the dogs age, a slowly progressive photoreceptor degeneration becomes apparent and is readily detectable in older (~5-year-old) dogs [17]. The *RPE65* protein was identified as the retinoid isomerase where it assists in vitamin A metabolism in the retina [18].

Without *RPE65* protein, there is a deficiency of 11-*cis* retinal in the retina. This compound is necessary for the generation of rhodopsin in rod photoreceptors. Without this, the cells cannot respond to light and initiate the series of biochemical/electrophysiologic events leading to vision. This accounts for the abnormal qualitative and quantitative measures of visual function that are apparent early in life in *RPE65*-deficient animals and humans.

43.1.3 PROOF-OF-PRINCIPLE OF GENE THERAPY FOR RETINAL DEGENERATION HAS BEEN ESTABLISHED

Efficacy of gene therapy for inherited retinal degeneration may be efficiently demonstrated by studying animal models. Proof-of-principle for such treatments has been demonstrated using multiple strategies, viral vectors, and in a number of animal models of different species [2,3,19–51]. Successful strategies include delivery of wild-type cDNA in the case of loss-of-function disease [22,23,27–34,40,41,52,42–46], delivery of ribozymes, which specifically target the mutant mRNA in the case of gain-of-function disease [36,53,49,50], delivery of neurotrophic factors [24–26,37], and delivery of genes with antiapoptotic function [38,51]. Rescue has been achieved with a number of different vectors, including adenovirus, adeno-associated virus (AAV), lentivirus, and gutted adenovirus. Clinical end points in many of these studies have involved electrophysiological evidence of improvement in retinal function as assessed by electroretinograms (ERGs). In some instances, additional tests of visual function have been utilized. Pupillometry was used in conjunction with ERGs in a murine study [54]. The Morris water maze test has been implemented where mice were placed in a water tank with the goal of locating the escape route [39]. Another visual function test that has been employed is OptoMotry, which measures the optomotor response to a rotating sine-wave grating [40,55]. Finally, visual-evoked potential (VEP) has been utilized to test responses to external stimuli [41]. ERGs, pupillometry, and VEPs have also been used in large-animal studies [27,28,42,45,55]. Studies in dogs have also shown improvements in nystagmus [55,56] and in cortical vision [57]. All of these measures can be recorded in a noninvasive fashion. Interpretation of the results benefits from the use of the contralateral eye as a control. Results from retinal function testing have been supplemented with histological/immunohistochemical data obtained in terminal studies. In some of these paradigms, rescue has been detected for years after treatment [27,46]. One *RPE65* mutant dog that is being followed for life still enjoys vision more than 7 years after treatment (Figure 43.1; Bennett et al., unpublished data).

43.1.4 TREATMENT STRATEGY THAT RESULTED IN RESCUE OF VISION IN THE *RPE65* MUTANT DOG

Restoration of vision in *RPE65* mutant dogs was first accomplished in July 2000 and was reported in 2001 [28]. Since

FIGURE 43.1 Seven years after subretinal delivery of AAV. *RPE65* in the right eye, Lancelot, an *RPE65* mutant dog, still enjoys vision. He is shown signing autographs at a research fundraiser. (October, 2006; K. Maguire, photographer.)

then, at least two other groups have confirmed these results [42,43,45,46]. In all of these studies, the experimental objective was to deliver wild-type copies of the disease-causing gene (*RPE65*) to cell populations primarily affected by the gene mutation (i.e., RPE). Delivery was achieved through subretinal injection of a recombinant AAV carrying the *RPE65* cDNA (Figure 43.2). This exposes cells bordering the subretinal space, RPE cells, photoreceptors, and Muller cells to the experimental reagent. Remarkably, the localized retinal detachment subsides within hours [58]. Additional controls assuring expression predominantly by RPE cells can be achieved through selection of the vector capsid or incorporation of RPE cell-specific promoters [27,42,55]. AAV2 targets RPE cells predominantly through this approach [27,55]. Production of *RPE65* protein by the transduced *RPE65* then restores the biochemical circuit by allowing production of 11-*cis* retinal.

43.2 LCA CLINICAL TRIAL: FROM BENCH TO BEDSIDE

43.2.1 CHALLENGES IN PLANNING A GENE THERAPY CLINICAL TRIAL FOR LCA

Why does it take so long to embark on a human clinical trial?

In July 2000 (and then reported in May 2001), AAV-2-mediated delivery of a wild-type version of the defective *RPE65* gene was used to provide retinal function in a canine model of severe early onset retinal degeneration [28]. Subsequent studies have demonstrated safety and reproducibility of this

FIGURE 43.2 Appearance of the eyes of affected Briard dogs immediately after subretinal injection of 150 μ l AAV2.hRPE65. In all of these eyes, the bleb (which prevents visualization of the speckled pattern of the underlying RPE) at least partially extends through the superior (tapetal) retina. The superior retina reflects light because of the tapetum. The inner retinal blood vessels are lifted up (with the rest of the neural retina) in the region of the bleb. The inferior (nontapetal) retina is the dark area below the optic nerve. (The entire optic nerve head is visible in the panel on the top right.) In panels going from top left to bottom right, the blebs are located as follows: superior, superior, mainly superior, and partially inferior (dumbbell-shaped), and equally superior and inferior. Photos were taken of eyes injected for studies described by Jacobson, S.G. et al., *Mol. Ther.*, 13, 1074, 2006. (Photographs were taken by Dr. A. Maguire.)

result [27,52,59,60]. Three clinical trials have been approved and one is already under way. Dr. Robin Ali of the Moorfields Eye Hospital and University College London began testing human LCA patients with a *RPE65* mutation in the spring of 2007. It is too early to assess the results of the patients that already had the procedure (<http://www.newscientist.com/article/dn11765-first-trial-of-gene-therapy-to-restore-human-sight.html>). Two other clinical trials are imminent for this disease. One will be under the direction of Dr. Samuel G. Jacobson (University of Pennsylvania) and will treat patients at University of Florida, Gainesville (under Dr. Barry J. Byrne) (<http://clinicaltrials.gov/>). The second trial will enroll pediatric subjects and will be carried out at the Children's Hospital of Philadelphia (CHOP) under the direction of Drs. Albert Maguire and Jean Bennett (with Dr. Katherine High, sponsor). Additional clinical trials, including one to be carried out in France, are likely to be initiated over the next few years (<http://www.osnsupersite.com/view.asp?rID=21894>). With the excellent safety and efficacy data, why did it take

nearly 7 years from the time of the initial experiments to get to the point of embarking on a human clinical trial?

There are many steps that must be taken before this treatment could be tested in humans with LCA. One of the challenges inherent in translational research is that the ideal construct (including species of origin of the cDNA, AAV capsid serotype, regulatory sequence, etc.) must be identified early on as all of the subsequent safety and efficacy testing using this vector is very costly and time-consuming. Safety testing must be extremely rigorous, especially since the ultimate goal is to treat a disease that is not lethal. Thus, we and others first evaluated a long list of variables for effects on safety and efficacy before selecting the clinical candidate vector. Special attention had to be paid to the possibility that the transgene could potentially be introduced to the brain via unwanted ganglion cell/optic nerve targeting [61–63]. The duration of the therapeutic effect needed to be characterized since LCA is a lifelong disease.

Vector selection was difficult because there was continued progress in developing viral vectors with slightly improved

transduction qualities. At a certain point, a choice had to be made: Whether to select a particular vector as the candidate for formal toxicity studies (in anticipation of initiating a human clinical trial using this vector) or whether to do additional efficacy tests on newly described vectors. The toxicity studies are rigorous, time-consuming, expensive, and use a large number of animals. It is preferable not to have to repeat them using a second vector or even with slight modifications of the original vector (unless the additional benefits of that vector warrant the effort). Thus, two of the teams planning clinical trials for LCA (University of Florida, Gainesville and CHOP, Philadelphia) use the AAV vector and regulatory element (AAV2 and a chicken β actin promoter) for which the most data was available. The team conducting the clinical trial in the United Kingdom also uses AAV2, but instead of a constitutive promoter, uses an RPE-specific promoter. The team planning a trial in France has chosen AAV4 as its vector [42]. In the United States, clinical-grade vector must be generated using protocols and quality assurance assays that are in compliance with Food and Drug Administration (FDA) guidelines. Similar safety assurances must be met in Europe.

For the trials that were already approved, once the ideal vector was selected, toxicity testing was conducted to verify that the treatment did not cause any impairment to the eye or to the rest of the body. This had to be performed using the same (clinical grade) virus that was to be used in humans. Typically, toxicity studies entail both acute and chronic studies and often are carried out in animals of two different species. Most of the data is collected and evaluated by outside consultants, thereby assuring its integrity. Therefore, it can take a long time to complete the data analyses. Once the data are collected, they are submitted for both institutional (including Institutional Review Board and Institutional Biosafety Committee) and federal regulatory agency approvals. This process is quite lengthy.

43.2.2 HOW CAN POTENTIAL SUBJECTS FOR LCA-RPE65 CLINICAL TRIALS BE IDENTIFIED?

Once an individual with LCA is identified and their disease is clinically characterized, they must be shown to carry disease-causing *RPE65* mutations to be eligible to participate in a gene therapy trial for LCA due to *RPE65* mutations. This is a challenge as LCA is a rare disease. There are at most, an estimated 3000 individuals in the United States with LCA. Genotyping must be carried out by a Clinical Laboratory Improvement Amendments (CLIA) certified laboratory to ensure quality-controlled test results. Such testing is often expensive and tedious and is generally not covered by health insurance. A tremendous aid for this effort was provided by Project 3000 in the United States. This project, implemented by two major sports figures, aims to provide free testing for every man, woman, and child affected by LCA in the United States (<http://carverlab.org/project3000/index.shtml>). The testing will be carried out at the John and Marcia Carver Genetic Testing Laboratory, a CLIA-approved laboratory, under the direction of Dr. Edwin Stone.

43.2.3 WHAT IS THE IDEAL AGE FOR A PARTICIPANT IN A HUMAN GENE THERAPY CLINICAL TRIAL TARGETING LCA-RPE65?

Recent studies have characterized and continue to characterize the progression pattern of the human disease (with respect to visual function measures and death of retinal cells) [64–69]. This will allow the selection of the optimal noninvasive outcome measures for evaluation of the effects of treatment in a human clinical trial. One question which arose was whether the first treatments, which are phase I safety and toxicity tests, should be performed on adult versus pediatric subjects. Two of the three different groups involved in the first set of human clinical trials (Directors Drs. R. Ali and S. Jacobson) argued that safety should be tested first in adult subjects. However, data from animals suggested improved efficacy in younger animals [56,64]. Also, photoreceptor cells in the retinas of animals and humans with *RPE65* mutations deteriorate over time, so that if one waits too long to treat the tissue, there will be few viable cells remaining. Finally, there is a vast amount of data demonstrating plasticity of the brain with respect to visual input in animals and humans that are young and a reduction in this plasticity with age [70]. Subjects with *LCA-RPE65* may have some light input at young ages, however, and so there may be more plasticity with respect to central nervous system (CNS) responses than is seen in other forms of vision deprivation [57]. After considering all of these issues, the team involved in the third clinical trial (Director Dr. A. Maguire) argued that treatment should be tested in pediatric subjects in order to optimize the risk–benefit ratio. Thus, the trial that is scheduled to be initiated at CHOP will enroll subjects aged 8 and older and will then include even younger subjects in follow-up studies (http://www.webconferences.com/nihoba/13_dec_2005.html).

43.2.4 WHAT ARE THE RISKS OF A GENE THERAPY CLINICAL TRIAL FOR LCA-RPE65?

There has been a vast amount of experience with AAV-mediated gene delivery to retinas of animal models of LCA-RPE. To date, the safety profile is excellent. Animals treated with AAV2.*RPE65* have remained healthy, active, and fertile. The most common clinical findings in safety/efficacy studies relate to the surgical delivery of the vector. This delivery leaves a small retinotomy scar, but this scar does not interfere with retinal/macular function. There are histologic changes after delivery to the fovea [60] and so in human studies, care must be taken to minimize toxicity to this region. The only significant inflammatory events reported to date occurred in animals that were injected subretinally with a research-grade virus preparation that was contaminated with foreign protein [27]. Despite the inflammation, animals treated subretinally with this lot of vector recovered vision. There have also been reports of low-level exposure of tear fluid, serum, optic nerve, and rare exposure to other organs

after intraocular injection of AAV-*RPE65*. There have been no reports to date of toxic cell-mediated immune responses after this mode of delivery [52, Bennicelli, in press]. Because low doses will be administered in human clinical trials and because these doses will be delivered to a geographically enclosed compartment (the immune privileged eye), immunologic complications are not expected.

43.3 EXTRAPOLATION OF SUCCESS TO OTHER FORMS OF EARLY ONSET RETINAL DEGENERATION

43.3.1 EXTRAPOLATION OF THE SUCCESS IN THE CANINE LCA GENE THERAPY STUDIES TO OTHER FORMS OF EARLY ONSET RETINAL DEGENERATION

A major challenge is how to extrapolate the success in the *RPE65* mutant dog to successful treatment of other severe retinal degenerative diseases. One approach to meeting this challenge is to identify the conditions that are responsible for the success of the *RPE65* dog study. Besides the virus delivery characteristics, there may be elements of the *RPE65*-caused disease, which make it particularly amenable to treatment. Is the success due to the fact that the *RPE65* mutant retinal photoreceptors degenerate very slowly and thus there is a large therapeutic window during which the retina can be rescued? In some animal models (those with homozygous mutations in the beta subunit of rod cGMP phosphodiesterase, for example), the degeneration is so rapid that rod photoreceptors do not even have a chance to fully differentiate before they are lost [71]. In that disease, it is likely that the treatment will have to be administered very early in life while the target cells are still viable [31,32].

In animal models, which can have a rapidly progressive retinal degeneration, the AAV2 vector may not have a rapid enough onset to make any impact in the disease progression of rapidly progressive degenerative diseases. Thus, for demonstration of proof-of-concept, one might want to employ a viral vector that results in a rapid onset of transgene expression. AAV-2 is slow to reach peak levels of transgene expression *in vivo* [72]. In contrast, cargo packaged within AAV capsids of serotypes other than AAV2 deliver transgenes that are expressed within a few days of injection [47,73] (Bennett, personal communication). It should be noted, however, that the time-of-onset limitation may not be as important with respect to human treatment since the disease process occurs on a slower timescale than in animal models.

In particular diseases, there may be requirements of the disease model that will have to be met by developing alternative vectors/vector strategies. For example, one challenge is how to proceed with AAV if the cDNA or transgene cassette is too large to be packaged. The AAV cargo capacity is a maximum of 4.8 kb. In such a situation, one would have to consider other vectors that could carry the intact transgene cassette. Options include lentivirus, which can carry a cassette

of ~8 kb, and gutted adenovirus, which can carry a cassette of >30 kb. If one wanted to use AAV even though the transgene cassette was too large, one could harness the AAV dual vector approach and split the transgene construct into two complementary vectors, which would be trans-spliced in the target cell [74]. Alternatively, particular novel or engineered AAV capsids may be able to package large DNA cargo [75].

Recently discovered LCA-causing mutations provide viable options for a gene therapy approach. Mutations in *LCA5*, which encodes for the protein lebercilin, have been shown to cause LCA [40]. Additionally, a mutation in *CEP290*, which causes premature protein truncation, has been demonstrated to cause LCA [76]. Finally, mutations in rod-derived cone viability factor (RdCVF), which is a protein expressed by photoreceptors, have been shown to disturb RdCVF's ability to maintain cone cell viability in LCA [77]. It may be possible to extrapolate the success of the *RPE65* mutation studies to any or all of these newly discovered LCA-causing mutations.

Finally, demonstration of safety of AAV vectors in therapy of human LCA will pave the way for treatment of other retinal diseases, including those targeting other cells types besides RPE and those involving gain-of-function disease such as autosomal dominant RP and macular degeneration. Once safety of the vector is demonstrated, these vectors can be used to test a host of other treatment targets/strategies. The latter include use of RNA interference as a treatment for gain-of-function disease and delivery of neurotrophic factors, which could enhance or prolong the function of the diseased target cells.

43.4 CONCLUSIONS

In summary, we and others have shown that efficacy of gene therapy for inherited retinal degeneration may be efficiently demonstrated studying animal models for the most clinically severe retinal degenerations, i.e., those that result in early onset blindness. AAV-2 was used to deliver corrective genes subretinally to a canine model of a severe retinal disease and efficacy of treatment was readily apparent. Success in this study led to identification of critical parameters for the success of gene therapy for retinal degeneration and also to human clinical trials designed to treat LCA. Safety and efficacy data derived from these clinical trials could pave the way for treatments of additional forms of LCA as well as other inherited and acquired forms of retinal degeneration.

ACKNOWLEDGMENTS

Since the article was submitted, initial results from two of the three clinical trials have been reported [78,79]. This study was supported by Children's Hospital of Philadelphia NIH grants EY10820, The Foundation Fighting Blindness; Research to Prevent Blindness; the Macular Vision Research Foundation, the Mackall Foundation Trust, and the F. M. Kirby Foundation.

44.1 IMPORTANCE OF VACCINES

44.1.1 HISTORICAL IMPORTANCE OF VACCINES

Vaccination is the deliberate introduction of foreign materials into humans or animals to elicit immune responses against the material that protect against disease [1]. The use of vaccines dates back to ancient times. In the seventh century, some

Indian Buddhists drank snake venom to protect themselves from snake bites [1]. During the ninth century in China, a manuscript entitled *The Correct Treatment of Small Pox* was written by a Buddhist nun. The manuscript recommended a mixture of ground dried smallpox scabs and herb to be blown into the nostrils of children. In March 1718, upon learning of the Turkish practice of inoculating healthy children with a

weakened strain of smallpox to confer immunity from the more virulent strains of the disease, Lady Mary Wortley Montague immediately had her son inoculated. Four years later, after returning home to England, she introduced this custom to the British nobility by having her daughter inoculated to demonstrate the practice. However, this procedure was risky as 1–2 of 100 inoculations resulted in death by smallpox. Worse, however, was that this practice could start an event of smallpox by infectious spread to uninoculated individuals. Even with such a long history, immunization was not widely used until Edward Jenner described deliberately injecting cowpox virus, vaccinia, into humans to protect them from the ravages of smallpox. He had observed that milkmaids were routinely infected with vaccinia from milking cows and these women were immune to smallpox, an immunologically cross-reactive viral infection. His procedure of vaccination was based on four principles of the immune response: (i) memory, those who received vaccinia were protected from smallpox for life; (ii) specificity, they were not protected from other infectious diseases such as polio; (iii) inducibility, the protected state needed to be created by immunization; and (iv) self versus nonself, somehow the smallpox was targeted and not the person themselves. Fifty years later, Pasteur went on to build on these results by directly attenuating a pathogen and demonstrating its vaccine potential. Over the next 150 years, the development of vaccines against pathogenic microorganisms has become one of the most important advances in the history of medicine. Vaccines have not only provided protection from smallpox, but also from poliomyelitis, measles, mumps, rubella, yellow fever, pertussis (whooping cough), hepatitis A, hepatitis B, rotavirus, varicella, and now human papilloma virus (HPV) as well as others. These vaccines dramatically reduced morbidity from infectious agents and combined with antibiotics have directly protected more human lives than all other avenues of modern medicine combined. Yet, as increased standards for effectiveness and safety and the increased costs of developing and manufacturing vaccines have become more restrictive, the development of new vaccines has slowed. Furthermore, as new pathogens continue to emerge, it is important that novel methods for vaccine development be developed to meet the demanding requirements of the twenty-first century.

44.1.2 VACCINE IMMUNOLOGY

Traditional vaccines have relied on either live-replicating or nonliving preparations of microorganisms as their antigen preparation. The injected material functions as a vaccine by generating immunity against the inoculum and the resulting immune responses function to prevent disease by preventing or slowing pathogen infection so that the immune system can effectively destroy the pathogen. This type of induced immunity is referred to as protective immunity and results from the vaccine-activating specific B and T lymphocytes, which compose the lymphocyte subsets of the white blood cells of the immune system [2].

As the major components of humoral immune response, B cells are lymphocytes that develop in the fetal liver and

subsequently mature in the bone marrow. Mature B cells carry surface immunoglobulins that act as their antigen-specific receptors. They move from the bone marrow through the circulation to secondary lymphoid tissues, the lymph nodes and spleen, where they respond to antigenic stimuli by dividing and differentiating into plasma cells under direction of cytokines produced by T cells. When they are activated, B lymphocytes become terminally differentiated to become plasma cells, which are entirely devoted to the production of secreted antibody. Antibodies are large water-soluble serum proteins, which are induced following contact with antigen. Antibodies bind to specific antigens (pieces of pathogens), which drive B cell expansion and antibody production. The induced antibodies can either directly neutralize or inactivate the pathogens or the antibodies can also direct other cells of the immune system such as macrophages and phagocytes to dispose of the antigen or infected cells. Furthermore, they can direct complement, highly toxic soluble immune mediators to bind to and destroy an invading pathogen.

T cells are lymphocytes that develop in the thymus. T cells acquire their antigen receptors in the thymus and differentiate into a number of subpopulations, which have separate functions and which can be recognized by their different cell surface markers. T lymphocytes develop as one of two subsets of white blood cells termed T helper cells or T cytotoxic or T killer cells. These cells are the basis of cell-mediated immune responses and function to eradicate pathogens in different ways. T helper cells, as their name implies, help and direct B cells to produce antibody, which targets and destroys extracellular pathogens, preventing their entry into host cells. T helper cells also cooperate with cytotoxic T lymphocytes (CTL) to expand them, aiding the destruction of virally infected cells. Activated T helper cells secrete small protein messengers termed cytokines, which activate and expand either or both humoral and cellular immune responses. New experimental data also indicates that CD4⁺ T-cell help is absolutely required for the generation of CD8⁺ T cells capable of efficient recall responses to antigen [3]. On the other hand, activated T cytotoxic cells seek out and destroy cells that have been infected with pathogens. These T killer cells bind and destroy allogeneic and virally infected cells, which display recognizable antigen-major histocompatibility complex (MHC) class I molecules. T killer cells induce these pathogen-infected cells to die either through the release of toxic proteins such as granzyme B or through initiating apoptosis or programmed cell death in the target cells. CD8⁺ cells can also mobilize the immune response at the point of antigen contact through the release of beta chemokines. In addition to defense against pathogens, CTL are particularly important in eradicating aberrant or pathologic host cells such as cancer cells. Humoral or cellular immunity can act independently or in concert to destroy the pathogenic organism within a vaccinated host. The T-cell response is initiated by unique antigen-presenting cells (APCs), the most efficient of these is the dendritic cell. Immature dendritic cells eat foreign invading organisms or their free antigens, and they process and present these to T cells in the context of the host MHC. The dendritic

cell signals the T cell to expand and fight the invading pathogens through specific molecules that are presented along with the MHC pathogen peptide complex to the T cell termed costimulatory molecules. This stimulation is absolutely required for the induction of effective long-lived immunity. Therefore all vaccines must deliver antigen in some form to the APC, in particular the dendritic cell, for the induction of T-cell immunity and they must usually deliver spatially relevant antigens to B cells to induce a protective antibody-mediated vaccine response.

44.1.3 TRADITIONAL VACCINES

In the case of live vaccines, the infectious material has been weakened or attenuated so that it no longer induces disease in the general population. In the case of the nonlive preparations, the vaccine material has been manufactured to contain killed organisms or pieces of killed organisms that cannot grow when inoculated into a host. In some instances, specific components can be purified away from other portions of the microorganism or artificially manufactured in the laboratory to function as a subunit vaccine. Both categories of vaccines are presently utilized throughout the world to protect individuals against specific pathogens. Each vaccine has its own general characteristics for generating immunity and exhibits properties that can be beneficial or deleterious to an individual.

Live attenuated vaccines, such as the polio and smallpox vaccines, stimulate protective immunity as they replicate in the body of an immunized host. These vaccines emulate the natural infection of pathogens and generate a broad spectrum of immune responses. Because they are a weakened form of the pathogen, no disease occurs. This category of vaccine induces broad protective immunity with induction of both antibodies and activated T cells. More specifically, because CTLs are only induced if an infectious agent or vaccine actually is produced within host cells, live attenuated vaccines are the most effective inducer of CTL. Attenuated vaccines have an additional benefit in that they frequently provide lifelong immunity. In contrast, nonliving inactivated vaccines (including subunit preparations), such as the vaccine for hepatitis B virus, produce protective immunity that is limited to the generation of antibodies and helper T cells but they cannot induce killer T cells. Accordingly, the ability of these preparations to induce protection is limited to pathogens that can be destroyed by extracellular defenses. Unlike the live-attenuated vaccines, the protective immunity induced by inactivated vaccines is normally short-term and requires repeated booster injections to promote lifetime immunity. Based on these immunological characteristics, live attenuated vaccines immunologically represent the vaccines of choice. Still, they are not without problems. For instance, there are safety concerns related to the use of live attenuated vaccines. The potential exists for the attenuated vaccine to mutate back to the original disease-causing organism through a process called reversion. Attenuated vaccines may also cause disease when inoculated into persons with weak or compromised immune systems, such as cancer

patients receiving chemotherapy, acquired immunodeficiency disease (AIDS) patients, or in the elderly where the immune system deteriorates with age. Furthermore, live vaccines can infect individuals other than the inoculated individual and thus inadvertently expose a disease to a susceptible unknowing individual.

Even though inactivated vaccines are safer in theory than their live attenuated counterparts, certain problems also exist with some inactivated vaccines. For instance, the whole organism used as the inactivated vaccine can be contaminated with components from cell culture that are not removed during the manufacturing process. This contaminated material may be a catalyst for an autoimmune disease. Additional shortcomings with inactivated vaccines include contamination by components of the pathogen that are not important in the generation of protective immunity. These components may generate immune responses that are not relevant to protective immunity. Deleterious reactions, such as inflammation and allergic reactions, may also result from vaccination with the inactivated whole organism. These concerns regarding contaminants and the safety issues related to whole organism vaccines point to the use of purified subunit component vaccines.

In subunit vaccines, only the components of the microorganism involved in conferring protective immunity are included in the final formulation, while other portions of the microorganism are removed in an extensive purification process. This increases the cost of manufacturing the vaccine. Subunit component vaccines have an increased specificity that can target induction of the immune response in a very effective manner; again these vaccines elicit protective immunity by the generation of antibodies and limited T helper responses. However, if antibodies alone are insufficient to provide protective immunity against a particular pathogen, it becomes necessary to also involve the activated T lymphocyte component of the immune response and subunit preparations are not very efficient in this regard. As a need for vaccines against new pathogens emerges, safe vaccines that elicit both antibodies and activated T cells will have an advantage, particularly when the requirements for protective immunity in the host are not yet unknown. It would be a distinct advantage for vaccine development to have a technology that could induce the broad immunity normally associated with a live attenuated vaccine while exhibiting the safety and the focus of the subunit preparations. In addition, any simplification in manufacturing and increase in vaccine product stability are likely to positively impact on vaccine production for the developing world. These advantages are the promise of DNA vaccines.

44.2 DNA VACCINES

44.2.1 CONCEPTS OF DNA VACCINES

Pioneering work from a small number of laboratories, including that of the authors, has demonstrated that the injection of a DNA plasmid containing foreign genes encoding proteins of a pathogen or cancer antigens directly into a host can give rise to specific immunity. This injection results in the subsequent

FIGURE 44.1 Induction of antigen-specific humoral and cellular immune responses following DNA immunization.

expression of the foreign genes in a host and the presentation of the specific encoded proteins to the immune system (Figure 44.1) [4]. DNA vaccine constructs can be produced as small circular vehicles or plasmids. These plasmids are constructed with a promoter site, which starts the transcription process, an antigenic DNA sequence, and a messenger RNA stop site containing the poly A tract necessary for conversion of the messenger RNA sequence into the antigen protein by the ribosomal protein manufacturing machinery (Figure 44.2). The concept of genetic immunization provides that both DNA and RNA that encode specific proteins can be used to generate specific immune responses. Since DNA and RNA are both nucleic acids, the term nucleic acid vaccine has also been used to describe this process.

44.2.2 HISTORY OF DNA VACCINES

The ability of genetic material to deliver genes for therapeutic purposes and its use in gene therapy has been appreciated for some time. Early experiments describing DNA inoculation into living cells were DNA transfer experiments performed by a number of investigators in the 1950s as well as 1960s [5–7]. These reports describe the ability of DNA preparations isolated from tumors or viral infections to induce tumors or virus infection following injection into animals. Importantly, many

FIGURE 44.2 Diagram of a DNA vaccine construct consisting of a mammalian expression vector. The plasmid is constructed with a CMV promoter, an antigenic DNA sequence, and a messenger RNA stop site containing the poly A tract.

such inoculated animals developed antibody responses to the proteins encoded within the injected DNA sequences. Over the next 20 years, a number of scattered reports, all focusing on gene function or gene therapy techniques, provided evidence that injection of viral DNA or plasmids containing foreign gene resulted in antibody production was related to the DNA inoculations. In 1985, Dobensky reported that plasmids containing insulin DNA sequences could produce insulin following inoculation into a living animal for some period of time. Longer term expression of foreign genes was described in 1990 by Wolff et al. following plasmid inoculation *in vivo* [8]. These two separate observations demonstrated that DNA in the absence of viral vectors could deliver proteins that might have biological relevance. While both of these studies focused on the use of this technology for gene replacement strategies, studies were already under way in several laboratories using this same technology for vaccine applications.

In 1992, Johnston and colleagues at the Southwest Foundation reported that injection of DNA encoding human growth hormone into mice resulted in transient hormone production followed by the development of antibodies in the inoculated animals specific for the human growth hormone gene [9]. This important work utilized a “genetic gun” or gene gun to shoot gold particles covered with DNA through the skin layers of mice. While these investigators were actually studying the use of this technology for a gene therapy replacement strategy, they described this development of antibody responses due to this unusual immunization procedure as genetic immunization. Simultaneously with the publication by Johnston and colleagues, a critical vaccine meeting was being held at the Cold Spring Harbor Laboratory, Long Island, New York, in September, 1992. Talks by Margaret Liu (Merck), Harriet Robinson (UMass), and David Weiner (UPenn) described the use of DNA immunization to generate humoral and cellular immune responses against a human pathogen as well as protection from both tumors and viral challenges in animal systems.

Liu reported on the induction of immune responses to intramuscular (IM) injected plasmid encoding pathogen proteins. She observed that both antibody responses as well as CTL responses were induced to influenza viral gene products by this immunization technique. Furthermore vaccinated mice were able to resist lethal viral challenge. Robinson and her colleagues at the University of Massachusetts reported on the use of the gene gun to deliver influenza virus genes in DNA plasmids and reported that both antibody and T lymphocyte responses were produced in vaccinated mice and chickens. In challenge studies, these responses were protective. The use of the gene gun allowed investigators to deliver very low nanogram amount of DNA at the site of injection and still observe immune responses. Weiner and his colleagues at the University of Pennsylvania reported the direct injection of DNA encoding the genes for the human immunodeficiency virus (HIV). Again both antibodies and T lymphocyte responses specific for the viral gene products were observed in experimental animals. As HIV does not infect

mice, an *in vivo* mouse model was used where tumor cells, which are normally lethal to the mice, were constructed to express HIV or tumor proteins. Animals vaccinated with the specific DNA vaccine were demonstrated to be immune to implanted antigen-expressing tumor cells. While the audience was skeptical of the ability of nonliving genetic material to produce useful immune responses, the large amount of data presented by each of these groups representing several years of successful work in diverse systems could no longer be ignored by the scientific vaccine community. DNA vaccines were officially born.

Following these initial reports, DNA vaccination and the generation of antibody and T lymphocyte responses as well as protective responses in a variety of animal models have been reported in the scientific literature for many human pathogens such as hepatitis B virus (HBV), rabies virus, herpes simplex virus, hepatitis C virus, human T cell leukemia virus, HPV, and tuberculosis (TB) [10–12]. Now over 16 years later, there are thousands of articles that have been published utilizing DNA vaccine technology. Many clinical trials have been undertaken. Here we review some of the basic biology and application of this still emerging technology.

44.2.3 MECHANISM OF DNA VACCINES

The exact mechanism for immune induction by DNA immunization has been at the center of a major debate [13–15], but is likely to be similar to traditional antigen presentation models. In the body’s immune system, APCs process and present antigenic peptides to lymphocytes in order to stimulate an antigen-specific immune response. Thus, antigen must be broken down and delivered to T lymphocytes by APCs [16]. Antigen presentation and recognition is a complex biological process that involves many interactions between APCs and T cells (Figure 44.3). There are four primary components that are critical in the professional APCs’ ability to present the antigen to T cells and activate them for appropriate immune responses. These components are MHC–antigen complexes, costimulatory molecules (primarily CD80 and CD86), intracellular adhesion molecules, and soluble cytokines. Naive T cells circulate through the body across lymph nodes and secondary lymphoid organs such as the lymph nodes and spleen. Their migration is mediated by intercellular adhesion molecules and cytokines. As the T cells travel through immune organs, they bind to and dissociate from various APCs. This action is mediated through adhesion molecules. When a naive T cell binds to an APC expressing relevant MHC:peptide complex, the T cell expresses high levels of high-affinity IL-2 receptor. Only when this T cell receives a costimulatory signal through CD80/CD86–CD28 interaction does the T cell make soluble IL-2, which then drives the now-armed effector T cell to activate and proliferate initiating the immune response.

Antigen is expressed at significant levels in muscle following IM inoculation of plasmid DNA [8]. Using reporter gene injections in mice, various investigators have reported the detection of gene expression after IM injection of DNA

FIGURE 44.3 (See color insert following blank page 206.) Effective T cell activation by APC. The interaction between antigen-MHC and T cell receptor leads to the expression of IL-2 receptor. This T cell proliferates when the second signal is provided from APC's costimulatory proteins. CD28-CD80/CD86 ligation initiates the production of IL-2 production and leads to the proliferation of activated T cell.

expression cassettes [8]. Protein expression was detected in the quadriceps muscle of mice after injecting plasmid vectors encoding chloramphenicol acetyltransferase, luciferase, and β -galactosidase reporter genes into the muscle.

Muscle cells have several structural and functional features, which make them well suited for DNA uptake *in vivo* [17]. Muscle consists of multinucleated contractile muscle fibers with a cylindrical shape and tapered ends. These muscle fibers have myogenic stem cells attached to them. When the muscle fibers are damaged or stressed, local stem cells become activated. The resulting myoblasts proliferate and eventually fuse to form new muscle fibers. It is believed that this continual activation and proliferation of the myoblasts allow a more opportunistic uptake of injected DNA. Because it has been shown that the uptake of the injected DNA and the subsequent production of protein occurs in muscle cells, they have been proposed as a potential site of antigen processing and presentation. However, the myocytes, which make up the muscle tissues, do not express CD80 or CD86 costimulatory molecules needed for efficient presentation. A recent study has identified an additional costimulatory molecule distinct from CD80 or CD86, which can be expressed in muscle cells [18]. However, if such molecules play a role in APC activity in the muscle requires more study. The question of ability of muscle cells to provide costimulatory signals

drives a current debate in the literature regarding the mechanism of antigen presentation following IM DNA immunization.

One potential mechanism is that the antigens produced in muscle are secreted from transfected muscle cells or released due to cell apoptosis [13,14]. Such exogenous antigen could then be taken up by professional APCs, locally which then migrate to, or shed antigen into the draining lymph nodes, where the antigen is processed via the MHC antigen presentation pathway on professional APC. These APCs are hypothesized to present the processed peptides to T cells. Recently, there have been reports that indicate that immune system has an inherent mechanism by which exogenous antigens access MHC class I molecules. One recent report identified dendritic cells as the potent mediator of such presentation antigen derived from phagocytosed apoptotic cells [19]. Immature dendritic cells engulf apoptotic cells and cross-present antigen from these sources to induce class I-restricted CTLs.

Another possible mechanism is the direct transfection of professional APCs by the injected DNA. Such a mechanism may be more probable in intradermal delivery of DNA because skin is rich in professional APCs, especially the dendritic cells. Condon et al. have reported that through DNA immunization into skin, they were able to show expression of proteins encoded by DNA plasmids [20]. On the other hand, such a mechanism is less efficient within the muscle tissue where there is a significantly lower presence of APCs. More recently, studies have reported that direct transfection of dendritic cells can occur following IM inoculation of DNA vaccine constructs, albeit at a lower level [21]. Studies support that macrophages and dendritic cells may be target cells for DNA transfection *in vivo* and that such a target might be important in driving immune responses [22]. A clear understanding of the role of APCs in DNA vaccination could have important implications for this technology.

44.2.4 POTENTIAL ADVANTAGES OF DNA VACCINES

As summarized in Table 44.1, DNA immunization affords several potential advantages over traditional vaccination strategies such as whole killed or live attenuated virus and recombinant protein-based vaccines without specific shortcomings and inherent risks associated with these vaccination methods. Like inactivated or subunit vaccines, DNA vaccines appear to be very well tolerated in humans. With several thousand persons having received DNA vaccines, the most common adverse effect has been injection-site irritation. Preclinical safety studies indicated that there was little evidence of plasmid integration which was an initial concern of scientists and regulators. The frequency of integration for DNA immunization by the IM, intradermal (ID), gene gun, or Biojet routes is at least three orders of magnitude below the spontaneous rate of gene-inactivating mutations [23-25]. In contrast to inactivated or subunit vaccines, DNA vaccine cassettes produce immunological responses that are more similar to live vaccine preparations. By directly introducing DNA into the host cell, the

TABLE 44.1
Potential Advantages of DNA Vaccines

Immunogenicity	Can induce both humoral and cellular immune responses Low effective dosages (micrograms) in animal models
Safety	Unable to revert into virulence unlike live vaccines Efficiency does not require the use of toxic treatments unlike some killed vaccines
Engineering	Plasmid vectors are simple to manipulate and can be tested rapidly Combination approaches are easily adapted
Manufacture	Conceptually low cost and reproducible large scale production and isolation Produced at high frequency in bacteria and easily isolated
Stability	More temperature-stable than conventional vaccines Long shelf life
Mobility	Ease of storage and transport Likely not to require a cold chain

host cell is essentially directed to produce the antigenic protein, mimicking viral replication or tumor cell antigen presentation in the host. Studies have shown that DNA can provide protection from infections from various pathogens, including viruses, bacteria, and parasites [26–29] in small animal models. DNA vaccines have been shown to be effective at eliciting antigen-specific CTLs, T helper cells, and antibodies similar to live infections. Unlike a live attenuated vaccine, the other major theoretical advantage of DNA vaccine is that they can be used for repeated administration as the efficacy of plasmid vectors are not influenced by preexisting neutralizing antibodies [10]. The ability to target multiple antigenic components may be a particularly important characteristic of DNA vaccines since multicomponent DNA vaccines can be engineered to include specific immunogens that can optimize and amplify desirable immunologic responses. Furthermore, DNA vaccines appear to be very stable and simple to produce. These features could allow for the rapid flow of DNA vaccines into use in developing countries. All these advantages of DNA vaccines make them appealing to both medical professionals and manufacturers in the health care industry.

44.3 STRATEGIES TO IMPROVE DNA VACCINES

Since the first DNA vaccines were described over 16 years ago, there has been great interest in developing a new generation of DNA vaccines that induce more potent immune responses. Recently, two veterinary DNA vaccines, a vaccine for West Nile Virus (WNV) in horses and a vaccine for infectious hematopoietic necrosis in salmon, have been licensed. Furthermore, license of a canine melanoma DNA vaccine is eminent. However, despite promising results in preclinical immunogenicity studies, DNA vaccines have been shown not to elicit robust antigen-specific immune responses in humans. Along with all of the advantages of DNA vaccines, an increase in potency would generate a vaccine that would appeal to the global health initiative. Thus, many strategies have been recently applied to improve the potency of the DNA vaccine platform.

44.3.1 IMPROVEMENT OF EXPRESSION AND IMMUNOGENICITY OF DNA VACCINES

Previous studies have demonstrated that the expression of viral or bacterial genes in mammalian cells can be hampered by the codon usage bias. For example, HIV viral RNA is AU-rich, in contrast to the high GC-rich content of the mammalian genome [30,31]. The tRNA pools required by HIV viral mRNA translation are different from those required by its host mammalian cells, resulting in poor expression of viral proteins in such cells. It is believed that the codon-optimized sequences for viral genes can be translated more efficiently using tRNAs in mammalian cells than the wild-type viral genes. For HIV plasmid vaccines, the issue of *rev* independence has appeared as another important problem. The structural genes of HIV are made as long unspliced transcripts that contain overlapping reading frames with small regulatory genes of HIV, *tat* and *rev*. These transcripts are retained in the nucleus and rapidly spliced to encode the small regulatory in the absence of the *rev* shuttle protein, thus preventing the transport of full-length message to the endoplasmic reticulum (ER) where structural gene translation can occur. Messages are inhibited from transport to the ER by both known and cryptic *rev*-dependent sequences. Previous studies suggest that optimization of codons to the usage of highly expressed human genes as well as deletion of residual inhibitory sequences significantly enhanced Gag expression, leading to potent augmentation of immune responses [32,33]. Therefore, codon optimization circumvents this problem. Wang et al. recently demonstrated that optimized DNA constructs were able to express much more envelope antigens than their wild-type counterparts, and one mechanism for higher expression was to have more newly synthesized, gp120-specific transcripts available for protein expression through increased stability of their mRNAs [34]. Scientists also found that optimized DNA vaccines could elicit more sustainable antibody responses than nonoptimized DNA vaccines [35,36].

RNA optimization suggested originally by the impact of HIV *rev* on HIV antigen expression appears to be another way

to increase the expression/immunogenicity of DNA vaccines [37,38]. Research has shown that sequences with GC-rich sequence stretches are more likely to form secondary structures that can hamper protein translation. During the RNA optimization process, the negative *cis*-acting motifs such as internal TATA-boxes, ribosomal entry sites, repeat sequences, splice sites, and poly(A) signals are also removed in order to make protein translation more efficient.

Modification of native leader sequences can play an important role on protein translation efficiency. To date, several highly efficient leader sequences have been used to increase the expression levels of DNA vaccines, such as human tissue plasminogen activator leader sequence (tPA) [39,40] and immunoglobulin leader sequence that have weak RNA secondary structure [41]. Previous studies indicated that the native signal sequence for HIV-1 envelope glycoproteins could inhibit gp120 folding inside the ER by delaying its own cleavage [42]. A significant increase in envelope protein production could be detected when the native leader sequence is replaced by a human tissue plasminogen activator leader sequence [39]. Data also suggest that the expression of IL-15 was enhanced dramatically when two native leader sequences were substituted by an IgE leader sequence [43]. Highly efficient leader sequences help to stabilize the mRNA and enhance the expression of DNA vaccines, thus exhibiting positive effects on immune responses.

Both cell-specific and ubiquitous promoters have been used to drive antigen-specific immune responses. Cell-specific promoters include the fascin promoter [44], the muscle creatine kinase promoter [45] and the keratinocyte K14 promoters [46]. While promising, the ubiquitous cytomegalovirus (CMV) promoter has been shown to be more effective at driving high levels of protein expression [47] and has been widely used to develop various DNA vaccines. The enhancement of antigen-specific immune responses was also observed in primates when the CMV promoter was used in a DNA vaccine cassette [48]. In addition, the CMV immediate early (IE) promoter has been shown to yield higher expression when it was tested in parallel with other promoters by both *in vitro* and *in vivo* experiments [40,49]. The intron A sequence, which is an enhancer, could cooperate with the CMV-IE promoter, yielding even higher expression levels [49]. A transcription factor-binding sequence that is thought to provide a promoter-specific regulatory element is located in the intron A sequence, and this sequence may contribute to the enhancing effect of intron A. However, limited results have been reported with this system. Studies on developing new efficient promoters, such as nonviral, synthetic, and chimeric promoters, capable of driving long-lasting transcription are also under way [50,51].

Besides the molecular strategies mentioned above, there are some other potential methods used to increase the expression of DNA vaccines. The inclusion of CpGs sequences in the backbone of plasmid DNA can enhance IL-12 and type I IFN secretion from murine bone marrow-derived DCs [52]. Toll-like receptor 9 (TLR9) recognizes unmethylated CpG motifs and CpGs activate TLR9-bearing APCs [53]. Studies

have also shown that constitutive transport elements (CTEs) increase the transport and stability of mRNA from the nucleus, thus enhancing the expression of DNA immunogens [54]. Taken together, all these approaches can contribute to the overall performance of the DNA vaccines through enhanced protein expression by increasing the efficiency of transcription and translation after DNA immunization. However, it is important to try several methods of optimization, as some can be inhibitory and others can be complementary.

Recent studies have indicated that improved immune responses came from an approach that combined and optimized several molecular strategies in a DNA vaccine design. Yan et al. [55] recently developed a novel engineered HIV-1 subtype B envelope DNA vaccine (pEY2E1-B) by incorporating several genetic modifications including codon optimization, RNA optimization, and the addition of a highly efficient immunoglobulin leader sequence to increase the immunogenicity. A highly efficient IgE leader sequence was fused in frame upstream of the start codon to facilitate expression. The codon usage of this envelope gene was adapted to the codon bias of *Homo sapiens* genes. In addition, RNA optimization [37] was also performed: regions of very high (>80%) or very low (<30%) GC content and the *cis*-acting sequence motifs such as internal TATA boxes, chi-sites, and ribosomal entry sites were avoided. They found that this novel envelope immunogen elicited much stronger cellular immune responses than a codon-optimized only envelope immunogen. Moreover, they developed a novel engineered SIV env construct (pSM-optEnv) by using the same strategies used for pEY2E1-B design and found this novel SIV env construct could elicit about fourfold stronger cellular immune responses as compared to these induced by a partially optimized SIV env construct (pSIV-Env) (Figure 44.4A). Previous studies have shown that the cellular immune response to SIV env DNA antigen in monkeys was weak and inconsistent. Since the number of SIV env-specific IFN- γ producing CD8 effector cells was low, it was difficult to detect CD8 T-cell proliferation. In contrast, more than 20% env-specific CD8 T-cell proliferation was detected in primates immunized with pSM-Env (Figure 44.4B), supporting the improved immunogenicity of this combination approach.

44.3.2 INDUCTION OF CROSSREACTIVE IMMUNE RESPONSES

The genomic sequences of viruses such as HIV and HCV are very plastic. Highly error-prone genetic replication system, unique to each of these viruses, leads to the generation and accumulation of such genetic diversity. In HIV, this high mutation rate is driven by at least two mechanisms: the low fidelity of the viral reverse transcriptase (RT), resulting in at least one point mutation per replication cycle [56] and the dual effects of the antiretroviral cellular factor APOBEC3G gene and viral infectivity factor Vif accessory gene [57,58]. Genomes with every possible mutation and many double mutations are generated during every replication cycle, resulting in tremendous antigenic diversity. Research has shown that genetic differences among HIV-1 groups M, N, and O are

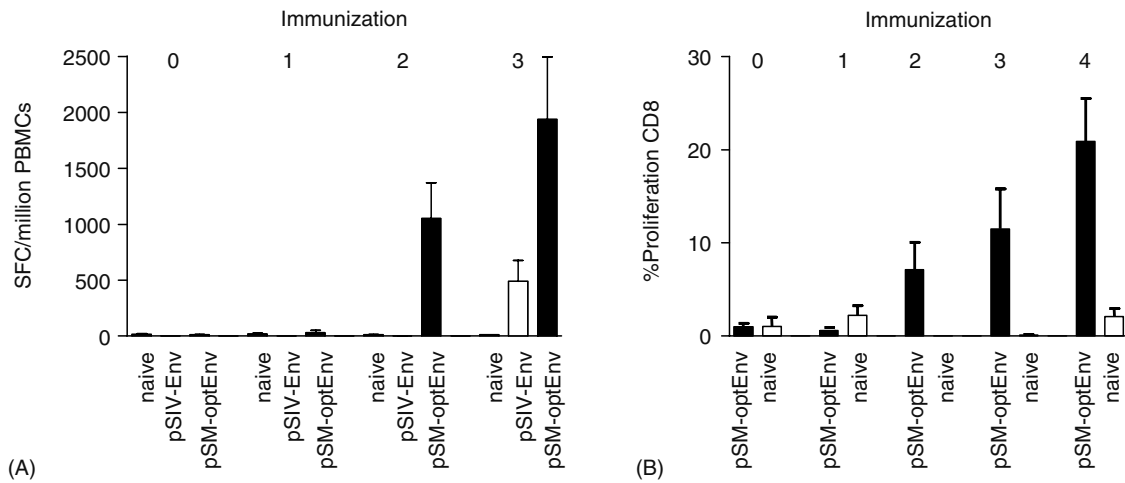

FIGURE 44.4 Improved potency of a genetically engineered optimized SIV envelope DNA vaccine. (A) SIV envelope-specific IFN- γ -producing cells following immunizations with the DNA vaccines. (B) SIV envelope-specific CD8 T-cell proliferation following immunizations with the pSM-optEnv DNA vaccine. Each group of macaques ($n = 5$) was immunized with 2 mg of DNA vaccine, and PBMCs were isolated and assessed for an SIV envelope-specific response by a standard IFN- γ ELISPOT assay and CFSE staining assay.

extensive, ranging from 30% to 50% in the *gag* and *env* genes, respectively [59–61]. The HIV-1 “major” (M) group viruses are primarily responsible for the AIDS pandemic and are further classified into nine genetically distinct subtypes (A, B, C, D, F, G, H, J, and K) [62]. The protein sequence differences between Env proteins from various subtypes differ up to 35% [63]. In addition, HIV-1 also frequently recombines among different subtypes to create circulating recombinant forms (CRFs) and novel recombinants [64]. Initial optimism that a vaccine designed from an HIV-1 primary isolate would eliminate disease caused by HIV-1 infection appears unfounded. Like other RNA viruses, HCV has a high mutation rate. The most divergent isolates sharing only 60% nucleotide sequence homology. The high level of genetic variability poses a major hurdle for developing vaccines against diseases caused by HIV, HCV, or other viruses. It has been argued that a candidate DNA vaccine derived from an individual isolate may not elicit sufficient crossreactivity to protect against diverse circulating viruses. In order to enhance the breadth of the elicited immune responses, scientists have applied an approach that includes using antigenic components from as many diverse HIV-1 isolates as possible in the vaccine, with the intention of inducing broader immune responses against divergent viral target antigens. Recently, in order to maximize the genetic similarity between the candidate vaccine and contemporary HIV-1 strains and to simplify immunogen production, new strategies, such as centralized sequence-based vaccines and polyvalent vaccines, are being developed.

44.3.2.1 Consensus-Based DNA Vaccines

A consensus sequence (CON) can be designed based on analysis of all circulating strains. In its simplest form, the CON is a sequence that has at each site the most frequent nucleotide

or amino acid residue across an alignment of homologous sequences. The CON will be genetically closer to currently circulating strains than any given individual natural virus isolate. Previous phylogenetic analysis of more than 70 HIV-1 subtype C genomes suggested that the amino acid distances to the consensus sequence were significantly lower than distances between samples within all HIV-1 subtype C isolates [65]. The evaluation of the predictive power of the consensus sequence showed the additional benefit using the consensus-based vaccine. Only 3% to 8% amino acid differences were found when comparing the subtype C consensus sequence with the sets of subtype C sequences. The translated amino acid distances to the consensus sequence were significantly lower than distances between samples within all HIV-1 subtype C proteins. The high probability that a new sequence will be within the identified consensus sequence, and the consensus consistency and stability to the introduction of a new isolate strongly suggest that a consensus-based vaccine should be able to enhance the breadth of cellular immune responses against any single virus within a population.

Recently, Gao et al. developed an HIV-1 group M consensus DNA immunogen (CON6) and found that this artificial immunogen could fold into native conformation, preserving envelope antigenic epitopes. This construct could elicit weak neutralizing antibody responses [66]. Further study on this consensus immunogen indicated that vaccination with the pCON6 could induce a greater number of T-cell epitope responses than any single wild-type subtype A, B, and C *env* immunogen [63]. On the other hand, previous studies have shown that there were high rates of selection identified in different regions of subtype B and C envelope proteins [67]. This may be caused by immune pressures on different regions of the envelope protein in subtype B and C. Therefore, there may be advantages in using a subtype-specific CON envelope

vaccines, as the immune responses to the vaccine and the circulating virus would share more antigenic domains. Yan et al. developed a novel HIV-1 subtype B consensus envelope DNA vaccine (pEY2E1-B) and peptide mapping results indicated that the EY2E1-B immunogen generated increased crossreactive cellular immune responses when compared to a primary envelope construct [55]. The use of consensus approaches is also being explored against other pathogens including influenza [68]. This is a promising area for further study of novel designed immunogens.

44.3.2.2 Ancestral Sequence-Based DNA Vaccines

Any consensus sequence may be biased by the limits of sampling and may associate polymorphisms in combinations not found in any natural virus, thus potentially resulting in improper protein conformations. Many scientists have proposed the use of ancestral sequence as a vaccine candidate to get around these issues [67,69–71]. The generation of an ancestral sequence involves reconstruction of the ancestral state of the antigen sequence [67]. An ancestral antigen that embodies the most recent common ancestor (MRCA) would have at least two advantages. First, it would be more genetically similar to all circulating strains than any other strains. Second, the protein generated from an ancestral sequence would more likely have native folding and function. Doria-Rose et al. constructed a full-length HIV-1 subtype B ancestral gene and demonstrated that the protein encoded by this gene could bind and fuse with cells expressing the HIV-1 coreceptor CCR5 [72]. When used as a DNA vaccine to immunize rabbits in a DNA prime-protein boost regimen, the artificial immunogen elicited neutralizing antibodies similar to those induced by a natural isolate, HIV-1 SF162. The cross-reactive cellular immune responses, however, were not determined due to the limitations in the rabbit model used. Further studies to explore whether these ancestor DNA immunogens could elicit broader cellular and humoral responses will be of great importance.

44.3.2.3 COT-Based DNA Vaccines

Gaschen et al. pointed out that an increasingly heterogeneous group of variants could lead to an ancestral sequence that is progressively more divergent from the variants [67]. Mullins and colleagues have recently developed a new hybrid method that produces a summary sequence that is tree-based while eliminating the influence of outlier sequences as seen in MRCA [73]. This new method identifies a point called the center of the tree (COT) on an unrooted phylogenetic tree. Theoretically, the COT minimizes the average evolutionary distance to all sequences in the data set and also could potentially enhance the breadth of immune responses. Rolland et al. computationally derived COT sequences from circulating HIV-1 subtype B sequences for the *gag*, *tat*, and *nef* genes [73]. The results indicated that all these COT genes retained biological functions, COT *gag* generated virus-like particles, while COT *tat* transactivated gene expression from the HIV-1 LTR, and COT *nef* mediated downregulation of cell surface

MHC-I. In addition, these COT-based DNA vaccines were capable of eliciting antigen-specific cellular immune responses in mice. COT *gag* and *nef* could also induce cross-clade CTL responses when studied for reactivity against subtype A, B, or group M peptide pools. These data provide another promising avenue for globally relevant DNA vaccine design.

44.3.2.4 Polyvalent Vaccines

Recently, Korber and colleagues present the design of polyvalent vaccine antigen sets, focused on T-lymphocyte responses and optimized for either subtype B and C or for group M [74]. Mosaic proteins resemble natural proteins and a mosaic set maximizes the coverage of potential population. They found the coverage of viral diversity using polyvalent vaccines was significantly enhanced for both variable and conserved proteins. Four mosaic proteins matched 74% of 9-amino-acid potential epitopes in global *gag* sequences and 87% of potential epitopes matched at least eight of nine positions, while a single natural *gag* protein covered only 37% (9 of 9) and 67% (8 of 9). Based on these data, a polyvalent DNA vaccine may also be developed using mosaic DNA sequences encoding potential T-cell epitopes in global HIV-1 variants. Overall, the area of synthetic immunogen design is getting traction as the DNA platform is the most simple for initial testing of innovative antigen design strategies.

44.3.3 IMPROVEMENT IN DELIVERY OF DNA VACCINES

An ideal delivery system for *in vivo* gene transfer should be simple and safe, and provide an appropriate expression of transgenes at therapeutic levels. Traditionally, plasmid-based technology has been limited in scope as expression levels following naked DNA transfer have been low, only a fraction of that of viral-mediated gene transfer. Improvements in delivery are critical to improve the response rates of DNA vaccines for activation of both cellular and humoral responses in humans.

Among the approaches for plasmid delivery *in vivo*, electroporation (EP) is receiving significant attention. This delivery method has great potential for DNA vaccination applications since a more efficient level of plasmid DNA transfer and transgene expression has been reported [75]. This physical process exposes the target tissue to a brief electric field pulse that induces temporary and reversible pores in local cell membranes. During the period of membrane destabilization, molecules such as plasmids may be taken up, resulting in 100- to 1000-fold increases in protein expression [76–79]. However, EP may cause mild localized tissue damage, resulting in the release of cellular components, which might provide a “danger signal” and thus provide an adjuvant effect [80]. EP also increases the number of tissue-resident transfected mononuclear cells [81], which could be very important for the induction of effective immune responses.

EP has been studied in large-animal species such as dogs, pigs, cattle, and more recently nonhuman primates to deliver

therapeutic genes that encode for a variety of hormones, cytokines, enzymes, or antigens [80]. Skeletal muscle cells have provided an ideal target for direct plasmid transfer for DNA vaccines and other applications [80]. The expression levels are increased by as much as three orders of magnitude over plasmid injection alone. For instance, a single injection of plasmid-encoding neuraminidase from influenza virus followed by EP in mice was able to provide long-term protection from influenza challenge [82]. However, similar results have been reported with other DNA delivery methods. Luckay et al. observed a 10- to 40-fold increase in HIV-1 antigen-specific responses in macaques immunized in combination with *in vivo* EP compared to those for macaques receiving a five-fold higher dose of vaccine without *in vivo* EP [83]. Importantly, *in vivo* EP was especially efficient at increasing the cellular immune responses against the less immunogenic antigens, such as nef, tat, and vif, resulting in a more balanced immune response overall. The data also suggested that *in vivo* EP could result in an approximate $2.5 - \log_{10}$ increase in antibody responses. Hirao et al. reported that the increased cellular and humoral immune responses were observed after IM delivery of plasmids by using a new constant-current device, including induction of polyfunctional responses. Data indicated that EP induced about four- to fivefold stronger cellular immune responses as compared to IM injection in mice (Figure 44.5). EP also induced between two- and fivefold stronger antibody responses as compared to IM injection and at DNA concentrations that were 20 \times less than the dose given by IM injection alone. Therefore, EP is an important method for further analysis as a DNA vaccine delivery technology [84,85].

FIGURE 44.5 Comparison of cellular immune responses induced by pConE6E7 using two DNA delivery methods: IM injection versus EP. The splenocytes were isolated from individual immunized mice (five mice per group) and stimulated *in vitro* with overlapping HPV-16 E6/E7 peptides pools. HPV-16 E6/E7 specific IFN- γ production was measured by a standard IFN- γ ELISPOT assay. pVAX immunized mice were included as a negative control.

Although EP can markedly augment immune responses induced by DNA vaccines, the tolerability of EP has been an important concern for vaccine delivery into humans. In many studies, the applied voltage was 150 to 250 V/cm. In addition, the long pulse length was also used when EP was performed. To make this technology feasible for human vaccination studies, more benign methods such as lower voltage, shorter pulse length should be investigated. Furthermore, skin delivery may be appealing. However, the increased delivery of this method may require additional studies of biodistribution and plasmid persistence.

Gene gun delivery has been shown to be another promising delivery method. Unlike IM injection, gene gun DNA immunization directly transfects cells by depositing DNA-coated gold beads within the cell cytoplasm [9]. Robinson and colleagues found that DNA immunization by IM injection induced a predominantly Th1 response while gene gun DNA immunization elicited a predominantly Th2 response [86]. It has been demonstrated that gene gun immunization used 100- to 1000-fold less DNA than IM immunization to generate an equivalent Ab response [87]. These findings have very important implications for vaccine design.

44.3.4 MOLECULAR ADJUVANTS

The primary goal of the first generation DNA vaccination studies was to demonstrate and evaluate the ability of DNA vaccines to elicit humoral and cellular responses *in vivo* in a safe and well-tolerated manner. As we explore the next generation of DNA vaccines, it would be desirable to refine current DNA vaccination expectations to demand that they elicit more clinically efficacious immune responses. In this regard, the next generation DNA vaccines may require better augmentation of the magnitude and direction (humoral or cellular) of the immune responses induced. Such modulation of immune responses may be accomplished by the use of genetic adjuvants encoded as part of the plasmid cocktail. Genetic or molecular adjuvants are different than the traditional adjuvants in that they are comprised of gene expression constructs encoding specific immunologically important molecules. These molecules include cytokines, heat shock proteins, chemokines, costimulatory molecules, and molecules that induce cell death among others. Molecular adjuvant constructs are coadministered along with immunogen constructs to modulate the immune responses induced by the vaccine cassettes themselves.

44.3.4.1 Cytokine Molecular Adjuvants

Many cytokines, including interleukins (IL), tumor necrosis factors (TNF), and interferons (IFN), have been evaluated as DNA vaccine adjuvants. The recent approval of therapeutic GHRH plasmid delivery for fetal wasting in pigs supports that this area is of importance. Here we describe several examples that illustrate findings and have potential implications for future vaccine and immune therapeutic exploitation.

Granulocyte-macrophage colony stimulating factor (GM-CSF) can recruit dendritic cells and promote their survival. It is one of the first cytokines to demonstrate clear potential to

enhance both humor and cellular immune responses to a DNA vaccine in mice. Previous studies have shown that coimmunization of GM-CSF with HIV-1 envelope gp120 in mice was able to increase cellular immune responses and CD4 T-cell proliferation [88,89]. However, studies in primates and humans showed that there was no dramatic boosting of the immune responses when GM-CSF was used as a DNA vaccine adjuvant in these species. This illustrates the need for examination of products in several systems prior to drawing final conclusions regarding adjuvant immune potency.

IL-12 is mainly produced by activated APCs including macrophages, dendritic cells, and B cells. It induces Th1-type immune responses through inducing the maturation of Th1 cells and promotes natural killer (NK) cell activity [88,90]. It has been shown that coimmunization with IL-12 plasmid results increased T helper cell proliferation and a significant enhancement of CTL responses in both mice and primates [88,89]. IL-12 has also been successfully used in cancer immunotherapy since it has a critical role in inducing antitumor immune responses [91,92]. Kim et al. observed a significant enhancement of CTL response *in vivo* with the coadministration of murine IL-12 genes with three different HIV-1 DNA immunogens (*gag/pol*, *envelope*, *vif*, and *nef*). Importantly, recent data have demonstrated that stronger and earlier CTL and antibody responses were induced when IL-12 was used as a molecular adjuvant in rhesus monkeys. This promising adjuvant has been now moved forward to clinical examination. Preliminary results from these studies should be available late in 2008.

IL-2 is another important immune adjuvant. IL-2 can activate both CD4, CD8 T cells and NK cells [93,94] and has been shown to enhance both cellular and humoral immune responses to HBV surface antigen in mice [95]. Barouch et al. reported that monkeys vaccinated with DNA vaccines expressing SIVmac239 Gag and HIV-1 89.6P Env in combination with the purified fusion protein IL-2/Ig demonstrated augmented secondary CTL responses, stable CD4 + T cell counts, very low viral loads, and no evidence of clinical disease by day 140 after a pathogenic SHIV-89.6P challenge [96]. Therefore, other adjuvants that target the same cytokine pathway may also be important in this context. This concept has been moved forward into clinical examination. In these studies, the IL-2/Ig is given 2 days following administration of the vaccine to maximize immune boosting.

The use of molecular adjuvant IL-15 has been considered as an important tool to increase the potency of DNA vaccines. Importantly, IL-15 has been reported to enhance memory CD8 + T cell proliferation as a DNA vaccine adjuvant [97]. It has been shown that there is a lack of memory phenotype CD8⁺ T cells in IL-15R α - and IL-15-deficient mice [98]. An optimized IL-15 construct was generated and coimmunization with this construct increased HIV-1 gag-specific CD8⁺ T-cell proliferation, IFN- γ secretion, and longevity of CD8 T cells [99]. In an influenza DNA vaccine model, stronger memory T-cell responses that protected mice from a lethal mucosal influenza challenge were induced in mice immunized with pHA + pIL-15-Opt compared to these immunized

FIGURE 44.6 Comparison of cellular immune responses induced by pConE6E7 with or without using molecular adjuvant IL-15. The splenocytes were isolated from individual immunized mice (five mice per group) and stimulated *in vitro* with overlapping HPV-16 E6/E7 peptides pools. HPV-16 E6/E7 specific IFN- γ production was measured by a standard IFN- γ ELISPOT assay. pVAX immunized mice were included as a negative control.

with pHA [99]. pIL-15-Opt could restore CD8 secondary immune responses in the partial absence of CD4⁺ T cell help, suggesting that IL-15 may be particularly useful as a candidate adjuvant for HIV immunotherapy. Moreover, Boyer et al. reported that macaques immunized with SHIV DNA vaccine together with IL-15 have an improved ability to control viral challenge and exhibit undetectable viral loads even 1 year after challenge. In addition, IL-15 was also shown to enhance the *in vivo* antitumor activity of adoptively transferred CD8⁺ T cells [100]. Yan et al. found that the IL-15 plasmid as a molecular adjuvant can improve the antitumor immunity induced by the DNA immunogen in a tumor model as well (Figure 44.6). The E6/E7 transgenic mice immunized with a plasmid-encoded HPV16 E6 and E7 (pConE6E7) and IL-15 exhibited smaller tumors compared to these only immunized with pConE6E7. Nine out of 10 mice survived in pConE6E7 + IL15 group while only 4 of 10 mice survived in pConE6E7 group 60 days after tumor implantation, indicating that vaccination with pConE6E7 in combination with IL-15 increased the ability of pConE6E7 to overcome immune tolerance and could cause better tumor regression in the E6/E7 transgenic mice (Figure 44.7). Collectively the advances in the cytokine area are impressive. More study in this rapidly developing area is important.

44.3.4.2 Chemokine Molecular Adjuvants

Similar to cytokine gene codelivery, coimmunization with chemokine genes along with DNA immunogen constructs can modulate the direction and magnitude of induced immune

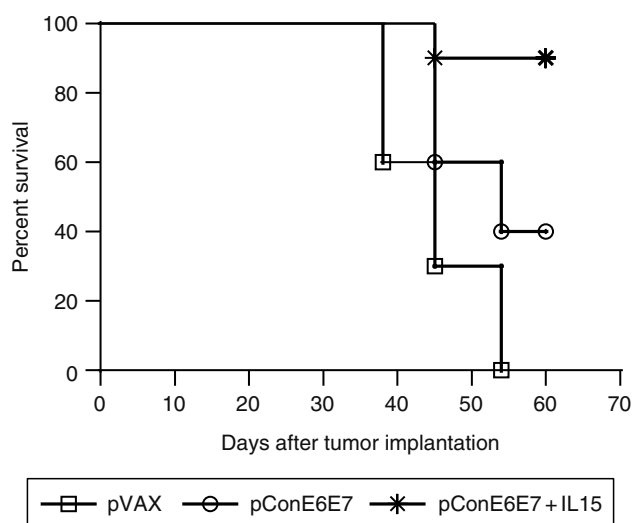

FIGURE 44.7 Vaccination in combination with IL-15 induced better tumor regression in C57BL/6 mice. On day 0, 5×10^4 TC-1 cells were implanted subcutaneously into C57BL/6 mice (10 mice per group). Starting on day 3, each group of mice was immunized with pVAX, pConE6E7 and pConE6E7 + IL15 for three times at weekly intervals and tumors measurement was performed.

responses [101]. For example, coimmunization with IL-8 and macrophage inflammatory protein 1 α (MIP-1 α) genes increased the antibody response in a similar manner to IL-4 or GM-CSF coimmunization. IL-8 and RANTES (regulated on activation, normal T expressed and secreted; CCL5) as adjuvants could also enhance T helper proliferation. RANTES and monocyte chemoattractant protein-1 (MCP-1) coinjections resulted in a high level of CTL enhancement, almost as significant as IL-12, a potent CTL inducer for DNA vaccines. There is evidence that suggests some chemokine-adjuvanted vaccines require a direct fusion of the immunogen with the chemokine. For instance, immunization against HIV gp120 with MCP-3/CCL7 or macrophage-derived chemokine (MDC/CCL22) requires the direct fusion of the two for effective immune response induction. Accordingly, coimmunization revealed minimal immune enhancement [102]. Therefore, the use of these chemokine adjuvants could be particularly important as HIV vaccine modulators of β -chemokines. It has been reported that β -chemokines as vaccine adjuvants augmented β -chemokine production in a vaccine antigen-specific manner [103]. This aspect could be especially important for a development of a vaccine that modulates the earliest aspects of the inflammatory response.

44.3.4.3 Costimulatory Molecule Molecular Adjuvants

Professional APCs initiate T-cell activation through binding of antigenic peptide–MHC complexes to specific T-cell receptor molecules. In addition, the APCs provide critical costimulatory signals to T cells, which are required for the clonal expansion and differentiation of T cells. Among different costimulatory molecules, B7 molecules (CD80 and CD86) have been observed to provide potent immune signals [104,105]. They bind to their

receptors (CD28/CTLA-4) present on T cells. The CD80 and CD86 molecules are surface glycoproteins and members of immunoglobulin superfamily, which are expressed only on professional APCs [104–106]. The blocking of this additional costimulatory signal leads to T-cell anergy [107].

CD86 molecules play a prominent role in the antigen-specific induction of CD8⁺ CTLs when delivered as vaccine adjuvants [101]. Coadministration of CD86 cDNA along with DNA encoding HIV-1 antigens intramuscularly dramatically increased antigen-specific T-cell responses without a significant change to the level of the humoral response. This enhancement of CTL response was both MHC class I-restricted and CD8⁺ T-cell-dependent. These results have been extended by other investigators who also found that CD86, not CD80 coexpression resulted in the enhancement of T-cell-mediated immune responses [108,109]. However, Santra et al. reported that either CD86 or CD80 administered concurrently with a plasmid DNA vaccine can fully costimulate vaccine-elicited CTL responses [110].

It is possible that engineering of nonprofessional APCs such as muscle cells to express CD86 costimulatory molecules could empower them to prime CTL precursors. On the other hand, the enhancement effect of CD86 codelivery could also have been mediated through the direct transfection of a small number of professional APCs residing within the muscle tissue. Subsequently, these cells could have greater expression of costimulatory molecules and could in theory become more potent. This issue has been investigated using bone marrow chimeras, which demonstrated the ability to cross prime CTL immunity [107]. This method of engineering nonhematopoietic cells to be more efficient APCs could be especially important in cases where antigen alone fails to elicit a CTL response due to poor presentation by the host APCs. However, recent studies of B7.2 containing DNA vaccines in the nonhuman primate model have not been very encouraging. Engineering this pathway to generate useful levels of cellular immunity in nonhuman primates remains an important challenge.

In addition to the B7 family of costimulatory molecules, the immunology of CD40 and its ligand has also been implemented to enhance DNA vaccine potency. CD40 functions by interacting with CD40 ligand (CD40L) expressed on activated CD4⁺ or CD8⁺ T cells. The attachment of CD40L onto APCs, with or without T helper cells, have been shown to “condition” the APCs for antigen-specific CTL activation [111–113]. Additionally, their ligation has shown to enhance the expression of B7 costimulatory molecules on APCs, including dendritic cells [114–116]. Therefore, the engagement of CD40 with its ligand becomes advantageous for activation of CTLs during an immune priming response. Accordingly, coimmunization of plasmids coding for beta-galactosidase and CD40L has been reported to induce immune enhancement [117]. Importantly, the addition induced enhancement of CTL responses without suppressing the development of antibody responses was observed [118,119]. Interestingly, coinjection of CD40L was revealed to be more effective than CD40 [120], indicating that expression of CD40L on muscle cells may also induce the “licensing” of APCs for the activation of CTLs. However, the possibility of direct transfection into antigen

specific infiltrating T-cells cannot be eliminated, although T-cells have not been yet established as an *in vivo* transfection target for DNA vaccines. Studies using multimeric forms of the CD40L molecule have been encouraging [121]. Such molecules maintain critical structure of the nature ligand. However, as with B7.2 initial studies in nonhuman primates have not been highly impressive.

Adhesion molecules have also been studied in this context. These molecules are particularly important in the initiation of the host immune response. Antigen-specific T-cell responses can be enhanced by the coexpression of DNA immunogen and adhesion molecules intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen 3 (LFA-3). Coexpression of ICAM-1 or LFA-3 molecules along with DNA immunogens resulted in a significant enhancement of Th cell proliferative responses. In addition, coimmunization with ICAM-1 (and more moderately with LFA-3) resulted in a dramatic enhancement of CD8-restricted CTL responses. Although vascular cell adhesion molecule-1 (VCAM-1) and ICAM-1 are similar in size, VCAM-1 coimmunization did not have any measurable effect on cell-mediated responses. Rather, these results imply that ICAM-1 and LFA-3 provide direct T-cell costimulation. These observations

were further supported by the finding that coinjection with ICAM-1 dramatically enhanced the level of IFN- γ and β -chemokines MIP-1 α , MIP-1 β , and RANTES produced by stimulated T cells. ICAM-1/LFA-1T-cell costimulatory pathways appear independent of CD86/CD28 pathways, and they may synergistically expand T-cell responses *in vivo*. Furthermore, these studies indicate that CD8⁺ effector T cells at the site of inflammation can regulate the level of effector function through the expression of specific chemokines and adhesion molecules (Figure 44.8) [101,103]. Therefore, the end-stage effector T cells in the expansion phase of an antigen-specific immune response could direct their own destiny through coordinated expression and release of these molecules. This pathway can likely be exploited in the DNA vaccine setting.

44.3.4.4 Molecular Adjuvants That Induce Cell Death

In addition to powerful signaling, dendritic cells often function as scavenger cells by engulfing and processing apoptotic bodies. For instance, immature dendritic cells phagocytose apoptotic bodies by employing the receptors alphavbeta5 integrin and CD36 [122–124]. Subsequent engulfment of the

FIGURE 44.8 (See color insert following blank page 206.) Regulation of CD8⁺ T cell expansion by adhesion molecules and chemokines in the periphery. Specific adhesion molecules and chemokines provide modulatory signals to CD8⁺ T cells in effector stage. This network of cytokine, chemokine, costimulatory molecules, and adhesion molecules represents a coordinated regulation and maintenance of effector T cells in the periphery.

apoptotic body by both immature and mature dendritic cells induces viral and tumor immunogens to activate MHC class I restricted CD8⁺ CTLs [19,124]. Interestingly, *in vivo* depletion of CD11c⁺ and CD8⁺ cells in mice fail to crossprime antigens to prime naïve T-cells, specifying its essential role in inducing T-cell activation [125]. Both dendritic cells and macrophages have been shown to present apoptotic engulfed antigens but the latter fails to activate naïve T-cells, which becomes a vital step in the activation of adaptive immunity [19,126]. In addition, Rovere et al. [124] and Ronchetti et al. [127] have demonstrated that there is a quantitative dependency on apoptotic bodies by dendritic cells in inducing the secretion of proinflammatory cytokines TNF- α and IL-1 β both *in vitro* and *in vivo*, respectively. Hence, an optimum strategy to develop potent vaccines would necessitate the activation of dendritic cells and the packaging of immunogens in these apoptotic bodies for uptake. Chattergoon et al. [128] employed a novel strategy whereby immunogen constructs were coimmunized with the death cell receptor Fas. In theory, this model induces the expression of both the immunogen and Fas within the same muscle cells and apoptosis would materialize through the interaction of Fas with its ligand, possibly via T-cell assistance. When these two constructs were coimmunized, there was a significant augmentation of immune responses as measured by enhanced CTLs and Th1 cytokines including IFN- γ and IL-12. Additionally, implementing Fas as the apoptosis receptor may also provide a compounding effect on dendritic cell maturation, as Fas engagement possesses multiple functional roles. For instance, Fas not only contributes with the induction of cell death, but also stimulates the maturation of dendritic cells when engaged with its ligand [129]. This is especially crucial, as direct *in vivo* transfection of dendritic cells have been proposed as a potential mechanism responsible for the induction of immune activation with respect to DNA vaccines [20–22]. More recent work by Sasaki et al. implemented mutant caspases to decrease apoptotic efficiency to aliquot ample time for immunogen expression, while still delivering apoptosis-mediated antigens to dendritic cells [130]. This raises an interesting question as these mutant caspases decreased apoptotic efficiency *in vitro* by nearly 10-fold compared to the native caspase proteases [130]. However, it is also currently understood that high quantities of apoptotic bodies are engulfed by scavenger macrophages and induce subsequent release of anti-inflammatory factors including IL-10, TGF- β , PGE₂, and PAF [131,132]. Accordingly, inflammation is observed when the clearance of apoptotic bodies become inefficient and results in their delayed removal from the surrounding environment [133]. This results in the development of postapoptotic necrosis, which may function to deliver additional signals for proinflammatory developments and dendritic cell maturation [133,134]. However, decrease in overall apoptotic quantity and potency with mutant caspases were able to provide enhanced immune response levels when compared to the more potent apoptotic signal [130]. Therefore, it is also likely that delaying the expression of the apoptotic signal or working upstream of caspases may validate the requirement

for the balance between immunogen expression versus apoptotic stimuli [130]. These studies reveal the necessity to delay the expression of apoptotic signals to maximize immunogen expression, while maintaining the potency of the death signal. It is also important to note that necrosis, not apoptosis, is traditionally the prime cell death mechanism by which inflammation and immune activation occurs [135]. Interestingly, recent work suggests several models may be involved to induce immune activation through cell death. For instance, one model suggests that necrosis in conjunction with apoptosis delivers the maturation signal to dendritic cells [134,136]. However, the role of postapoptotic necrosis as the stimulus is ruled out or insufficiently strong to deliver a maturation signal. Another model suggests that both primary necrotic and apoptotic cells are equivalent at inducing the maturation of dendritic cells and initiating immune activation [137]. Therefore, either channel of cell death may be competent to stimulate the immune system for activation. Lastly, it is suggested that cell death or injury releases adjuvanting properties from the cytoplasm and is able to effectively stimulate immune activation [138]. Therefore, components are actively secreted from dead cells that trigger the induction of immune responses. It is also evident that apoptosis and necrosis may function together to deliver immunogens to dendritic cells while inducing potent maturation signals [136]. However, further studies are crucial to validate the precise roles that these cell death components may play in the generation of inflammatory responses induced by DNA immunization.

44.3.5 RECOMBINANT PRIME/BOOST STRATEGIES IN PRECLINICAL AND CLINICAL STUDIES

The generation of potent CTL responses through the DNA immunization has become an attractive approach targeting many pathogens including HIV-1. The inefficient generation of antibodies possessing high crossneutralizing activity against different HIV strains has limited antibody based approaches for HIV [139,140]. On the other hand, an inverse correlation can be made between HIV viral load and CTL frequency, indicating its importance in both treatment and vaccine applications [141,142]. In fact, virus-specific CTLs attribute significantly to the control of acute phase infection and denote the mechanism by which viral loads are controlled [143–145]. Furthermore, studies on SIV infection models have also indicated that viremia of viral load could be effectively controlled by CD8⁺ T cells [145,146]. As a result, recent applications have concentrated on maximizing the cellular arm of the immune system by generating potent CTLs to target and eliminate virally infected host cells. Previously DNA vaccines showed efficacy in inbred primate models of animals challenged with nonpathogenic AIDS viruses [147,148] and against pathogenic SHIV-89.6P [96]. DNA vaccines were less effective in outbred animals and against stringent SIV challenge [149]. Heterologous prime boost regimens have been employed to improve DNA immune potency and to address the issue of preexisting vector immunity. Studies by differing groups have reported significant enhancement of CTLs by

priming with DNA and boosting with attenuated viral vectors in SIV, HIV, hepatitis B, and other model systems.

Studies have reported that the order of priming and boosting is important. For instance, vaccine regimens in reverse (virus priming and DNA boosting) or merely DNA alone exhibit minimal amplification in many studies and fail to provide protective immunity against subsequent challenges [150–152]. Historically, the order of application in attenuated prime/boost strategies has also exhibited similar results, as priming with a recombinant influenza virus and boosting with recombinant vaccinia resulted in enhanced CD8⁺ responses and protective immunity against malaria [153]. It was proposed that perhaps the influence of the viruses to preferentially migrate CTLs to sites favored by the boosting virus may influence the overall potency of the vaccine [154]. However, another study proposed that the immunogenicity might be correlated to the immunodominance of the boosting, as the antigen-specific memory responses from the priming may provide a greater focused isolation of the antigen of interest. Consequently, boosting with recombinant viruses concentrates the primed antigens from the recombinant and enhances its amplification [152–154]. This theory correlates with other reports indicating that homologous prime/boosting with the same virus with heterologous antigens fail to proliferate antigen specific CD8⁺ cells [155]. Meanwhile, heterologous boosting with the modified vaccinia virus Ankara (MVA) and fowlpox viruses, while maintaining the same immunogen, provided significant enhancement of CTLs [156]. It is also likely that the enhanced assembly of memory T cells that resulted from the primed immunization may augment the boost's proliferation by providing a larger memory T-cell pool.

In addition to its efficacy, attenuated virus boosting specifically with MVA provides a resilient history of safety, as it was employed to vaccinate 120,000 humans during the smallpox eradication campaign [152,157]. Furthermore, the inability of the virus to replicate in humans while maintaining efficient viral gene expression makes it a perfect component for recombinant boosting approaches [158,159]. Cytokine studies of these viruses indicate an elevated degree of Th1 versus Th2 responses, corresponding to the potent CTLs essential for an efficacious HIV-1 DNA vaccine [160,161]. Further reports on the immunology of the MVA recombinant virus both *in vitro* and *in vivo* demonstrate that potent CTLs are generated as indicated by enhanced CD8⁺ populations and secretion of proinflammatory cytokines interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF- α) [162–165]. Consequently, the natural immune response of the virus correlates well with essential characteristics of vaccines by compounding the host's cellular responses.

To date, many different viruses have been studied to function as recombinant boosters for DNA vaccines including the modified vaccinia Ankara, fowlpox, adenovirus, AAV as well as alphaviruses-VSV [166–171]. While most studies have reported potent CTLs and enhanced Th1-biased cytokine

expression, the studies focused on are recent studies implementing the DNA/MVA boost scheme, as well as the DNA/Adeno5 model. In the rhesus macaque model, these studies induced protective responses against subsequent pathogenic SHIV89.6P challenge by preventing clinical AIDS while displaying low to no viral loads. The overall comparisons indicate that the most promising model is the Ad5 through survival of higher T-cell counts and lower viral loads [171]. Egan et al. added an SIVgag plasmid DNA priming regimen to a series of rVSV vectored booster immunizations and found both SIVgag-specific cell-mediated immune responses and humoral responses were significantly increased [172]. The viral loads post-SHIV89.6P challenge were much lower compared to macaques receiving only the rVSV vectored immunizations. Moreover, the inclusion of the plasmid DNA priming regimen also increased the preservation of peripheral blood CD4⁺ cells and reduce the incidence of AIDS-like disease symptoms and death associated with SHIV89.6P infection. Mattapallil et al. recently demonstrated that systemic vaccination with a DNA-prime recombinant adenovirus boost regimen preserved CD4 T cells [173]. Letvin et al. [174] immunized monkeys with a DNA-prime recombinant adenovirus boost regimen and then challenged them with pathogenic SIV and their data indicated a prolonged survival. This survival was associated with preserved central memory CD4⁺ T lymphocytes. Shiver et al. reported that an effective DNA vaccine prime combined with an Ad5 booster resulted in a T-cell immune response that was similar to those observed with multiple high doses of an Ad5-based vaccine [175]. Taken together, these immune correlates of vaccine efficacy should be of great help to guide the development of AIDS vaccines in humans.

Despite the potential functional breadth of the antiviral T-cell response, the immunogenicity of HIV-specific T-cell responses and candidate T-cell-based vaccine constructs is largely determined by the production of IFN- γ as mentioned to date in ELISpot assays. However, other functional activities of CD8⁺ T cells may also play an important role in controlling HIV replication. The recent use of polychromatic flow cytometry to measure multiple phenotypic and functional parameters of T cells stimulated with vast libraries of peptides that represent the entire HIV proteome has revealed valuable immune correlates. Research has demonstrated that the functional profile of HIV-specific T cells in HIV-1 progressors is limited compared to that of nonprogressors, who consistently maintain polyfunctional T cells (as measured by the number of cytokines produced) [176,177]. Polyfunctional T-cells are a hallmark of existing vaccines such as the effective smallpox vaccine and are also believed to be important for an effective HIV vaccine. A most recent study indicated that the DNA prime/Ad5 boost regimen could elicit more polyfunctional HIV-specific CD4⁺ and CD8⁺ T cells than either candidate alone in macaques. Therefore, recombinant prime/boost immunizations, especially DNA prime/Ad5 boost immunization, may provide better immune responses against HIV-1 infection [178–180].

44.4 DNA VACCINES FOR INFECTIOUS DISEASES AND CANCER

44.4.1 DNA VACCINES AGAINST HIV-1

The WHO and UNAIDS estimated that approximately 35.5 million people living with human immunodeficiency virus-1 (HIV-1), 2.9 million individuals died as a result of AIDS-related diseases and 4.3 million people were newly infected with HIV-1 in the year 2006 [181]. HIV-1 is a retrovirus, which preferentially infects and kills CD4⁺ T cells and macrophages, ultimately resulting in immune system failure and multipathogen infections. The development of antiretroviral therapies has resulted in a decrease in morbidity and mortality associated with AIDS in many developed countries. However, the costs and the stringent administration regimen requirements of these therapies make it clear that these therapies will only be effectively utilized in a limited part of the world population. Therefore, to address the worldwide problem of HIV-1 infection, there remains a need for a prophylactic vaccination strategy designed to control the epidemic through mass immunization campaigns.

There have been about 30 ongoing or completed human clinical trials to test the safety and immunogenicity of HIV-1 DNA vaccines in humans (Table 44.2). Several important conclusions can be made by inference. One is that the primate studies do not directly translate to similar levels of immunity in humans. Overall it happens that humans have less of an overall immune response induced to DNA vaccines than do macaques. However, clinical trials using DNA prime/boost strategies, such as DNA prime/protein boost by Lu et al. at Umass and by Barnett et al. from Novartis, and DNA prime/MVA boost from the Karolynskia group and DNA prime/Ad5 boost by the VRC have all reported positive effects on the resulting immune response in these prime boost strategies. Similar positive effects of DNA prime/MVA boost in humans have been reported by Hill et al. at Oxford. Furthermore, efficacy trials are being planned by the VRC using the DNA prime/Ad5 boost approach. These are very exciting developments. We will learn a great deal from these studies on the clinical efficacy of such prime/boost strategies for HIV over the next several years.

44.4.2 DNA VACCINES AGAINST OTHER VIRAL DISEASES

There is a growing list of DNA vaccines targeted against other human diseases. One of the central attractions of the technologies is its flexibility in modulating immune responses. As a consequence, several vaccine cocktails have been created that specifically target highly immunogenic antigens, which results in potent antiviral immune responses.

Influenza is a good example of the potential utility of DNA vaccines. In fact, an initial study by Ulmer et al. targeted the nucleoprotein of influenza as its antigen and effectively generated CTLs to achieve protection against subsequent challenge with a heterologous strain of influenza A virus [182]

in mice. Protection was also achieved through immunization against the hemagglutinin antigen [183]. A recent phase I trial using a DNA vaccine encoded HA delivered by gene gun technology induced protective antibody responses after three immunizations [184]. While the ability of antibodies to prevent influenza infection is well established, the antibody responses may give no protection if the challenge virus is divergent from the virus strain used to generate vaccines. In contrast, cellular immune responses are less specific and far more crossreactive [68]. Subsequent studies detailing the crossreactivity induced by these DNA vaccines, in addition to the ability of these vaccines to show protection against broad lethal virus challenges, are currently in progress.

HBV affects 350 million people worldwide and there are no commercially available therapeutic vaccines for the treatment of chronic HBV infection. Studies have demonstrated that immunization of DNA vaccines encoding HBsAg elicit rapid, stronger and long-lasting cellular and humoral immune responses and the efficacy could be significantly enhanced by coexpression of IL-2 [95]. Moreover, a DNA vaccine encoding the HBV major and middle envelope proteins has been shown to induce strong antibody responses in chimpanzees [185]. In 2006, a DNA vaccine expressing HBsAg and HBcAg received U.S. IND approval together with approval from Singapore, Hong Kong, and Taiwanese and entered Phase I Clinical Trials. Assessments of immunogenicity and possible clinical response will be made soon.

Smallpox, a devastating disease caused by the variola virus, was eradicated in 1979 by smallpox vaccination. However, with renewed concerns regarding bioterrorism, the potential threat from an outbreak of smallpox through deliberate release has caused a re-examination of the vaccine status. Dryvax, a licensed smallpox live virus vaccine, carries a high risk of complications for people with suppressed immunity and other conditions. Since a DNA vaccine would not have the adverse side effects, recently many studies have been performed in the area of developing smallpox DNA vaccines. Hooper et al. have reported that vaccination with a DNA vaccine expressing four vaccinia virus genes (L1R, A27L, A33R, and B5R) could protect rhesus macaques against lethal challenge of monkeypox virus [186]. Therefore, DNA vaccines as a promising alternative approach may contribute greatly to vaccination strategies aimed at reducing the health hazards of the conventional smallpox vaccination.

The WNV is transmitted through the bite of an infected mosquito to humans, horses, and other animals by virus-carrying mosquitoes and it induces brain inflammation and death in endemic regions. Introduction of WNV into the United States in 1999 created major human and animal health concerns. There have been more than 16,000 reported cases of WNV in humans and more than 650 deaths since 1999. In addition, more than 21,000 WNV-infected cases in horses have been reported since 1999. As there is no specific therapy for the WNV infection at this moment, there is an increasing demand for the development of vaccine strategies to prevent disease from this virus. Encouraged by an initial study that

showed a DNA vaccine expressed the WN virus prM and E proteins could induce protective immunity [187], CDC and Wyeth Fort Dodge Animal Health Unit established a research and development agreement in 2001 to test a DNA vaccine and make it commercially available. On July 8, 2005, they were able to successfully develop the world's first licensed DNA vaccine that could protect horses from WNV with no adverse or major side effects. This is an exciting scientific breakthrough that has potential benefits far beyond preventing WNV infection in horses.

Almost at the same time, a DNA vaccine against infectious hematopoietic necrosis virus (IHNV) was licensed in Canada. IHNV, the causative agent of IHN, is endemic to the western coast of North America. The viral infection causes the deaths of large numbers of commercially raised salmon and trout and is an economic problem for commercial fisheries. The only method of reducing the risk IHNV poses to the Atlantic salmon farming industry is through the use of an efficacious vaccine. As of 1999, a DNA vaccine encoding the surface glycoprotein G of IHNV was being tested and the results indicated that immunization of this vaccine could cause protective immunity [188–191]. Thereafter, more than six million salmon were inoculated while this vaccine was evaluated by Canadian regulators. Tests showed the vaccine, called Apex-IHN, protected the fish without adverse effects. In July 2005, Canada licensed the DNA vaccine product for sale. Taken together, these two veterinarian DNA-based vaccines have become the first to make it from the laboratory into commercial use, buoying hopes for similar vaccines for human diseases, such as Ebola, HIV/AIDS, and SARS.

44.4.3 DNA VACCINES FOR CANCER

Although advances in science have led to countless theories and methods designed to combat human cancers, the battle is far from over. Surgical excision of tumors, drug therapies, and chemotherapy have been effective in certain cases but in other situations, particularly when the tumor has begun to metastasize, effective treatment is far more difficult and far less potent. Thus researchers are continually investigating novel and more effective treatment strategies for various forms of cancer. The concept of vaccinating against cancer has been around for many decades starting with nonspecific immunostimulatory approaches. The recent identification and characterization of genes encoding for tumor-associated antigens has made it possible to design antigen-specific cancer vaccines based on plasmid DNA and recombinant viral vectors [192].

Since the first human tumor antigen (MAGE-1) recognized by CD8⁺ T cells was identified, numerous tumor antigens have been confirmed as CD8⁺ T-cell targets. Studies also provided direct evidence that CD8⁺ T cells play a key role in tumor rejection in humans [193,194]. The capacity of DNA vaccines to induce CD8⁺ T-cell responses has been demonstrated in many preclinical and clinical studies in infectious diseases. However, it is important to note that immune responses to microbial antigens in healthy individuals are not

comparable to immune responses to cancer antigens in cancer patients. Little is known as to how the host-antigenic tolerance to tumor antigens in patients with active cancers interferes with immune responses induced by DNA vaccines. Development of cancer DNA vaccines has to face several generic problems, such as how to break immune tolerance and how to avoid the negative impact of regulatory T cells on the induction of antitumor responses etc.

44.4.3.1 DNA Vaccines against Prostate Cancer

Prostate cancer is the most common form of cancer and the second most common cause of cancer-related death in American men. The appearance of prostate cancer is much more common in men over the age of 50 [195]. Three of the most widely used treatments are surgical excision of the prostate and seminal vesicles, external beam irradiation, and androgen deprivation. However, conventional therapies lose their efficacy once the tumor has metastasized, which is the case in more than half of initial diagnoses [196,197].

PSA is a serine protease and a human glandular kallikrein gene product of 240 amino acids, which is secreted by both normal and transformed epithelial cells of the prostate gland [198,199]. Because cancer cells secrete much higher levels of the antigen, PSA level is a particularly reliable and effective diagnostic indicator of the presence of prostate cancer [200]. PSA is also found in normal prostate epithelial tissue and its expression is highly specific [201].

The immune responses induced by a DNA vaccine encoding for human PSA has been investigated in a murine model [201]. The vaccine construct was constructed by cloning a gene for PSA into expression vectors under control of a CMV promoter. Following the injection of the PSA DNA construct (pCPSA), various assays were performed to measure both the humoral and cellular immune responses of the mice. PSA-specific immune responses induced *in vivo* by immunization were characterized by enzyme-linked immunosorbent assay (ELISA), T helper proliferation CTL, and flow cytometry assays. Strong and persistent antibody responses were observed against PSA for at least 180 days following immunization. In addition, a significant T helper cell proliferation was observed against PSA protein. Immunization with pCPSA also induced MHC Class I CD8⁺ T-cell-restricted cytotoxic T lymphocyte response against tumor cell targets expressing PSA. The induction of PSA-specific humoral and cellular immune responses following injection with pCPSA was also observed in rhesus macaques [202].

44.4.3.2 DNA Vaccines against Colon Cancer

Human carcinoembryonic antigen (CEA) is a 180 kDa glycoprotein expressed in elevated levels in 90% of gastrointestinal malignancies, including colon, rectal, stomach, and pancreatic tumors, 70% of lung cancers, and 50% of breast cancers [203,204]. CEA is also found in human fetal digestive organ tissue, hence the name carcinoembryonic antigen [205]. It has been discovered that CEA is expressed in normal adult colon epithelium as well, albeit at far lower levels [206,207].

Sequencing of CEA shows that it is associated with the human immunoglobulin gene superfamily and that it may be involved in the metastasizing of tumor cells [205].

The immune response to nucleic acid vaccination using a CEA DNA construct was characterized in a murine model. The CEA insert was cloned into a vector containing the CMV early promoter/enhancer and injected intramuscularly. CEA-specific humoral and cellular responses were detected in the immunized mice. These responses were comparable to the immune response generated by rV-CEA [206]. The CEA DNA vaccine was also characterized in a canine model, where sera obtained from dogs injected intramuscularly with the construct demonstrated an increase in antibody levels [208]. Cellular immune responses quantified using the lymphoblast transformation (LBT) assay also revealed proliferation of CEA-specific lymphocytes. Therefore a CEA DNA vaccine was able to induce both arms of the immune responses [208].

Although numerous cancer DNA vaccine candidates have been reported, only a few have been evaluated in clinical trials. Conry et al. [209] tested the safety and immunogenicity of a plasmid DNA vaccine encoding the CEA antigen and the HBV surface antigen (HbsAg) in a bicistronic vector. The results showed that this DNA vaccine induced HbsAg-specific antibodies but CEA-specific antibodies were not able to be detected. Four out of 17 patients developed lymphoproliferative responses against CEA after vaccination. No objective clinical responses were observed. Antigen-specific cellular immune responses were not observed in another clinical study testing a DNA vaccine expressing melanoma antigen (gp100) delivered either intradermally or intramuscularly [210]. Take together, cancer DNA vaccines are safe and could induce modest immunogenicity in cancer patients. More studies are needed to improve immunogenicity of cancer DNA vaccines.

44.4.3.3 DNA Vaccines against B-Cell Lymphoma

Several studies have shown that DNA immunization encoding the idiotypic determinants of a B cell lymphoma generates tumor-specific immunity. Although DNA vaccines containing single chain Fv sequences alone induced low levels of anti-idiotypic antibody responses, an enhanced antibody responses were able to be induced by fusing the gene for fragment C of tetanus toxin to the C terminus of human scFv [211]. Timmerman et al. performed a phase I/II clinical trial to study the safety and immunogenicity of DNA vaccines encoding chimeric idio type in patients with follicular B-cell lymphoma [212]. The data showed that seven of 12 patients mounted both cellular and humoral immune responses. These results will help guide the design of such future DNA vaccine trials.

44.4.3.4 DNA Vaccines against Cervical Cancer

Cancers associated with the HPV pose a significant international health problem. Cervical cancer is the second most common cancer among women worldwide, but it is the most common cancer in developing countries [213]. Moreover, HPV-associated head and neck cancer affects as many as 115,000 people each year globally [214,215]. The development

of these cancers is closely associated with infection by high-risk types of HPV [216]. Studies have shown that HPV-16 is the predominant subtype in both cancers, accounting for 46%–63% of cervical cancer cases and 90% of head and neck cancer cases [215,217].

There are two major families of vaccine that can be considered in the fight against HPV-related cancer. Prophylactic vaccines are aimed at inducing natural immunity against HPV infection in naïve individuals. Anti-L1 and L2-directed vaccines are efficient in this role. Preventive vaccines developed to date [218] are constructed of VLPs or even pentameric L1 capsomerases. When used as vaccines, they generate strong serum-neutralizing antibodies. HPV prophylactic vaccines have shown significant clinical efficacy. They can prevent about 70%–80% of all cervical cancers worldwide based on strains used in the vaccine [219]. However, prophylactic HPV vaccines would not be effective in controlling existing HPV infections or HPV-associated lesions. Therefore, an important need is to develop therapeutic HPV vaccines focused on women with active disease and aimed at eliminating or controlling existing infection or disease progression through the induction of a strong cell-mediated response. There has been a lot of work in this area.

Two HPV gene products, E6 and E7, are expressed in most and perhaps all HPV-related pre- and cancerous cells. These genes are responsible for the transformation of cells and are required for the maintenance of HPV associated malignancies, thus making them ideal immunotherapeutic targets [220,221]. Heat shock proteins have been found to induce tumor immunogenicity and their levels of expression is enhanced by highly immunogenic necrotic bodies [222–224]. In view of this, the HSP70 of mycobacterium TB was fused to the human HPV-16 E7 antigen to construct a chimeric DNA vaccine. The E7-HSP70 DNA vaccine induced significantly enhanced levels of cellular responses including a ratio of 435:14 (E7-HSP70 to E7) of E7 specific IFN- γ spot-forming CD8⁺ T cells via ELISPOT assays [225]. In a similar fashion, another member of the HSP family that has been shown to augment the potency of DNA vaccines is calreticulin [112]. Accordingly, when calreticulin was fused to HPV-16 E7 antigen as a DNA vaccine, a potent, antitumor effect was provoked. The resulting response was attributed to both the enhanced immunogenicity against E7 and the generation of antiangiogenesis [226]. Although therapeutic vaccines that target either HPV-16 E6 or HPV-16 E7 have been previously described [227,228], few vaccines that target both oncoproteins have been developed and demonstrated to have effective antitumor activity. Research suggests that the combination of E6 and E7 DNA vaccines may have better antitumor potential than alone [229]. Yan et al. developed an engineered consensus-based HPV-16 DNA vaccine by using a multiphase design strategy [230]. When studied as a DNA vaccine, compared to a primary HPV-16 E7 DNA vaccine, this synthetic construct elicited strong cellular immune responses in both C57BL/6 and the E6/E7 transgenic mice. Prophylactic administration of this vaccine results in 100% protection against HPV E6 and E7-expressing tumors in both murine models. Therapeutic studies indicate that vaccination

with this DNA vaccine induces tumor regression. Moreover, coadministration of IL-15 with this vaccine enhances its efficacy against established tumors.

Most animal models for HPV vaccine studies are based on analysis of fast-growing transplantable tumors; however, malignancies in cervical cancer patients in general develop much more slowly, which may lead to immune suppression or immune tolerance [231]. Therefore, whether HPV-specific vaccines are potent enough to overcome the tolerance becomes an important concern. In this regard, research has demonstrated that vaccination of HPV16 E7 protein-based vaccine reduced the growth of pre-established TC-1 tumors although there was no measurable CTL response detected [232]. Previous studies have also indicated that recombinant Semliki forest virus (SFV) expressing a fusion E6/E7 protein had the capacity to induce HPV16 E7-specific cytotoxic T cells in HPV-transgenic mice [231]. Furthermore, Souders et al. found that *Listeria*-based vaccines can partially break tolerance by expanding low avidity CD8⁺ T cells capable of causing tumor regression in a E6/E7 transgenic mouse model [233]. In contrast, several recent studies showed that immunization with HPV16 E6/E7 DNA vaccines was not able to induce HPV-specific CTL activity in E6/E7 transgenic mice and overcome E6- or E7-specific tolerance [231,234]. Yan et al. reported for the first time that a HPV E6/E7 DNA vaccine could have the ability to induce HPV-specific CTL activity and partially overcome immune tolerance in the E6/E7 transgenic mouse model system [230]. Building on these results will be important. Taken together, these data suggest further study of such DNA immunogens in the eventual context of immune therapy for select HPV-associated cancers are wanted.

44.4.3.5 DNA Vaccines against Melanoma

Canine malignant melanoma (CMM) is an aggressive form of cancer that typically appears in a dog's mouth, but also may appear in the nail bed, foot-pad, or other areas. CMM is the most common tumor in the dog, representing about 4% of all canine tumors [235,236]. To date, the most common treatments for CMM and advanced human melanoma (HM) have been radiation and surgery. Also, CMM and HM are chemo-resistant neoplasm [235,237]. Based on these similarities, CMM is a good clinical model for evaluating new treatments for advanced HM.

While controversial, some studies have indicated that immunization of mice with plasmids encoding cancer differentiation antigens is not effective when self-DNA is used, but effective tumor immunity can be induced by orthologous DNA from another species [238]. Wang et al. demonstrated that the xenogeneic human DNA encoding tyrosinase family proteins induced both cellular and humoral immune responses against syngeneic B16 melanoma cells in C57BL/6 mice [239]. Xenogeneic DNA immunization protected tumor growth from syngeneic melanoma challenge and autoimmune hypopigmentation [240,241]. A phase I veterinary clinical trial conducted by Bergman and colleagues showed that xenogeneic human tyrosinase DNA vaccination of dogs was safe and potentially

efficacious. Only minimal local toxicity and a lack of systemic toxicity was detected and the clinical antitumor responses and remarkably prolonged median survival time was also observed after vaccination with this DNA vaccine. Importantly, the USDA has issued a conditional U.S. Veterinary Biological Product License for this therapeutic vaccine in May 2007. This conditional license is a response to an application and assurance of safety and purity, and a reasonable expectation of efficacy based on initial trials performed at MSKCC and AMC. This DNA vaccine will be used to improve the health and well-being of dogs, and this is the first time that the U.S. government has approved a therapeutic vaccine for the treatment of cancer in either animals or humans. Since humans and dogs develop this cancer in a similar manner, the use of this vaccine in dogs may result in improved cancer treatment in humans.

44.4.4 DNA VACCINES FOR AUTOIMMUNE DISEASES

A breakdown in tolerance to self-antigens is often considered to result in autoimmune disease. However, the similar immunological reactions that control immune responses to foreign antigens are also involved during the progress of autoimmune disease. Th1 cells have been shown to be involved in many autoimmune diseases while Th2 cells may inhibit disease development [242,243]. Data also indicated that skin delivery of DNA by gene gun DNA immunization is associated with a rapid induction of Th2 responses. Therefore, the induction of Th2 responses by DNA vaccines may be one method whereby autoimmune responses can be inhibited. For example, many studies have reported the use of DNA vaccination as a means of preventing the autoimmune disease experimental allergic encephalomyelitis (EAE). Ramshaw et al. demonstrated that DNA immunization could induce MBP-specific antibody immune responses in mice [244]. Data also showed that the vaccination of a DNA vaccine encoding an immunodominant MBP peptide targeted to Fc of immunoglobulin G suppressed clinical and histopathological signs of EAE [245]. Taken together, DNA vaccines may find a place in the treatment of autoimmune diseases. However, this is an early area of investigation and more study is needed to define the themes that are most likely to bring successful interventions to this area.

44.5 CONCLUSIONS

DNA immunization holds great promise for providing safe and effective vaccines for many infectious diseases and cancers. The direct injection of foreign genes by genetic immunization has resulted in specific immune responses that exhibit characteristics of protective immunity against a number of infectious agents in a variety of animal models. For example, genetic vaccination cassettes targeting each of HIV-1's three major genes (*env*, *gag*, and *pol*), regulatory genes, and accessory genes have been developed and studied in small animals, primates, and humans. DNA vaccine constructs for cancers targeting tumor-specific antigens have also been studied in a variety of animal models. Developing successful vaccines for HIV-1 or cancers will likely involve targeting multiple antigenic

components to direct and empower the immune system. Such a collection of immunization cassettes should be capable of stimulating broad immunity against both humoral and cellular epitopes, thus giving a vaccine the maximum ability to deal with viral immune escape or tumor growth. There is still considerable room for advancing the current technology. The combination of genetic modifications, including codon and RNA optimization, and addition of high efficient leader sequence and promoter have shown great impact on improvement of DNA vaccine immunogenicity. The "centralized" sequences provide a novel method to maximum the crossreactivity induced by DNA vaccines. In addition, the potential of the molecular adjuvant coadministration to dramatically enhance and regulate the antigen-specific humoral and cellular immune responses induced by DNA immunogens represents important new avenue for vaccine and immune therapeutic exploration. DNA vaccines can be combined with other vaccines including recombinant protein, poxvirus, adenovirus, as well as others to further enhance initial immune responses. In addition, improved transfection efficiency and delivery methods such as the gene gun and EP are also central areas in the continued development of the field. It is clear that there has been steady progress and recently there has been real excitement realized by the approvals in the veterinary area and the generation of immune responses with some potency in humans. It is likely that through a combination of technology enhancements and incremental advances, DNA vaccine technology will become a central strategy for prevention of infectious diseases and treatment of human cancers over the next 10 years. We are looking forward to seeing this important change in the field.

45.1 INTRODUCTION

Diseases of the central nervous system (CNS) are frequently characterized by the degeneration of specific cells and a consequent continuous deterioration of function. Advances in molecular biology, genetic engineering, proteomics, and genomics are identifying potentially efficacious proteins, peptides, and other compounds. Unfortunately, most of these compounds are not active following systemic administration, largely because the blood-brain barrier (BBB) restricts exchange between the vasculature and brain parenchyma [1,2]. A number of strategies have been described to circumvent the BBB including: (1) carrier-, or receptor-mediated transcytosis [3,4]; (2) osmotic opening [5,6]; (3) direct infusion with stereotactic guidance [7-9]; (4) osmotic pumps

[10,11]; (5) sustained-release polymer systems [12-14]; (6) cell replacement/cell therapy [15-20]; and (7) direct gene therapy [21-25].

One form of cell-based therapy uses xenogeneic cells encased within a selectively permeable polymeric membrane. The polymer membrane containing the cells can be implanted into the brain allowing cell-based delivery of secreted products directly to the target site. This process, known as immunoisolation, is enabled because the encapsulated cells are protected from host rejection by the immunoisulatory, semi-permeable membrane. The selective, semipermeable membrane barrier admits oxygen and required nutrients and releases bioactive cell secretions, but restricts passage of larger cytotoxic agents from the host immune defense system.

TABLE 45.1
Advantages and Disadvantages of Encapsulated Cells

	Advantages	Disadvantages
Unencapsulated cells or tissue	Permits anatomical integration between the host and transplanted tissue Good cell viability and neurochemical diffusion	Likely requires immunosuppression Limited tissue availability Difficult retrieval Societal and ethical issues
Microencapsulation	Permits use of allo- and xeno-grafts without immunosuppression Thin wall and spherical shape are optimal for cell viability and neurochemical diffusion	Mechanically and chemically fragile Multiple implant sites Limited retrievability
Macroencapsulation	Permits use of allo- and xeno-grafts without immunosuppression Reasonable mechanical stability Adequate cell viability and neurochemical diffusion Retrievable	Dimensions may limit neurochemical diffusion and cell viability Multiple implant sites May produce significant tissue damage/displacement during implantation

Immunoisolation therefore eliminates the need for chronic immunosuppression of the host and allows the implanted cells to be obtained from nonhuman sources, thus avoiding the constraints associated with cell sourcing, which have limited the clinical application of unencapsulated cell transplantation. This chapter discusses the preclinical and clinical evaluation of encapsulated cells across a range of CNS diseases highlighting the therapeutic potential of genetically modified, encapsulated cells for Alzheimer's disease (AD), Parkinson's disease (PD), and Huntington's disease (HD).

45.2 CELL IMMUNOISOLATION

There are generally two categories for cell encapsulation, micro- and macro-, each with some benefits and limitations shown in Table 45.1 [26–29]. This chapter focuses primarily on macroencapsulation (Figure 45.1). Macroencapsulation involves filling a hollow, usually cylindrical, selectively permeable membrane with cells, generally suspended in a matrix, and then sealing the ends to form a capsule. Polymers used for macroencapsulation are biodegradable, with a thicker wall than

FIGURE 45.1 Diagram illustrating the different components of a macrocapsule contributing to successful implantation and cell viability. The manufacturing process involves several different aspects each with its own complexities. The initial choice of cell types includes primary, immortalized, or engineered. Intracapsular cell biology issues following encapsulation include a consideration of the need to use a compatible extracellular matrix (ECM) and other considerations specific to that cell type because they impact cell nutrition and product synthesis. A series of other device-related issues include membrane geometry, morphology, and transport of molecules into and out of the device. Finally, the device must be sealed and depending on the site of implantation could require a tether for subsequent retrieval or the inclusion radio-opaque markers for imaging purposes.

FIGURE 45.2 Scanning electron micrograph of a typical macrovoid-containing membrane used in cell encapsulation.

that found in microencapsulation. While thicker wall and larger implant diameters can enhance implant stability, these same features may also impair diffusion, compromise the viability of the tissue, and slow the release kinetics of desired factors. Macrocapsules can be retrieved from the recipient and replaced if necessary.

Macroencapsulation is generally achieved by filling pre-formed thermoplastic hollow fibers with a cell suspension. The hollow fiber is formed by pumping a polymer solution in a water-miscible solvent through an outer annular region of a nozzle while an aqueous solution is pumped through a central bore. The polymer precipitates upon contact with the water and forms a cylindrical hollow fiber with a permselective inner membrane. Further precipitation of the polymer occurs as the water moves through the polymer wall, forcing the organic solvent out and forming a trabecular wall structure. The hollow fiber is collected in an aqueous water bath, where complete precipitation of the polymer and dissolution of the organic solvent occur. The ends of the hollow fiber are then sealed to form a macrocapsule. This final step is not a trivial one, since reliably sealing the ends of capsules can be difficult, and provides the barrier paramount for successful immunoisolation. Figures 45.2 and 45.3 depict cross-sections of typical macrofibers.

A second method of macroencapsulation, called coextrusion, avoids the sealing problem by entrapping cells within the lumen of a hollow fiber during the fabrication process [30]. Pinching the fiber before complete precipitation of the polymer causes fusion of the walls, providing closure of the extremities while the cells are inside. The advantages of coextrusion over loading preformed capsules include distributing the cells more uniformly along the entire length of the fiber,

FIGURE 45.3 Example of encapsulated fibroblasts retrieved from monkey lateral ventricle (LV) illustrating many of the components listed above. Cells were modified to produce NGF and were encapsulated using Vitrogen as an ECM. Under these conditions, numerous H&E positive cells were visible and evenly distributed within the full length of the capsule one month following implantation.

reducing the shear stresses on the cells during the loading process and the potential for mass production.

While polymer capsules are relatively sturdy, it is critical to ensure that the encapsulating membrane is compliant enough to meet the dynamics of the surrounding tissue while remaining mechanically resilient to resist failure during device implantation/retrieval. To accomplish this, the macrocapsule can be designed to provide added strength and device integrity. One approach includes the addition of a crosslinked hydrogel, e.g., a 2% alginate solution, within the device. This modification enhances structural support during the implantation procedure [31]. However, with time, the hydrogel loses structural integrity and does not provide added strength, especially with regard to tensile strength, an important consideration for device retrieval. Mechanical supports can also be used for added strength. Such supports are better served from within the device to not impede diffusion between the encapsulating membrane and the surrounding tissue. Titanium wires and braided materials are examples of approaches that may be used to provide added tensile strength.

45.2.1 CELLS AND EXTRACELLULAR MATRICES USED IN ENCAPSULATION

Cells placed within encapsulation devices generally fall into one of three categories. The first category is primary postmitotic cells such as islets of Langerhans for diabetes, adrenal chromaffin cells for chronic pain, or hepatocytes for liver devices. Secondly, immortalized (or dividing) cells such as PC12 cells have been utilized to deliver dopamine for PD. The third category is cell lines genetically engineered to secrete a bioactive substance such as baby hamster kidney (BHK) cells to secrete factors such as nerve growth factor (NGF). Dividing tissue has advantages over postmitotic tissue; it can be expanded, banked, and easily tested for sterility and contaminants. However, dividing tissue is also constrained by the potential for overgrowth within the capsule environment, resulting in an accumulation of necrotic tissue that can diminish the membrane's permeability characteristics, reducing cell viability and neurochemical output.

In vivo, ECMs control cell function by regulating morphology, proliferation, differentiation, migration, and metastasis [32,33]. Within a capsule, ECMs were originally employed simply to prevent aggregation of cells (immobilization) and central necrosis, but are also beneficial to the viability and function of cells that require immobilization or scaffolding for anchorage. For example, immobilizing adrenal chromaffin cells in alginate prevents aggregation that, in turn, reduces central necrotic cores from forming [34]. The chromaffin cells appear to thrive in alginate whereas mitotically active fibroblasts do not. In this case, the use of alginate is essential to the optimal functioning of this device since some anchorage-dependent cells such as fibroblasts or endothelial cells are present with the adrenal chromaffin cells. In the absence of alginate or other immobilizing matrices, the fibroblasts expand and overgrow the capsule, resulting in a device deficient in bioactive factors produced from the chro-

maffin cells [35]. In contrast, fibroblastic BHK cells prefer collagen, while PC12 cells prefer distribution within precipitated chitosan, which provides a scaffolding structure on which the cells anchor [36].

In order to provide a substratum designed for more specific functions, the matrix material can be manipulated chemically or mechanically, which in turn may influence cell attachment, differentiation, and/or proliferation. For example, peptides, such as arginine-glycine-aspartic acid (RGD), have been immobilized on a variety of surfaces to promote cell adhesion [37]. Integrin receptors on the cell surface membrane interact with the RGD sequence, a known ligand for fibronectin receptors. Glass microbeads have been modified by attaching RGD or tyrosine-isoleucine-glycine-serine-arginine (YIGSR) motifs to provide sites for cell adhesion [37]. Spherical ferromagnetic beads have been coated with specific receptor ligands to mediate cell attachment [38]. With competitive binding assays and a mechanical stress testing apparatus, the endothelial cell's interaction with the ECM receptor, integrin beta-1, supported a force-dependent stiffening response, while nonadhesion receptors did not. A laminin-derived oligopeptide sequence, CDPG-YIGSR, has also been derivatized within an agarose hydrogel and permitted a dose-dependent increase in neurite outgrowth of neuronal cell bioassays [39]. Similarly, YIGSR and isoleucine-lysine-valine-alanine-valine (IKVAV), both of which are found in laminin, have been immobilized on surfaces to promote neuronal cell adhesion and neurite outgrowth [40]. Poly(ethylene oxide) (PEO)-star copolymers have been fabricated as a potential synthetic ECM [41]. The star copolymers provide many hydroxyl groups where various synthetic oligopeptides can be attached to desired specifications.

The survival and differentiation of encapsulated cells can be influenced by the matrix interactions. A variety of matrices for use in immunoisolatory devices, such as alginate, rat tail collagen extracts, gelatin shards, porous gelatin, or collagen microcarriers, carrageenan, chondroitin sulfate, fibrin, hyaluronic acid, the positively charged substrate chitosan, and an acrylamide-based thermoresponsive gel are available and were recently reviewed [42]. All in all, successful cell encapsulation involves the choice of the cells to be encapsulated, the type of intracapsular matrix used, and the ability to control membrane properties such as geometry, morphology, and transport. The interactions between the encapsulating membrane characteristics and the capsule core, or matrix within, should be rigorously characterized to determine the optimal configuration for each cell type.

45.2.2 VALIDATION OF THE CONCEPT OF IMMUNOISOLATION

45.2.2.1 *In Vitro* Studies

The maintenance of immunoisolation can be easily confirmed *in vitro*. In one study, a polydisperse (10^3 – 10^6 g/mol) dextran solution was encapsulated into hollow fibers and the flux of the molecules across the semipermeable membrane into a

surrounding reservoir was monitored over time. A dextran rejection curve was produced from the filtrate and reservoir concentrations measured using gel permeation chromatography [43]. With control devices that had been damaged, the large molecular weight dextran species rapidly escaped. In contrast, intact capsules retained the encapsulated dextran. Capsule integrity can also be confirmed using immunological assays such as measuring the protection of encapsulated cells against the cytotoxic killing of antibody (IgG)-mediated complement lysis [29]. With integral PC12 cell-loaded capsules, in the presence of antibody and complement, the membrane prevented antibody-mediated complement lysis (<10% cell death), while complete killing (100%) occurred with damaged capsules or unencapsulated cells.

45.2.2.2 *In Vivo* Studies

The importance of polymer capsule integrity for xenografted cell survival is illustrated in studies where unencapsulated PC12 cells, or cells encapsulated in intentionally damaged membranes, have been implanted in the brains of guinea pigs [30]. Intact PC12 cell-loaded capsules implanted into the guinea pig striatum showed no lymphocytic infiltration and a minimal astrocytic reaction assessed by glial fibrillary acidic protein (GFAP) staining. In contrast, cell survival was poor in damaged capsules, with marked inflammation and heavy lymphocytic invasion into the capsule. Parallel studies confirmed that unencapsulated PC12 cells do not survive following implantation into either the guinea pig or the monkey striatum while encapsulated PC12 cells were viable for 6 months in monkeys [44]. Similar results have been obtained in rats that received intraventricular implants of bovine adrenal chromaffin cells [45]. There was no evidence of elevated serum levels of rat antbovine adrenal chromaffin cell IgG or IgM with encapsulated xenogeneic adrenal chromaffin cells for nearly 1.5 years *in vivo*. In contrast, a robust host immune response was induced in animals after implantation of unencapsulated bovine adrenal chromaffin cells.

45.2.3 BIOCOMPATIBILITY

Transplant survival, with and without an encapsulating membrane, is mediated by many factors. The cellular/tissue reaction generated by a host in response to a foreign body (i.e., biocompatibility) impacts the success of the transplant. Factors affecting biocompatibility include the method of implantation, the implant site, and implant properties, such as composition of the polymer, potential residual processing agents, surface integrity and microgeometry, and the size and shape of the implant. The constituents of the implants should be assessed rigorously, both *in vitro* and *in vivo*, to determine the safety of the materials. The CNS tissue is not only privileged from an immunologic standpoint, but it also lacks the primary reactive cells, fibroblasts, and macrophages found in peripheral locations. The brain therefore offers a unique environment both in terms of the inflammatory response, as well as the cellular constituents that comprise the reactive cells. Immunospecific antibodies are available to delineate the roles

of the brain reactive cells, the astrocytes and microglia, with respect to their reactivity. Nevertheless, few studies have systematically examined the reaction of host brain tissue to the presence of polymeric devices.

Early investigations utilized electron microscopy to characterize the brain tissue reaction to plastic-embedded metal electrodes and polymer implants [46–48]. Necrosis of the tissue surrounding the polymer capsules implanted into the striatum of rodents was minimal with small Nissl-positive cells and capillaries invading the open trabeculae in the capsules [48]. GFAP immunocytochemistry revealed local reactive astrocytes 1 to 2 weeks after implantation. The intensity of the GFAP reaction diminished rapidly such that by 4 weeks after implantation, the gliotic reaction surrounding the polymer implant was minimal. No significant changes in myelin basic protein reactive oligodendroglia were observed, and neuron specific enolase-reactive neurons were readily identifiable adjacent to the implant. Subsequent studies with an immunospecific antisera against rat microglia, OX-42, revealed a reaction in magnitude and time course similar to that seen for the astrocytes.

The lack of a significant host tissue reaction to the implant is crucial for the initial viability of the encapsulated cells as well as diffusion from the capsule. While capillary invasion into the capsule walls helps provide nutrients and oxygen in proximity to the encapsulated cells the process of angiogenesis for neovascularization typically evolves in a 4–7-day period [49]. The encapsulated cells must endure an initial period of nutrient and oxygen deprivation obtaining these essential factors only by diffusion. Moreover, since the only means of delivery of the desired cellular products from an encapsulated cell implant is by diffusion, any reaction around the capsule can diminish the diffusion of therapeutic products from the encapsulated cells. Studies demonstrating biocompatibility within the CNS therefore suggest that the bidirectional transport of low molecular weight solutes across the permselective membrane can be maintained *in vivo*. The inclusion of cells such as bovine adrenal chromaffin cells or PC12 cells does appear to significantly impact the host reaction to the polymer device.

It should be noted that in an effort to maintain or even further enhance the biocompatibility for cell line-containing implants, or reduce protein adsorption that may negatively impact the ability to maintain adequate long-term diffusive characteristics, several postsynthesis modifications have been attempted. Poly(acrylonitrile-*co*-vinyl chloride) (PAN/VC) hollow fiber membranes, which were surface modified by grafting PEO groups, exhibited improved biocompatibility in brain tissue over the unmodified PAN/VC controls [50]. Similar observations were made with PEO-modified poly(hydroxyethyl methacrylate-*co*-methyl methacrylate) membranes utilized extensively in cellular microencapsulation [26].

45.2.4 LONG-TERM PRODUCT SECRETION AND DELIVERY

Before patients suffering from chronic CNS diseases can be routinely implanted with encapsulated cells, long-term survival of the encapsulated cells and continued release of the

therapeutic molecule must be demonstrated. Although effective immunoisolation should result in long-term survival of encapsulated cells, surprisingly few studies have examined implant viability for more than a few months. A few notable exceptions exist and provide compelling evidence about the potential for long-term survival and release of molecules from the cells. Following encapsulation, PC12 cells have been maintained *in vitro* and *in vivo* for at least 6 months, while maintaining a typical morphology and clustered arrangement along the lumen of the device [30,44,51]. The cells remain tyrosine hydroxylase (TH)-immunoreactive and mitotically active, with necrosis primarily in regions of high cell density. Electron microscopy confirmed the presence of numerous mitochondria, polysomes, and electron-dense secretory vesicles distributed within the cytoplasm. Spontaneous and evoked release of dopamine can be detected from capsules maintained both *in vitro* and following explantation from the CNS. Both rodent microdialysis and positron emission tomography (PET) studies in primates have confirmed that encapsulated PC12 cells continue to produce L-dopa/dopamine *in situ* [51,52].

Other cell types, including encapsulated bovine adrenal chromaffin cells, also survive for prolonged periods of time [45,53]. Intraventricular implants of encapsulated bovine chromaffin cell implants survived for nearly 1.5 years and continued to produce catecholamines and met-enkephalin [45]. Polymer-encapsulated, genetically modified cells also survived and continued to secrete NGF for 12–13.5 months in rats [54,55]. The cells remained viable and the NGF secreted from the encapsulated cells was 64% higher following removal from the rat LVs [55]. NGF transgene copy number was equivalent to preimplant levels, indicating NGF gene stability. No deleterious effects from long-term NGF were detectable on body weight, mortality rate, motor/ambulatory function, or cognitive function as assessed with the Morris water maze and delayed matching to position [55]. There was no evidence of NGF-induced hyperalgesia, although tests of somatosensory thresholds did reveal effects related to the NGF delivery. NGF from the encapsulated cells produced a marked hypertrophy of cholinergic neurons within the striatum and nucleus basalis as well as a robust sprouting of cholinergic fibers within the frontal cortex and lateral septum proximal to the implant site. Although no deleterious behavioral effects were observed, the profound anatomical changes and their relationship to functional alterations in normal and diseased brain warrant additional study.

45.2.4.1 Host-Specific Effects on Output of Encapsulated Cells

The available data suggest substantial variability in the *in vivo* performance of encapsulated cells even during the first few months. For example, there was a large range in dopamine and L-dopa output from explanted rodent-sized devices, from 0 to more than 50 pmol/device [56]. In fact, 15% of the devices from that study had no detectable output after only 4 months *in vivo*. Similar variability in device performance has been observed in the majority of *in vivo* studies. In a primate study that produced

therapeutic effects in two-thirds of the 1-methyl-4-phenyl-12,3,6 tetrahydropyridine (MPTP) monkeys implanted with PC12 cells, all five devices implanted in one monkey had virtually 0 output after explantation, while all five devices implanted in another monkey had relatively high output and all five devices in the third monkey had catecholamine output in the midrange [44]. These results suggest some of the variability in device performance may be attributable to individual differences between hosts, a result consistent with that reported for NGF output from encapsulated BHK cells implanted into the LV of rodents [57]. The exact mechanism for these individual differences remains undetermined but deserves serious attention.

45.2.5 DIFFUSION OF MOLECULES FROM POLYMER DEVICES

Tresco et al. [51] conducted a series of *in vivo* experiments to elucidate the relationship between diffusion of dopamine from encapsulated PC12 cells and behavioral recovery in dopamine-depleted rodents. Dopamine was detectable up to 200 μ m from PC12 cell-loaded macrocapsules, as determined by microdialysis, in concentrations similar to those seen in unlesioned control striatum. In contrast, the levels of dopamine in the perfusate of animals that did not exhibit behavioral recovery were undetectable. Immunocytochemistry was used to estimate the diffusion of NGF from encapsulated cell implanted into the striatum of rats [58]. One month after implantation, the diffusion of NGF was approximately 1 mm. Ciliary neurotrophic factor (CNTF) has also been reported to be detectable in the cerebrospinal fluid (CSF) of amyotrophic lateral sclerosis (ALS) patients receiving intrathecal implants of encapsulated CNTF-producing BHK cells [59]. In contrast, CSF levels of NGF were not detectable in nonhuman primates that received intraventricular grafts of NGF-producing cells [60]. At best, these data suggest that diffusion of molecules from encapsulated cells is limited. Moreover, the majority of degenerative CNS diseases will likely not be treatable by delivering drugs from the ventricular space given that diffusion of compounds in CNS tissue is generally severely limited when only governed by passive diffusion. Future work, particularly clinical studies, must seriously consider this issue when determining the optimal numbers and spacing of polymer devices.

45.3 CURRENT THERAPY USING ENCAPSULATED CELLS

Table 45.2 shows a summary of diseases currently being targeted by encapsulated cell therapy in different stages of investigation. While this list is quite extensive, we will concentrate the discussion on the CNS therapies with the highest level of characterization.

45.3.1 PARKINSON'S DISEASE

45.3.1.1 Effects of Catecholamine-Producing Cells

PD is an age-related neurodegenerative disorder characterized by hypokinesia, rigidity, and tremor secondary to the loss

TABLE 45.2
Diseases for Which Cell Encapsulation Is Being Applied

Disease/Model	Encapsulated Cell/Experimental Paradigm	Results
<i>Hormonal and whole organ diseases</i>		
Diabetes	Islets in rodents and dogs	Normoglycemia for 2 years
Hypoparathyroidism	Parathyroid tissue in rats	Normocalcemia for 30 weeks
Kidney failure	Orally delivered <i>Escherichia coli</i> bacteria to rats	Normalized urea metabolism
Growth hormone deficiency	Growth hormone producing cells in dogs	Hormone secretion for 1 year
<i>Single gene diseases</i>		
Hemophilia	Factor 9 cells in rats	Cell survival and secretion
Lysosomal storage disease	Beta-glucuronidase cells in mice	Behavioral normalization
<i>Age-related/neurodegenerative diseases</i>		
Age-related motor decline	Catecholamine and GDNF cells in rats	Improvement in motor function
Amyotrophic lateral sclerosis	CNTF producing cells in mice	Protection of motor neurons
Alzheimer's disease	NGF cells in rat and primates	Protection of cholinergic neurons, improved memory
Huntington's disease	NGF and CNTF cells in rat and primates	Protection of neurons, improved behavior
Parkinson's disease	Catecholamine and GDNF cells in rat and primate brain	Improved behavior, protection of dopaminergic neurons
Retinitis pigmentosa	Human cells secreting hCNTF into the vitreous	Rod preservation
Spinal cord damage	BDNF cells in rats	Outgrowth of neurites
<i>Oncology</i>		
Colon cancer	iNOS cells (tet-regulated system) in mice	Enhanced survival
Glioblastoma	Endostatin cells in mice and rats	Reduced tumor growth, enhanced survival
HER-2/neu positive tumors	IL-2 fused with anti HER-2/neu antibody in mice	Modest survival benefit
Leukemia	Hybridoma producing antibodies to p15E in mice	Enhanced survival
Ovarian cancer	iNOS cells (tet-regulated system) in mice	Enhanced survival, cures
<i>Other</i>		
Acute and chronic pain	Chromaffin cells in rats	Reduced pain
<i>Clinical trials</i>		
Amyotrophic lateral sclerosis	CNTF cells intrathecally	Sustained delivery, no toxicity
Chronic pain	Chromaffin cells in subarachnoid space	Prolonged cell survival, no pain reduction in phase II trials
Diabetes	Human islets intraperitoneally	Insulin independence for 9 months
Huntington's disease	CNTF cells into ventricles	Delivery for 6 months
Hypoparathyroidism	Parathyroid tissue	Successful in two patients
Pancreatic cancer	CYP2B1 cells in tumor vessel	Local tumor growth controlled, well tolerated
Retinitis pigmentosa	CNTF cells in eye	Ongoing

of dopaminergic neurons in the pars compacta of the substantia nigra. Replacing or increasing striatal dopamine levels with oral L-dopa significantly improves the motor deficits in the early stages of PD. Unfortunately, this pharmacological approach has limitations. Systemic administration results in drug distribution to extrastriatal dopamine receptors producing psychoses and vomiting. The therapeutic window of L-dopa's beneficial effects becomes progressively limited as the disease continues its degenerative course. Pulsatile delivery also seems to be associated with more adverse effects than continuous delivery [61]. Studies using pumps to deliver dopamine continuously and directly to the striatum in both rodent and primate models of PD have reported improved motor function with few adverse effects [62–64].

45.3.1.1.1 Rodent Studies

Given the promise of continuous, local L-dopa delivery to the striatum, several studies have detailed the effects of implanting encapsulated dopamine-producing cells into the striatum in rodents and primates (Table 45.3). Rats with PC12 cell-loaded capsules implanted in a 6-hydroxydopamine (6-OHDA) lesioned striatum exhibit fewer rotations after apomorphine administration than nonimplanted rats, which suggests that the devices are releasing catecholamines at levels sufficient to reduce the degree of synaptic supersensitivity that develops after dopamine-depleting lesions. Within 2 weeks following implantation, the number of apomorphine-induced rotations decreased 40%–50% and remained at that level for up to 6 months [51]. Reductions in rotational behavioral do not occur following

implants of empty polymer devices and are only evident in rats implanted in the denervated striatum and not in rats with devices implanted into the LVs [56,65]. The behavioral effects persist only as long as the devices remain in the striatum.

Measures of drug-induced rotations provide a convenient method for assessing potential efficacy, and significant information has been acquired using this initial preclinical screen. However, relying exclusively on changes in drug-induced rotations has limited clinical relevance and specificity. Accordingly, the effects of PC12 cells on a battery of non-drug-induced behaviors have been examined in 6-OHDA-lesioned rats. Neurological testing revealed behavioral deficits in the affected forelimb that were significantly attenuated by oral Sinemet® [56,66]. Since any transplantation procedure will be utilized as an adjunct to L-dopa administration, these data provided the opportunity to investigate the effects of PC12 cells on both relevant behavioral measures and on the therapeutic window of oral Sinemet. Rats with severe unilateral dopamine depletions received striatal implants of encapsulated PC12 cells and were evaluated on a series of behavioral tests over a range of doses of oral Sinemet. Delivery of L-dopa and dopamine from the encapsulated PC12 cells to the denervated striatum attenuated parkinsonian symptoms. The magnitude of the therapeutic effect produced by continuous, site-specific delivery of catecholamines was greater than the effect produced by acute, systemic oral Sinemet. The beneficial effects of oral Sinemet and striatal implants of PC12 cells were additive, but there were no adverse effects related to the implantation of the PC12 cells and these devices did not increase the adverse effects related to oral Sinemet [67]. Therefore, striatal implants of catecholamine-producing devices have direct therapeutic effects and perhaps more importantly and may widen the therapeutic window of oral Sinemet.

In addition to motor deficits produced experimentally by depleting nigrostriatal dopamine systems in young rodents, motor deficits are also observed with increased age. Age-related deficits in motor functions include deficits in balance, coordinated movement, and generalized locomotion. Enhancement of striatal dopamine function in aged animals by induction of dopamine receptor upregulation or administration of dopaminergic agonists can reduce age-related motor deficits. Since the motor deficits observed in aged rodents appear to be mediated partially by striatal dopamine systems, studies evaluated the potential efficacy of striatal implants of polymer-encapsulated PC12 cells on age-related motor dysfunction in rats [68]. In these studies, aged rats were significantly hypoactive relative to young animals. Moreover, compared to young rats the aged rats (1) remain suspended from a horizontal wire for less time, (2) are unable to descend a wooden pole covered with wire mesh in a coordinated manner, (3) fall more rapidly from a rotating rod, and (4) are unable to maintain their balance on a series of wooden beams with either a square or rounded top of varying widths. Following baseline testing, aged rats received bilateral striatal implants of empty capsules or PC12 cell-loaded capsules. Three weeks later, the aged rats that received PC12 cells showed a robust improvement in performance on the rotarod task and balance on the wooden beams.

45.3.1.1.2 Primate Studies

The studies conducted in the 6-OHDA rat model of PD generally support the clinical utility of encapsulated catecholamine-producing cells. Nonhuman primates are a more relevant model due to their size and complexity of the nervous system, which more closely approximates humans. In terms of tissue volume, diffusion through a rat brain is easier to accomplish than adequate diffusion through the much larger human brain. The nonhuman primate model allows

the assessment of therapeutic potential at this level in a way that cannot be approximated in rodents. The potential efficacy of encapsulated PC12 cells has been evaluated in a unilateral MPTP-lesioned primate model. Cynomolgus monkeys trained to perform a task that involved picking food from small food wells that were unilaterally lesioned with an injection of MPTP in the right carotid artery. The resulting MPTP-induced lesion produced a significant and stable impairment in the ability of the animals to use the contralateral limb to retrieve food rewards from the wells. The times required to empty the wells were measured for 3 months postlesion, and the monkeys were then implanted with a U-shaped device that was immediately filled with a suspension of PC12 cells [69]. Following implantation of the cells, manual dexterity was improved and the time required for the monkeys to empty the tray using the impaired hand gradually decreased. Although the PC12 cells attenuated the parkinsonian deficit in this task, some tremor remained and the animals did not recover to prelesion levels. Prior to the implantation of cells, the monkey's left arm was essentially immobile. After implantation, the monkeys could consistently move both their arm and use their fingers. When the cells were flushed out of the device, performance declined to preimplant levels. Together, these data indicated that encapsulated cells survived, were functional, and promoted behavioral recovery even in primate models of PD.

Similar results were obtained in a study by Kordower et al. [44] where four cynomolgus primates were trained on a skilled reaching task similar to that described above and then rendered hemiparkinsonian with an intracarotid injection of MPTP. Three animals received implants of encapsulated PC12 cells into both the caudate and putamen and one animal received implants of empty capsules and served as a control. After a transient improvement, limb use in the control monkey dissipated and returned to post-MPTP levels of disability. Two of the three PC12 cell implanted monkeys recovered on the task to near normal levels for up to 6.5 months posttransplantation. Capsules retrieved from the monkeys who recovered limb function contained abundant viable PC12 cells that continued to release L-dopa and dopamine. In contrast, capsules retrieved from the monkey that did not recover contained few viable PC12 cells. Neuroanatomical and neurochemical evaluation of the implanted striatum failed to reveal any host-derived sprouting of catecholaminergic or indolaminergic fibers, which further suggested that the observed behavioral recovery was due to secretion of catecholamines from the encapsulated PC12 cells.

45.3.1.2 Effects of Neurotrophic Factor-Producing Cells

Several studies have investigated the ability of encapsulated neurotrophic factor-secreting cells to exert neurotrophic effects in rodent models of PD [70–72]. In an initial study [71], encapsulated cells releasing approximately 5 ng of glial derived neurotrophic factor (GDNF)/day were implanted immediately rostral to the substantia nigra. The medial forebrain

bundle was transected 1 week later and the ability of encapsulated GDNF-producing cells to minimize the behavioral effects of the lesion and prevent the degeneration of dopaminergic neurons was determined. GDNF treatment reduced the numbers of amphetamine-induced rotations in lesioned animals and attenuated the loss of neurons in the substantia nigra but had no effect on striatal dopamine levels. Using the same model system, neurturin-producing cells, a homologue of GDNF, were investigated for its neurotrophic activity [72]. Neurturin-treated animals had significantly more TH-positive neurons in the substantia nigra (51% compared to 16% in controls) but failed to show any behavioral improvement as measured by rotational behavior. Together, these data suggest that encapsulated cells may have a role in neurotrophic therapy for PD. However, additional studies in animal models are required to determine the relationship between the anatomical and behavioral consequences of cell-based delivery.

45.3.1.2.1 Encapsulated Neurotrophic Factor-Producing Cells to Enable Survival of Unencapsulated Cografts

The transplantation of encapsulated genetically modified cells also represents a potential means of delivering trophic factors to the brain to support the survival of cografied cells or tissue. In a series of studies, NGHF-secreting BHK cells were encapsulated and implanted into the left LV or the left striatum of hemiparkinsonian rats approximately 1.5 mm away from cografied unencapsulated adrenal medullary chromaffin cells [73]. Although the animals receiving adrenal medulla alone or adrenal medulla with intraventricular NGF-secreting cell grafting did not show recovery of apomorphine-induced rotational behavior, the animals receiving adrenal medulla with intrastriatal NGF-secreting cell implants showed a significant recovery of rotational behavior 2 and 4 weeks after transplantation. Histological analysis revealed that intraventricular NGF increased the number of surviving chromaffin cells five to six times above that seen in animals receiving adrenal medulla alone. Even more impressively, intrastriatal NGF-secreting cells increased the number of surviving chromaffin cells by more than 20 times than that in animals receiving adrenal medullary cells alone. The beneficial effects of NGF-producing cells were evident for as long as 12 months post-grafting (i.e., the longest time point examined) and were independent of the age of the chromaffin cell donor [54,74]. These results indicate the potential use of intrastriatal implantation of encapsulated NGF-secreting cells for augmenting the survival of cografied chromaffin cells as well as promoting the functional recovery of hemiparkinsonian rats.

45.3.2 ENCAPSULATED NGF-PRODUCING CELLS IN ANIMAL MODELS OF ALZHEIMER'S DISEASE

AD affects approximately 5% of the population over the age of 65 and is the most prevalent form of adult-onset dementia. The most prominent feature of AD is a progressive deterioration of cognitive and mnemonic ability, which is at least partially related to the degeneration of basal forebrain cholinergic

neurons. Treatments do not slow or prevent cholinergic neuron loss or the associated memory deficits. Several converging lines of evidence indicate that NGF has potent target-derived trophic and tropic effects upon cholinergic basal forebrain neurons [75,76].

45.3.2.1 Rodent Studies

Although no model faithfully recapitulates the complex etiology and time-dependent loss of cholinergic neurons seen in AD patients, model systems have been developed to determine if NGF prevents the death of damaged cholinergic neurons following trauma. Initial studies determined whether encapsulated NGF-secreting BHK cells (Figure 45.4) could prevent cholinergic neuron loss following aspiration of the fimbria/fornix [77]. Rats received lesions followed by intraventricular implants of either NGF-producing or control (nontransfected) cells. Control-implanted animals had an extensive loss (88%) of ChAT-positive cholinergic neurons ipsilateral to the lesion that was prevented by NGF cell implants (14% loss).

One of the cardinal behavioral symptoms of AD is a progressive loss of cognitive ability. Just as no animal model faithfully mimics the complex etiology and pathophysiology of AD, comparable behavioral abnormalities are difficult to reproduce in animal models. However, the aged rodent shows a progressive degeneration of basal forebrain cholinergic neurons together with marked cognitive impairments that are partly reversible by administering NGF. Lindner et al. [57] trained 3-, 18-, and 24-month-old rats on a spatial learning task in a Morris water maze (Figure 45.5). Cognitive function, as measured in this task, declined with age. Following training, animals received bilateral intraventricular implants of encapsulated NGF or control cells. The 18- and 24-month-old animals receiving NGF cells showed a significant improvement in cognitive function. No improvements or deleterious effects were observed in the young nonimpaired animals. There was no evidence that the NGF cells produced changes in mortality, body weights, somatosensory thresholds, potential hyperalgesia, or activity levels, suggesting that the levels of NGF produced were neither toxic nor harmful to the aged

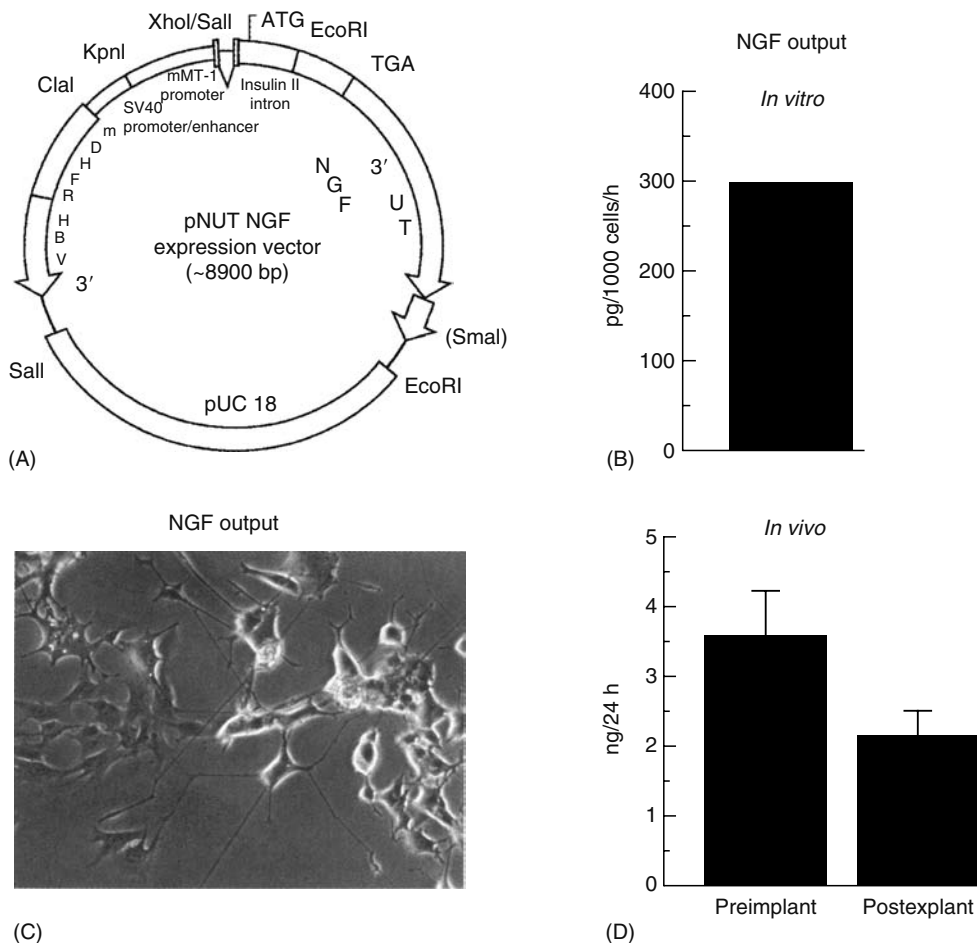

FIGURE 45.4 (A) Expression vector containing the human NGF gene. (B) NGF levels, as determined by ELISA, in unencapsulated (top) and encapsulated (bottom) BHK cells. The *in vivo* levels were determined from devices 3 months following explant from rodent striatum. (C) The biological activity of the NGF from encapsulated BHK cells is shown in phase-contrast photomicrographs of PC12 cells that exhibit extensive neurite processes. Original magnification = 25 μm.

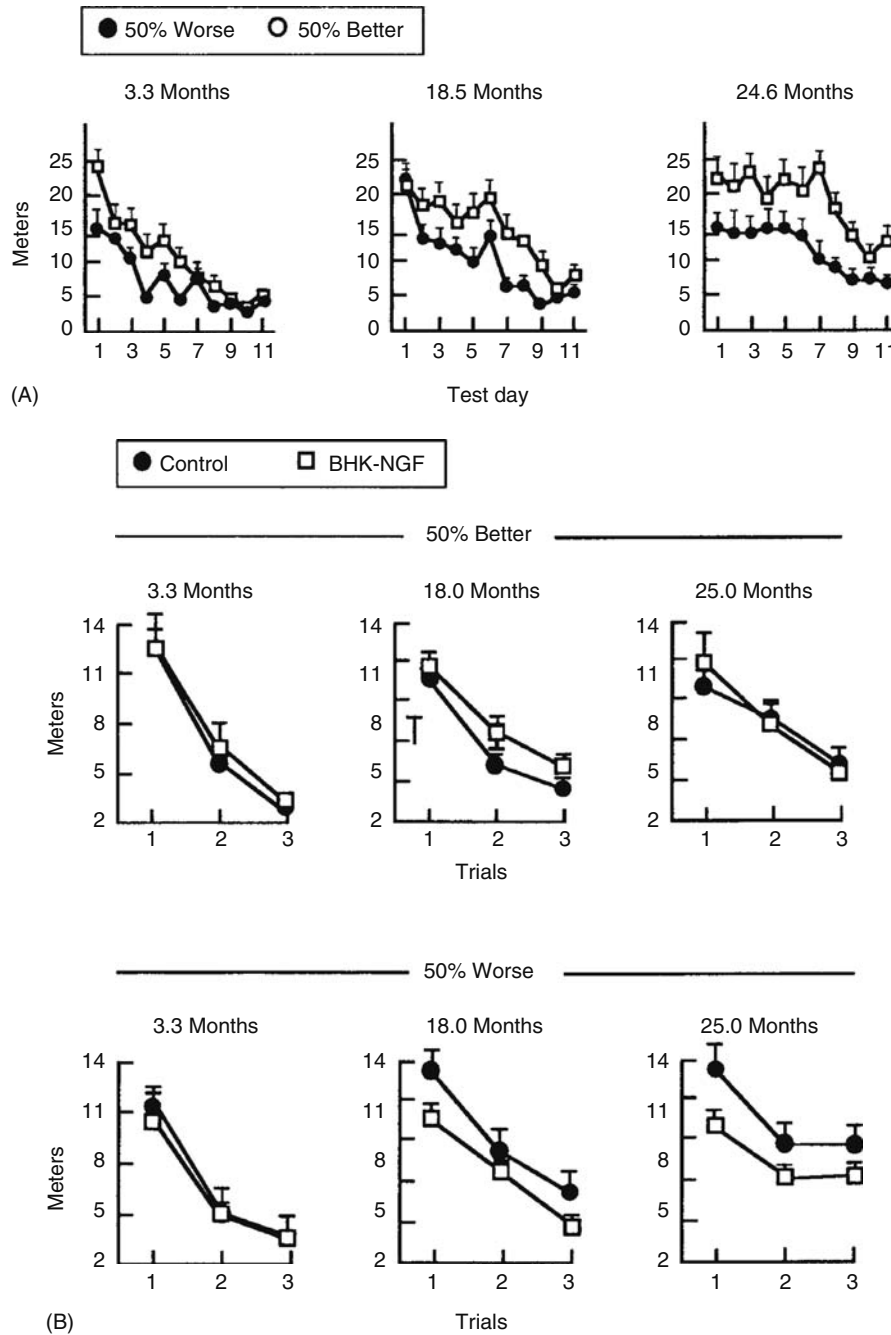

FIGURE 45.5 Cognitive function in young, middle-aged, and aged rats following implantation of encapsulated NGF-producing cells into the LVs. (A) Prior to implantation, animals were divided into the 50% worse and 50% better performers in a water maze task. (B) Following implantation, NGF was found to improve performance in the middle-aged and aged animals. Moreover, the improvements in cognitive performance were greatest in those animals that demonstrated the worst initial performance.

rats. Evidence of age-related atrophy of cholinergic neurons was observed in the striatum, medial septum, nucleus basalis, and vertical limb of the diagonal band. These anatomical changes were most severe in animals with the greatest cognitive impairments, suggesting a link between the two pathological processes. Anatomically, the NGF released from the encapsulated cells increased the size of the atrophied basal forebrain and striatal cholinergic neurons to the size of the neurons in the young healthy rats.

45.3.2.2 Primate Studies

Results similar to those obtained in rodents were obtained in nonhuman primates [60], an essential prerequisite to human clinical trials (Figure 45.6). Cynomolgus primates received transections of the fornix followed by placement of encapsulated NGF-secreting BHK or control cells into the LV. In the control animals, a significant reduction in the number of cholinergic neurons was observed in the medial septum and vertical limb of the diagonal band of Broca. Again, loss of

FIGURE 45.6 Photomicrographs through the septal diagonal band complex of cynomolgus monkeys. Monkeys received a fornix transection together with polymer-encapsulated implants of either BHK-control (A) or a BHK-NGF cells (B). Note the extensive loss of NGF receptor positive neurons ipsilateral to the lesion (right) in the control-implanted monkeys. In contrast, numerous NGF cholinergic neurons were observed in fornix transected monkeys receiving the BHK-NGF implant. High-power photomicrographs illustrating the morphology of cholinergic neurons within the medial septum of young monkeys receiving BHK-NGF (C–E) implants. Note the enlarged perikarya and extensive neuritic arbor displayed by monkeys receiving the BHK-NGF implants.

cholinergic neurons was prevented by implants of NGF-secreting cells. It also appeared that cholinergic neurons within the medial septum of NGF-treated animals were larger, more intensely labeled, and elaborated more extensive proximal dendrites than those displayed by BHK-control animals.

In addition to the effects on cell viability, NGF implants induced a robust sprouting of cholinergic fibers proximal to the implant site [60]. All monkeys receiving NGF implants displayed dense collections of NGF receptor-immunoreactive fibers throughout the dorsoventral extent of the lateral septum. This effect was unilateral as the contralateral side displayed only a few cholinergic fibers in a manner similar to that seen in control-implanted monkeys. The cholinergic nature of this sprouting was confirmed by an identical pattern of fibers that

were ChAT-immunoreactive and AChE-positive. These fibers ramified against the ependymal lining of the LV adjacent to the transplant site and were particularly prominent within the dorsolateral quadrant of the septum corresponding to the normal course of the fornix. The cell sparing and sprouting results have been replicated (Figure 45.7) in a group of aged nonhuman primates [78].

45.3.3 POLYMER-ENCAPSULATED CELLS TO DELIVER NEUROTROPHIC FACTORS IN ANIMAL MODELS OF HD

HD is an inherited, progressive neurological disorder characterized by a severe degeneration of basal ganglia neurons, particularly the intrinsic neurons of the striatum. Accompanying

FIGURE 45.7 Sprouting of cholinergic fibers in young (A,B) and aged (C,D) NGF-treated monkeys. Low (A,C) and high (B,D) power photomicrographs of NGF receptor immunostained sections illustrating a dense plexus of cholinergic fibers on the side of NGF treatment (arrows) adjacent to the LV. Scale bar in (A) = 1000 μ m for (A) and (C), scale bar in (D) = 50 μ m for (B) and (D).

the pathological changes is a progressive dementia coupled with uncontrollable movements and abnormal postures. From the time of onset, an intractable course of mental deterioration and progressive motor abnormalities begins with death usually occurring within 15–17 years. Overall, the prevalence rate of HD in the United States is approximately 50 per 1,000,000. There is no treatment that effectively addresses the behavioral symptoms or slows the inexorable neural degeneration in HD.

Intrastratial injections of excitotoxins such as quinolinic acid (QA) are a useful model of HD and can serve to evaluate

novel therapeutic strategies aimed at preventing, attenuating, or reversing neuroanatomical and behavioral changes associated with HD [79–82]. The use of trophic factors in a neural protection strategy may be particularly relevant for the treatment of HD. Unlike other neurodegenerative diseases, genetic screening can identify individuals at risk providing an opportunity to design treatment strategies to intervene prior to the onset of striatal degeneration.

45.3.3.1 Rodent Studies

Infusions of trophic factors such as NGF or implants of cells genetically modified to secrete NGF have proven effective in preventing the neuropathological sequelae, resulting from intrastratial injections of excitotoxins including QA [83–86]. We [87,88] examined the ability of encapsulated trophic factor-secreting cells to affect central striatal neurons in a series of defined animal models of HD. In these experiments, rats received intraventricular implants of encapsulated NGF- or CNTF-producing cells (Figure 45.8). One week later, the same animals received unilateral injections of QA (225 nmol) or the saline vehicle into the ipsilateral striatum. An analysis of Nissl-stained sections demonstrated that the size of the lesion was significantly reduced in animals receiving NGF and CNTF cells relative to controls. Moreover, CNTF cells attenuated the extent of host neural damage produced by QA as assessed by a sparing of cholinergic, diaphorase-positive and GABAergic neurons (Figure 45.9). Neurochemical analyses confirmed the protection of multiple striatal cell populations using this strategy. Importantly, behavioral studies offer additional and compelling evidence of neuronal protection that can be produced in animal models of HD. Trophic factor-secreting cells have provided extensive behavioral protection as measured by tests that assess both gross and subtle movement abnormalities. Moreover, these same animals show improved performance on learning and memory tasks, indicating the anatomical protection afforded by trophic factors in this model is paralleled by a robust and relevant behavioral protection [89].

45.3.3.2 Primate Studies

The ability of cellularly delivered trophic factors to preserve neurons within the striatum in a rodent model of HD led to similar studies in nonhuman primates [90]. Polymer capsules containing CNTF-producing cells were grafted into the striatum of Rhesus monkeys. One week later, a QA injection was placed into the putamen and caudate proximal to the capsule implants. As seen in the rodent studies, the volume of striatal damage was decreased and both GABAergic and cholinergic neurons destined to degenerate were spared in CNTF-grafted animals. Although all animals had significant lesions, there was a threefold and sevenfold increase in GABAergic neurons in the caudate and putamen, respectively, in CNTF-grafted animals relative to controls. Similarly, there was a 2.5-fold and fourfold increase in cholinergic neurons in the caudate and putamen, respectively, in CNTF-grafted animals (Figure 45.10).

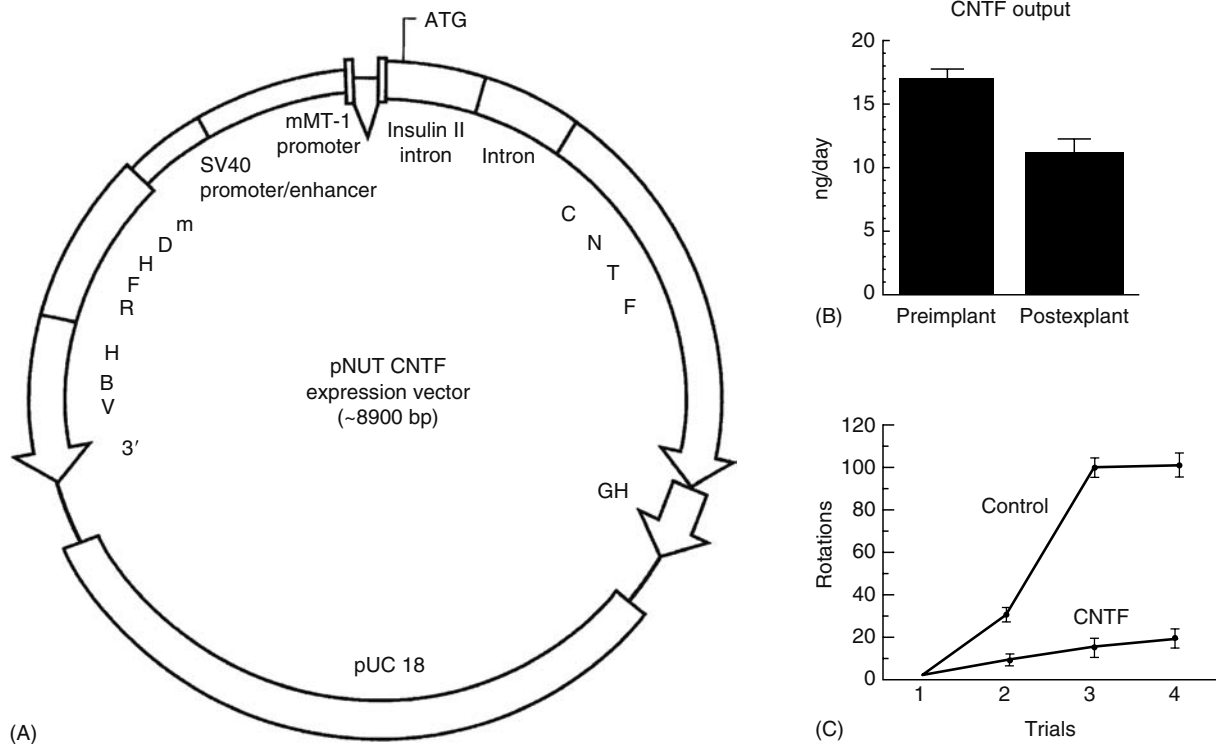

FIGURE 45.8 (A) Expression vector containing the human CNTF gene. (B) CNTF levels, as determined by ELISA, in encapsulated BHK cells immediately prior to implantation (left) and immediately following retrieval from rodent LV 70 days following implantation (right). (C) Implants of encapsulated CNTF producing cells reduce apomorphine rotations in rats after unilateral striatal injection of QA.

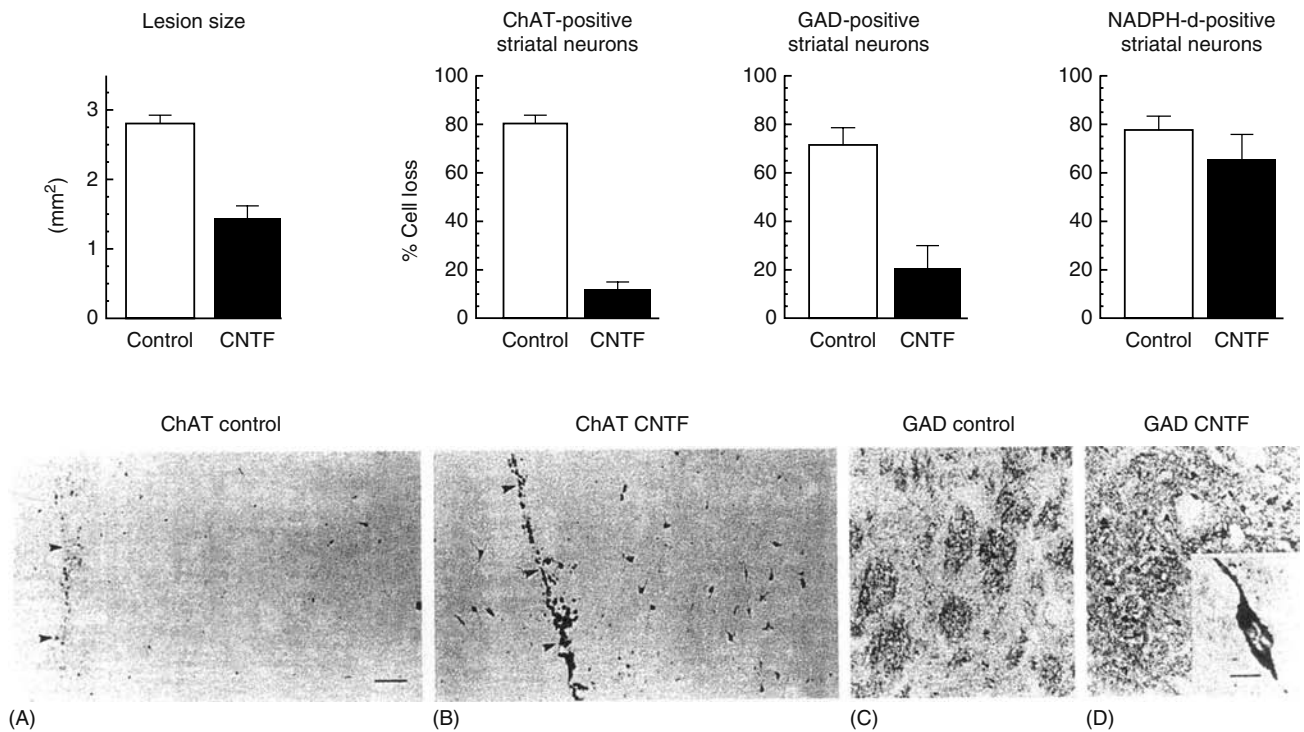

FIGURE 45.9 Lesion volume and neuronal cell counts in QA-lesioned rats. Control-implanted animals displayed a marked lesion volume (A) determined by Nissl staining and a significant loss of multiple types of striatal cell types including cholinergic (B), GABAergic (C), and diaphorase-positive neurons (D). The cholinergic and GABAergic neuronal losses were largely prevented in animals receiving CNTF implants, while the loss of diaphorase-positive neurons was not affected. In each case, data are presented as a percent loss of neurons on the lesioned/implanted side compared to intact contralateral side. Representative photomicrographs for cholinergic and GABAergic cells are shown for both control and CNTF-implanted animals. Note the appearance of numerous healthy appearing cholinergic and GABAergic neurons in the CNTF-treated animals. Scale bar in ChAT control = 500 μ m for ChAT control/CNTF and scale bar in insert = 100 μ m for GAD control/CNTF and 17 μ m.

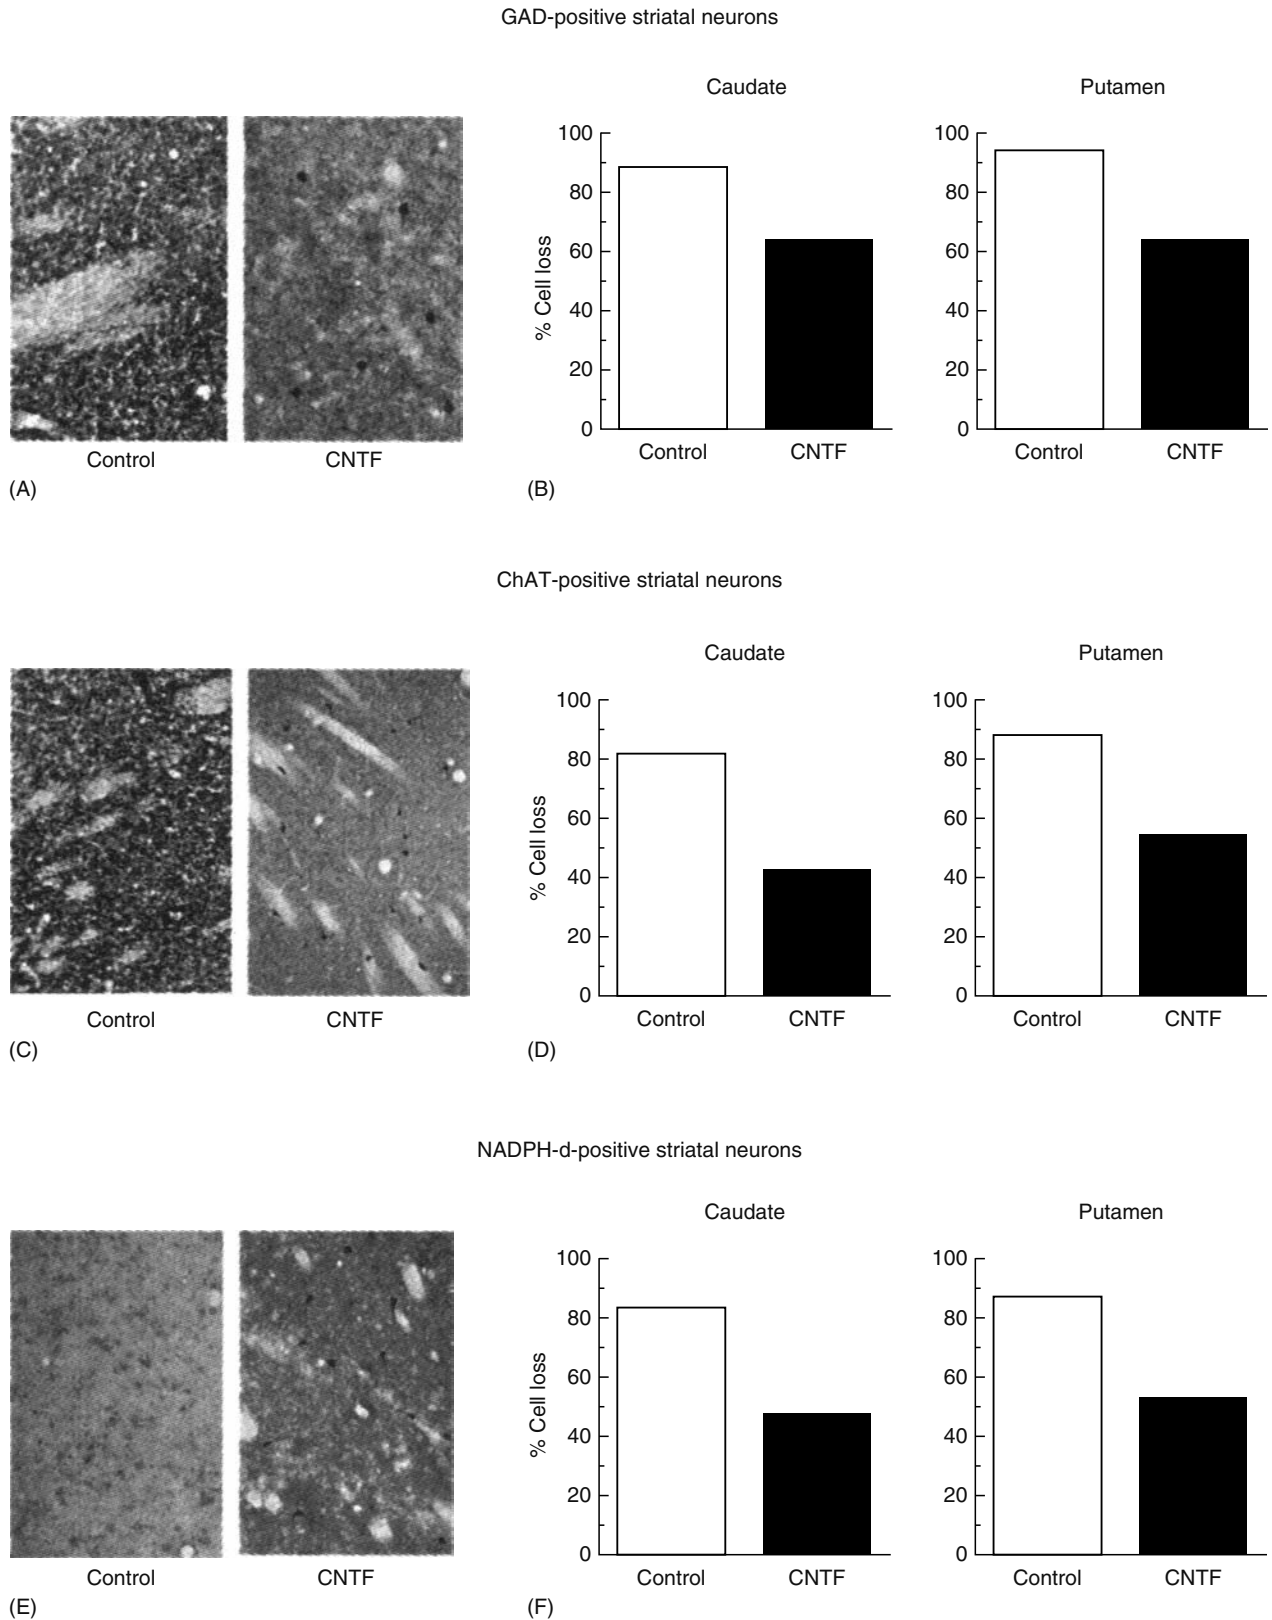

FIGURE 45.10 Neuronal cell counts in QA-lesioned monkeys. Control-implanted animals displayed a significant loss of multiple types of striatal neurons including GABAergic (A and B), cholinergic (C and D), and diaphorase-positive neurons (E and F). Although neuronal loss was still present in animals receiving CNTF implants, it was significantly attenuated in both the caudate and putamen. In each case, data are presented as a percent of neurons on the lesioned/implanted side compared to the intact contralateral side. Representative photomicrographs for all three cell types are shown for both control and CNTF-implanted animals (A = GABAergic, C = cholinergic, and E = diaphorase-positive neurons).

The ability to preserve GABAergic neurons in animals models of HD is an important, though not entirely sufficient, step to develop a useful therapeutic. If the perikarya are preserved without sustaining their innervation, then the experimental therapeutic strategy under investigation is not likely to yield significant value. The striatum is a central station in a series of loop circuits that receive inputs from all of the neocortex, projecting to a number of subcortical sites, and then returns information flow to the cerebral cortex. One critical part of this circuitry is the GABAergic projections to the globus pallidus and substantia nigra pars reticulata, the parts of the direct and indirect basal ganglia loop circuits. The integrity of this circuit can be evaluated immunocytochemically using an antibody that recognizes GABAergic terminals (DARPP-32) to determine if the preservation of GABAergic somata within the striatum also results in the preservation of the axons of these neurons to critical extrastriatal sites. Using quantitative morphological assessment of DARPP-32 optical density, monkeys receiving QA lesions had significant reductions in DARPP-32 immunoreactivity within the globus pallidus and substantia nigra. The lesion-induced decrease in GABAergic innervation for both of these regions was prevented in CNTF-grafted monkeys (Figure 45.11), demonstrating that this treatment strategy protected GABAergic neurons and sustained their normal projection systems [90].

The intrinsic striatal cytoarchitecture can be preserved in monkeys by CNTF grafts, and once exposed to these grafts, the cells apparently maintain their projections. But are the afferents to the striatum, specifically from the cerebral cortex, also influenced by these grafts? This may be particularly critical if some of the more devastating nonmotor symptoms seen in HD result from cortical changes secondary to striatal degeneration. Since layer V neurons from motor cortex send a dense projection to the postcommissural putamen, a region that was severely impacted by the QA lesion, the effects of QA lesions and CNTF implants on the number and size of cortical neurons in this region were examined. Although the QA lesion did not impact the number of neurons in this cortical area, layer V neurons were significantly reduced in cross-sectional area on the side ipsilateral to the lesion in control-grafted monkeys. This atrophy of cortical neurons was reversed by CNTF grafts [90].

A recent set of studies using CNTF producing cells in 3NP-treated monkeys have replicated and extended these results [91]. Following 10 weeks of 3NP treatment, monkeys displayed pronounced chorea and severe deficits in frontal lobe cognitive performance as assessed by the object retrieval detour test. Following implantation of CNTF-producing cells, a progressive and significant recovery of motor and cognitive recovery occurred. Histological analysis demonstrated that

FIGURE 45.11 Photomicrographs of Nissl-stained sections through the striatum of monkeys that received QA injections into the striatum followed by implants of encapsulated CNTF producing (A) or control (B) BHK cells. A paucity of healthy neurons is observed in the striatum of control monkeys that is in stark contrast to the numerous healthy appearing neurons seen in the same region of the CNTF-treated monkeys. Together with the sparing of striatal neurons is a preservation of the GABAergic projection from the striatum to the globus pallidus. DARPP-32 immunocytochemistry revealed an intense, normal appearing immunoreactivity within both the external and internal segments of the globus pallidus of CNTF-treated animals (C). In contrast, DARPP-32 immunoreactivity is reduced in control-implanted animals as a consequence of the lesion (D). Quantitative analysis confirmed the sparing of this projection in CNTF-treated monkeys.

CNTF was neuroprotective and spared NeuN and calbindin-positive cells in the caudate and putamen.

While the sparing of striatal neurons and maintenance of intrinsic circuitry are impressive, the effect is less than that seen in rodents. In primates, robust protection is limited to the area of the capsules and the total area of the lesion remains extensive, likely because the diffusion of CNTF from the capsule is not sufficient to protect more distant striatal regions undergoing degeneration. This concept is supported by a recent experiment examining the effects of intraventricular grafts of encapsulated CNTF grafts in the nonhuman primate model of HD [92]. In contrast to when the capsules were placed directly within brain parenchyma, intraventricular placements failed to protect any striatal cell types. The complete lack of neuroprotection provided by intraventricular implants in primates should be considered more carefully in clinical trials where encapsulated cells have to date been placed into the LVs of HD patients [93,94]. If human trials are to yield clinically relevant positive effects, the means of CNTF delivery utilized in these studies needs to be improved. Whether this entails grafting more capsules, enhancing the CNTF delivery from the cells by changing the vector system or cell type employed or changing the characteristics of the polymer membrane remains to be determined.

45.3.4 ENCAPSULATED CELLS FOR TREATING BRAIN TUMORS

Malignant tumors of the brain represent 2%–3% of all adult neoplasms occurring in up to 9 in 100,000 individuals. Gliomas account for approximately half of all primary brain tumors. Despite the continued refinement of neuroimaging techniques, progress in microsurgery and evolving chemotherapeutic drugs, the prognosis for glioma patients is poor with a median survival of around 1 year. Surgical debulking of the growing tumor mass is the primary treatment modality. While surgery provides short-term improvement for subsequent treatments it is ultimately ineffective because of the infiltrative nature of glioma resulting in tumor recurrence neighboring the resection margin.

If a means of delivering therapeutic molecules directly to the region of tumor recurrence could be developed, then the prognosis for glioma patients might be significantly improved. Cell encapsulation has recently been suggested as one means of achieving this goal [95–102]. While the majority of the data obtained so far utilizes microencapsulation techniques, the data sufficiently intriguing to be presented here. Of particular relevance to glioma, recent studies demonstrate that experimental gliomas could be successfully treated with endostatin-producing alginate encapsulated cells. In one study, BT4C glioma cells and endostatin-producing capsules were implanted into the brains of syngeneic rats [99]. The encapsulated cells survived well and secreted endostatin for up to 4 months *in vivo*. Survival was increased by 84% relative to control animals. Histological assessment of the transplant revealed that the endostatin-producing cells produced cellular apoptosis and the formation of large necrotic areas within the

treated tumors. The treatment was otherwise reportedly well-tolerated with no serious side effects. These data were supported by a similar study in nude mice. Endostatin-producing BHK cells were encapsulated into alginate microspheres and injected 10 days prior to a subcutaneous injection of U87 glioma cells. At 21 days posttreatment, the growth of the glioblastoma xenografts was reduced with less neovascularization surrounding the tumor [96]. Similar results have been achieved using encapsulated kidney 293 cells modified to produce endostatin [103]. Intravital video microscopy revealed reductions in the density, diameter, and function of tumor-associated microvessels.

Another approach to treating glioma uses encapsulated cells to enable gene transfer *in vivo*. Martinet et al. [98] encapsulated mouse psi20VIK packaging cells into alginate microspheres. The capsules were then stereotaxically injected into established C6 glioblastomas and the animals were treated with gancyclovir. After 14 days, the tumors were harvested and it was determined that 3%–5% of the tumor cells had been transduced, resulting in a 45% reduction in tumor volume.

Together, these data represent a young but encouraging application of encapsulated cell therapy. The ability of cell-based therapies to provide continuous, local delivery of a wide range of therapeutic molecules will likely lead to further refinements in this area. Still, as recently pointed out [101], optimization of capsule biostability, tissue biocompatibility, cell choice and viability, dose-release, and biodistribution of therapeutic molecules represent unresolved areas of preclinical research.

45.3.5 ENCAPSULATED CELLS FOR RETINITIS PIGMENTOSA

Retinitis pigmentosa (RP), an inherited degenerative disease of the retina, affecting roughly 1 out of 4000 individuals worldwide and is the sixth leading cause of blindness [104]. The disease progresses slowly from mild degeneration of the rod photoreceptors in the periphery to a more pronounced loss of vision involving the cones in the central retina. The end result is complete blindness that occurs on the order of months or years depending on the etiology of the disease.

RP is a disease with an extremely complex genetic profile, and over 100 rp-inducing mutations have been identified to date [105]. While there has been progress on this front, the influence of genetic medicine on the development of therapeutics for RP continues to be minimal. Current clinical strategies focus on optimization of the light path (lens replacements) and treatment of secondary effects of the disease. Work in the field of protein therapeutics, specifically neurotrophic factors, has led to the use of CNTF as a potential neuroprotective mediator of RP. For example, in the *rd* rodent model of retinal degeneration, it was shown that gene transfer of CNTF retarded the degeneration of photoreceptors [106,107]. Purified CNTF also slows photoreceptor degeneration in the *rd/rd* and *nr/nr* murine models of the disease [108]. Because of the relatively short half-life of the recombinant protein and the immunoprivileged environment of the eye, encapsulated cell technology is an extremely attractive mode of delivery for CNTF and other potential protein therapeutics to the eye.

More recently, retinal epithelial cells have been transfected with a plasmid containing the CNTF gene. CNTF is released *in vivo* at a rate of approximately 1.5 ng/day. Initial efficacy studies with the CNTF-producing cell line were carried out in s334ter-3 transgenic rats [109]. Naked cells were injected into the vitreous of rat eyes and after 20 days, eyes were enucleated and processed for histology. While untreated eyes or eyes injected with the nontransfected parental cell line showed severe progression of retinal degeneration (about one row of the outer nuclear layer [ONL] remaining), eyes treated with the CNTF-secreting cell line showed five to six times thicker ONL throughout the retina.

The canine *rcdl* model for retinal degeneration [110,111] was used to evaluate the device loaded with the CNTF-secreting cell line [109]. In this experiment, various amounts and combinations of parental cells and secreting cells were used to achieve five different doses between <100 pg/day to 15 ng/day. Again, as with the work in rodents, neuroprotection was shown to occur, and in this case, it was dose-dependent. Untreated eyes showed on average three layers of the ONL, while treated eyes showed between three and six layers. In all cases, the distribution of retinal preservation was homogenous throughout the retina.

45.4 INITIAL CLINICAL TRIALS

45.4.1 AMYOTROPIC LATERAL SCLEROSIS

Neuromuscular disorders such as ALS are marked by a progressive degeneration of spinal motor neurons. Different families of neurotrophic factors demonstrate therapeutic potential *in vitro* and in animal models of motor neuron disease [112–119]. The cytokine CNTF has neuroprotective effects for motor neurons in *wobbler* mice [116] and homozygote pmn (progressive motor neuropathy) mice [117,118]. The delivery of CNTF to motor neurons by peripheral administration proved difficult due to severe systemic side effects, short half-life of CNTF, and the inability of CNTF to cross the BBB [120–122].

Continuous intrathecal delivery of CNTF proximal to the nerve roots in the spinal cord is a practical alternative that could result in less side effects and better efficacy of CNTF in ALS patients. After safety, toxicology, and preclinical evaluation [123], a clinical trial to establish safety has been performed in ALS patients using polymer-encapsulated cells genetically modified to secrete CNTF [124]. A total of six ALS patients with early stage disease indicated by a forced vital capacity greater than 75% with no other major illness or treated with any investigational drugs for ALS were included. These patients were baseline tested for Tufts Quantitative Neuromuscular Evaluation, the Norris scale; blood levels of acute reactive proteins, and CNTF levels in the serum and CSF. BHK cells were encapsulated into 5 cm long by 0.6 mm diameter hollow membranes and implanted into the lumbar intrathecal space. The device included a silicone tether that was sutured to the lumbodorsal fascia and the skin was closed over the device. CNTF concentrations in the CSF

were not detectable prior to implantation, but were found in all six patients at 3–4 months postimplantation. All six explanted devices had viable cells and CNTF secretion of approximately 0.2–0.9 µg/day. No CNTF was detected in the serum. More recently, a phase I/II clinical trial was initiated in 12 ALS patients using the same approach. Again, CNTF was detectable for several weeks in the CSF of 9 out of 11 patients. Concurrent *in vitro* studies using CSF samples from these same patients revealed only a very weak antigenic immune response with bovine fetuin as the main antigenic component [125].

45.4.2 CHRONIC PAIN

Numerous studies with rodent models of acute and chronic pain have suggested that adrenal chromaffin cells implanted into the intrathecal space and in the periaqueductal gray reliably produce significant analgesic effects [126,127]. While the majority of these studies have used unencapsulated cells, recent studies suggested that encapsulated cell implants also produce analgesia in rats. The analgesic effects of adrenal chromaffin cells in rodent model have provided the rationale to pursue clinical trials in patients with chronic pain. Small, open label trials demonstrated that the implantation procedure was minimally invasive and well tolerated [128,129]. Neurochemical and histological studies determined that the encapsulated cells survived and were biochemically functional for up to 1 year. Because reductions in morphine intake were noted following implantation (suggesting efficacy), larger scale, randomized studies were initiated in a collaborative study between CytoTherapeutics and Astra Pharmaceuticals. The trials were recently halted because the efficacy achieved did not reach a level high enough to warrant further study [130].

Interestingly, several recent reports indicate encapsulated adrenal chromaffin cell implants may not produce efficacy as originally suggested [131–133]. Extensive studies in acute and chronic rodent pain models have failed to find any evidence of analgesia. This lack of effect occurred under conditions that were apparently designed to exactly reproduce previous testing procedures that did demonstrate efficacy. Among the variables examined were the location of implant (intrathecal vs. intraventricular), a wide range in cell preparation techniques, and an exhaustive battery of acute and chronic pain tests with and without nicotine stimulation. Importantly, the authors reported that systemic administration of morphine produced significant analgesia when tested in parallel in the same models. While subtle testing differences cannot be ruled out as contributing factors in the differences between these recent and previous studies, together with the only well controlled clinical trial conducted to date, it appears that, at the least, adrenal chromaffin cells do not produce analgesic effects as consistently as previously reported.

45.4.3 HUNTINGTON'S DISEASE

Recently, clinical trials were completed to determine the safety and tolerability of CNTF-producing cells (0.15–0.50 µg

CNTF/day) implanted into the LV of HD patients [134,135]. HD symptoms were also analyzed using neuropsychological, motor, neurological, and neurophysiological tests and the striatal pathology monitored using MRI and PET scan imaging. Six subjects with stage 1 or 2 HD had one capsule implanted into the right LV; the capsule was retrieved and exchanged for a new one every 6 months over a total period of 2 years. No sign of CNTF-induced toxicity was observed; however, depression occurred in three subjects after removal of the last capsule, which may have correlated with the lack of any future therapeutic option. All retrieved capsules were intact but contained variable numbers of surviving cells, and CNTF release was low in 13 of 24 cases. Improvements in electrophysiological results were observed and were correlated with capsules releasing the largest amount of CNTF. This phase I study shows the safety, feasibility, and tolerability of this gene therapy procedure. Heterogeneous cell survival, however, stresses the need for improving the technique.

45.4.4 RETINITIS PIGMENTOSA

Phase I clinical studies have just been completed examining the safety of encapsulated CNTF-secreting cells surgically implanted into the vitreous of the eye. The trial restricted study participants to RP patients with 20/100 vision or less, a central visual field diameter of 40° or less, and a flicker ERG amplitude of 2 μ V or less. Ten participants received CNTF implants in one eye. When the implants were removed after 6 months, they contained viable cells with minimal cell loss and gave CNTF output at levels previously shown to be therapeutic for retinal degeneration in *rd1* dogs. Although the trial was not powered to demonstrate clinical efficacy, of seven eyes for which visual acuity could be tracked by conventional reading charts, three eyes reached and maintained improved acuities of 10–15 letters, equivalent to two- to three-line improvement on standard Snellen acuity charts. This phase I trial indicated that CNTF is safe for the human retina even with severely compromised photoreceptors [136]. Neurotech is currently progressing to a multicenter phase II clinical trial.

45.5 CONCLUSIONS AND FUTURE DIRECTIONS

There is considerable promise of encapsulated cell therapy for treating a wide range of CNS disorders. Still, a number of research avenues exist, which are incompletely explored and deserve attention. In some preclinical studies, the extent of diffusion from the implants appears to limit the therapeutic effectiveness of the encapsulated cells [51,58]. Given the size of the human brain relative to the rodent and nonhuman primate brain, the potential problems related to limited tissue diffusion should be examined empirically.

Encapsulation allows the use of cells from human and animal sources with and without genetic modification. In theory, the capsule should isolate the cells from the surrounding tissue. Still, should a capsule rupture during implantation or retrieval, a deleterious host immunological response could

be induced. Though the host immune system should reject any released cells following capsule damage, the potential for tumor growth remains. Alterations in the ability of the host immune system to reject cells following damage to implants could also change upon long-term residence of the cells within the host. To date, no studies have systematically evaluated these risks, particularly with regard to the long-term effects of encapsulated cell implants. Again, large animal studies using intact and intentionally damaged devices would provide a useful starting point for evaluating these issues. These studies could use normal and immunosuppressed animals and evaluate potential tumorigenicity and changes in the host immune system over long periods of time.

Regulation of dosage is another area that deserves attention. In its most basic iteration, varying the numbers of cells within an implant, the size of the implant, or the use of multiple implants, may permit a range of doses to be delivered. While some long-term cell survival studies have been conducted, they tend to utilize only CSF-filled spaces and have not systematically examined cell survival and output of the desired molecule over long periods of time. Rather, studies have provided a “snapshot” of survival and output at a single time point. Large, long-term, well-controlled studies need to be conducted to examine the relationship between variables that include time, cell survival, gene expression (when modified cells are used), neurochemical output, the initial numbers of cell encapsulated, and the type of semipermeable membrane and ECM used for encapsulation. Obviously, such studies are time-consuming and expensive. But without them, the conditions optimal for successful cell encapsulation will remain speculative.

Another area that has attracted very little attention concerns the variability in the *in vivo* performance of encapsulated cells and the possible role that the host tissue environment plays in this variability. As discussed earlier, it appears that at least some of the variability in device performance is attributable to differences between hosts. While the mechanisms underlying these individual differences remain undetermined, several potential candidates exist including the variations in the general health of the animals, between animal differences in immune function and undetected microbreaches in the polymer membrane prior to or during implantation. The notion that the viability of grafted cells may depend in part on host-related variability in the CNS environment has only been suggested for encapsulated cells to date [56]. However, this emerging concept might also prove to be relevant for all CNS transplantation approaches that are cellular based. Indeed, the entire field of neural transplantation might benefit from this new perspective uncovered using encapsulated cells.

Finally, very few clinical studies have been conducted to date. While several small safety studies have been completed, only one large, controlled clinical study has been performed using encapsulation technology. This study evaluated the use of encapsulated adrenal chromaffin cells for the treatment of pain but failed to reveal analgesia sufficient enough to continue the trials. As we have already discussed in a previous section, the selection of pain as an initial indication for

detailed study might have been an unfortunate choice given that recent preclinical data using encapsulated chromaffin cells are mixed at best. The only other clinical targets under investigation are ALS and HD and these are apparently modest efforts. Until, larger, controlled clinical trials are conducted, the potential of this technology will not be fully realized.

In conclusion, it appears that the implantation of encapsulated cells may provide an effective means of alleviating the symptoms of numerous human conditions/diseases. One particularly attractive avenue of research continues to be the application of trophic factors to minimize or halt the progression of neural degeneration or promote regeneration of damaged central nerves. However, caution must be applied when considering any novel therapy for treating brain disorders and the wide scale use of polymer neural implants should be considered only after rigorous scientific experimentation in animal models and their demonstrated efficacy and safety in human clinical trials.

46.1 BACKGROUND

Alteration of the vascular system leading to subsequent chronic structural and functional vessel damage is directly related to rising age and cardiovascular risk burden. Its consequences are primarily manifested in the heart (coronary artery disease [CAD]), lower extremities (peripheral vascular disease [PVD]), and the brain (cerebrovascular disease). Arteriosclerosis, atherothrombosis, endothelial dysfunction, inflammation, and thrombosis have been characterized as distinct key players in vascular pathology [1,2]. Research performed during the last

few decades has provided insight into the molecular and cellular processes underlying vascular disease. In addition to strategies for prevention, the knowledge gained has enabled progress toward the gold standard of anti-arteriosclerotic, pleiotropic drug treatment to attenuate the progression or to promote the regression of vascular alterations.

Vascular diseases are the main causes of morbidity and mortality worldwide. In developed countries, projections indicate that the two main contributors to morbidity and mortality in 2020 will be ischemic heart disease and cerebrovascular

disease [3]. Approximately 1.2 million individuals in the United States experience coronary events each year, 40% of whom will eventually develop chronic heart failure of ischemic origin [4]. In the peripheral vasculature, PVD predominates and leads to intractable ischemia, impaired mobility, ulceration, impaired wound healing, and amputation; 8 million Americans are currently affected by PVD-associated morbidity and mortality [5]. Occlusion of cerebral vessels can lead to stroke-induced neurological deficits and life-long disability; in 2004, the estimated prevalence of stroke in the United States was 5.7 million [4].

During the later stages of vascular disease, mechanical revascularization strategies can effectively alleviate ischemia. Surgical techniques designed to clear or bypass obstructed arteries have improved substantially over the years. Less invasive interventional therapies such as angioplasty and stent implantation may delay or potentially supplant operative revascularization. Both surgical and interventional techniques are well-established strategies for restoring tissue perfusion and alleviating the symptoms of vascular disease, particularly for CAD and PVD. However, the feasibility of conventional revascularization in severe vascular disease is limited.

Despite modern medical treatments and revascularization strategies, the consequences of vascular disease remain devastating. In addition, advancements in modern medicine have produced an aging, multimorbid society that suffers from diffuse, severe, and often occlusive vascular diseases. As a result, there is a growing subpopulation of individuals with symptomatic cardiovascular disease who have received numerous revascularization procedures and lack options for further treatment. In extreme cases, these individuals experience intractable chest pain, recurrent decompensation from unstable heart failure, disabling claudication, or nonhealing wounds. The fundamental cause for all of these afflictions is an inadequate blood supply during low levels of activity or even at rest.

Clinical experience indicates that myocardial tissue possesses only a limited capacity for regeneration, so the Holy Grail of cardiovascular medicine is the growth of new vasculature in critically ischemic tissue, thereby relieving symptoms, improving organ function, and rescuing at-risk tissues by re-establishing perfusion. The modern concept of cardiovascular gene therapy grew from pioneering work by Folkman et al. in the 1970s, who demonstrated that the development and maintenance of an adequate vascular supply were essential for the growth of normal as well as neoplastic tissue [6]. Subsequent insights into the underlying mechanisms included the identification and detailed characterization of angiogenic growth factors and led to modern treatment paradigms for promoting (via gene therapy) or inhibiting (via antiangiogenic tumor therapy) angiogenesis.

Gene therapy is an attractive treatment option for inducing new vascular growth in critically ischemic tissue. However, the development of gene therapy has been slowed by technical challenges; for example, a decade passed before sufficient amounts of growth factors could be produced for preclinical experiments [7]. After preclinical

studies of gene therapy in animal models of cardiovascular disease supported the concept of this treatment strategy, its feasibility and safety was established by early nonrandomized, uncontrolled, clinical studies [8,9]. Subsequent randomized, controlled clinical trials yielded variable results that may be explained by biological, technical, methodological, or disease-related factors. Gene therapy has also been used for other clinical conditions, such as heart failure, postinterventional vascular remodeling/restenosis, maintenance of vascular prosthesis and bypass grafts, and prevention of hyperlipidemia and hypertension [10].

The purpose of this chapter is to review the current status of cardiovascular gene therapy. Angiogenic therapy will be emphasized because it is the most clinically advanced application of gene therapy.

46.2 NEOVASCULARIZATION

In postnatal life, new blood vessels form by three distinct mechanisms: arteriogenesis, angiogenesis, and vasculogenesis. Neovascularization comprises the latter two mechanisms [11].

Collateral (macrovascular) vessel formation from conduit arteries is driven by biomechanical forces in response to significant vessel obstruction and occurs through the in situ enlargement and growth of muscular collateral vessels from pre-existing arteriolar anastomoses. A portion of the new vasculature may evolve through the proliferative remodeling of medium-sized arteries into larger collateral vessels [12]. It is unknown whether this remodeling is induced by growth factors or by the flow-mediated maturation of collateral conduits, which is referred to as arteriolization.

Angiogenesis is the growth of new blood vessels via the sprouting, bridging, intussusception, and/or enlargement of preexisting capillaries. Angiogenesis is driven by ischemia and is crucial for the preservation of tissue function on the microvascular level during critical ischemia. The underlying mechanism is characterized by the proliferation and migration of mature endothelial cells (ECs) from adjacent vessels in response to stimuli such as hypoxia, ischemia, mechanical stretching, and inflammation [11,13]. Angiogenesis plays an essential role in both physiological (e.g., wound healing) and pathological (e.g., neoplasm, proliferative diabetic retinopathy) processes.

Vasculogenesis was previously believed to occur only during embryonic vascular development as mesodermal precursor cells (angioblasts) differentiate into ECs, which subsequently assemble into a vascular labyrinth (the primary capillary plexus) [14]. Hematopoietic stem cells were first linked to postnatal angiogenesis in a seminal study by Asahara et al. [15], who showed that CD34⁺ progenitor cells isolated from mature tissue can differentiate into ECs and thereby demonstrated the importance of circulating stem and progenitor cells for postnatal angiogenesis [15]. The identification of bone marrow-derived endothelial progenitor cells (EPCs) in sites of ischemia-induced neovascularization further demonstrated that neovascularization in adults

comprises both angiogenesis and vasculogenesis [16,17]. Recent reports from our laboratory and others indicate that the clinical application of stem cells is beneficial and associated with enhanced perfusion in ischemic heart and limb tissue [18,19].

46.3 THERAPEUTIC TARGETS

A variety of growth factors possess angiogenic potential. *In vivo*, these factors induce neovascularization by stimulating both angiogenesis and vasculogenesis. Therapeutic angiogenesis has been achieved by gene transfer of vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), hypoxia-related transcription factor (e.g., hypoxia-inducible factor 1 α [HIF1 α]), and many other agents [20,21]. Investigations of VEGF and FGF predominate in

both preclinical studies and clinical trials, which reflect the well-established link between VEGF receptor 2 or basic FGF and the differentiation of angioblasts during embryonic vasculogenesis [22–24]. In addition to these established candidates (Table 46.1), recent preclinical studies have identified stromal cell-derived factor 1 (SDF-1) [25–28] and sonic hedgehog (Shh) [25,29] as potential targets for future research, and several other angiogenic factors may soon be investigated clinically.

46.3.1 VASCULAR ENDOTHELIAL GROWTH FACTOR

In the complex process of new vessel formation, the role of VEGF is often crucial. It is involved in all types of vascular growth, is one of the key regulators in vascular embryogenesis [22,23], and is essential for neovascularization and vascular maintenance in both early and later adult life [30].

TABLE 46.1
Gene Therapeutic Targets

Therapeutic Goal	Underlying Mechanism	Potential Targets
Therapeutic angiogenesis	Angiogenesis Arteriogenesis Lymphangiogenesis	Adrenomedullin, Ang-1/-2, Del-1, EGR-1, eNOS, Ets-1, ezrin, FGF-1/-2/-4/-5, GM-CSF, HGF, HIF-1, Id1, IGF-1/-2, iNOS, kallikrein, MCP-1, PDGF-A/-B/-C/-D, PIGF, PDGF, netrin-1/-4, PR39, SDF-1, Shh, secretoneurin, thrombopoietin, thymidine phosphorylase, VEGF-A/-B/-C/-D/-E
Prevention of post-interventional vascular remodeling	Endothelial function Endothelial repair Re-endothelialization SMC proliferation matrix Production/degradation Apoptosis	β -adrenergic receptor kinase, β -interferon, activator protein-1, C-type natriuretic peptide, Bcl, catalase, cecropine A, CDC2 kinase, CDK-2, CGRP, COX, c-myc, CyA, E2F, cyclin B1/ G1, E2F, ecSOD, eNOS, Fas ligand, FGF-2, Forkhead, gax, G $\beta\gamma$, HGF, HO-1, homeobox gene, gax, ICAM, iNOS, kallikrein, lipoprotein-associated phospholipase A2, MCP-1, midkine, NFkB, p16, p21, p27, p16 Chimera, p53, PAI-1, PCNA, PDGF-B, PDGFR- β , prostacyclin, PPAR, ras, RAD50, Ras, Rb, RB2/p130, Rho kinase, sdi-1, TGF- β 3, thymidine kinase, TIMP, TNF, TGF- β , soluble TGF- β type II receptor, VCAM, VEGF-A/-B/-C/-D/-E
Stabilization of vulnerable plaque and aneurysm	Cholesterol homeostasis Cholesterol uptake Inflammation	COX, Ets-1, LDL receptor in liver, MCP-1, PDGFs, soluble scavenger-receptor decoy, soluble VCAM, TGF- β , TIMP, TNF α
Treatment of hyperlipidemia	Cholesterol homeostasis	apoA-1, apoAI, apoB-100, apoB editing enzyme, apoE, LP(a), antioxidant enzymes, LCAT, LDL receptor, lipid transfer proteins, lipoprotein lipase, hepatic lipase, soluble scavenger-receptor decoy, soluble ICAM, soluble VCAM, VLDL receptor
Treatment of hypertension	Renin-angiotensin system Sympatoadrenergic system Vasoconstriction/-dilatation	β -adrenergic receptor, angiotensinogen, ACE, adrenomedullin, ATII R1, atrial natriuretic peptide, eNOS, kallikrein
Treatment of heart failure	Cardiomyocyte homeostasis Cellular contraction Hypertrophy Fibrosis Apoptosis	β -adrenergic receptor kinase, β 2-adrenergic receptor, adenylyl cyclase VI, Ang-1, Bcl-2, cyclin A2, ecSOD, HGF, HO-1, kallikrein inhibitor-2, leukemia inhibitory factor, MCP-1, norepinephrine transporter uptake-1, p38 kinase, p35 phosphoinositide kinase domain, parvalbumin, phospholamban, PKC α , S100A1, SEK-1, SERCA1/2a, sorcin, TGF- β , TIMP-1, VEGFs, V2 receptor
Treatment of thrombotic state	Platelet degradation Fibrin formation Coagulation factors	C-type natriuretic peptide, COX, hirudin, tPA, TFPI, thrombomodulin, ectonucleoside triphosphate diphosphohydrolase, tissue factor
Modulation of arrhythmic activity	Spontaneous rhythmic	β 2-adrenergic receptor, hyperpolarization-activated cyclic nucleotide-gated genes 1–4, hyperpolarization-activated nonselective channel, Kir2.1

Since the discovery of VEGFA (also called VEGF1) in 1989, VEGFC (VEGF2), VEGFB (VEGF3), VEGFD, VEGFE, and placental growth factor (PLGF) have also been identified as distinct members of the human VEGF superfamily. These proteins share homology but are encoded by distinct genetic loci located on different chromosomes. Whereas the diverse pro-angiogenic properties of VEGFA identify it as a prime candidate for therapeutic angiogenesis, the roles of the other VEGF superfamily members in vascular biology remain elusive. The involvement of VEGFA and VEGFC is critical during embryonic vascular development [23], but only VEGFA is abundant in fully vascularized tissue, which suggests that low VEGF levels are sufficient for vascular homeostasis in adult life [31]. Expression of VEGFA is upregulated postnatally during pathological vessel growth [32].

Alternative splicing of VEGFA pre-mRNA generates distinct isoforms identified by the number of amino acids: VEGF₁₂₁, VEGF₁₆₅, VEGF₁₈₉, and VEGF₂₀₆ [20]. These isoforms show angiogenic potential in animal models [33], and differences in their solubility and binding characteristics (e.g., to heparin and the extracellular matrix) generate variations in their abilities to bind target cells. The VEGF₁₆₅ isoform has the greatest therapeutic potential because of its high biological potency (100-fold higher than VEGF₁₂₁) and its ability to generate developmental gradients in tissue, which is required for the patterning of vessel growth [34]. Three distinct receptor subtypes (endothelial-specific, fms-like tyrosine kinases) are bound by VEGF in an overlapping pattern: VEGFR1 (Flt1), VEGFR2 (Flk1/KDR), and VEGFR3 (Flt4). Certain tumor cells and ECs also express cell-surface VEGF binding sites (neuropilins, NPR1, and NPR2) with distinct affinities [35].

ECs are the principal cellular target of VEGF. Expressions of both VEGF protein and VEGF receptor are upregulated in ECs in response to hypoxia [36], and VEGF functions as a survival factor for ECs both *in vitro* and *in vivo* [37,38]. The formation of ECs into tubes and subsequently into vessels is mediated by VEGFR1 [39], and VEGFR1 is also involved in the biological activity of stem and progenitor cells. The proliferation and migration of mature ECs [40,41] is mediated by VEGFR2, which thereby influences embryonic, neonatal, and pathological angiogenesis [38]. In contrast, the primary function of VEGFR3 appears to be in lymph angiogenesis [42]. Thus, the VEGF ligands and their receptors possess distinct functions in different tissue compartments.

The VEGF protein possesses several qualities that may facilitate effective gene therapy. First, the hydrophobic leader sequence comprises a secretory signal that induces VEGF secretion from intact cells, thereby triggering a cascade of paracrine effects [43]. Second, the high-affinity binding sites for VEGF are endothelial-specific, so its mitogenic effects are restricted to ECs (acidic and basic FGF induce mitogenesis of smooth muscle cells and fibroblasts in addition to ECs) [44,45]. Third, the protein sequence includes an autocrine loop that is shared by other angiogenic factors and modulates EC response. After activation by hypoxia, the autocrine loop amplifies the effect of exogenously administered VEGF, and factors secreted by hypoxic tissue also upregulate VEGFR expression.

This localized receptor expression explains why angiogenesis is generally limited to the site of ischemia. Finally, studies in both mice and humans indicate that the number and regenerative potential of circulating EPCs are augmented by VEGF gene transfer [46–48].

Although other members of the VEGF superfamily exhibit angiogenic potential, the evidence that identifies VEGFA as a key component of physiological and pathological angiogenesis is convincing. The bi-allelic requirement of VEGF during embryonic vasculogenesis, its hypoxia-inducible expression, and its robust induction of angiogenesis and of vascular permeability underscore the therapeutic potential of VEGF. For these reasons, VEGF may be considered the prototype angiogenic growth factor for use in gene therapy [10], and the great majority of cardiovascular gene therapy trials have been conducted with VEGF/VEGFA.

46.3.2 FIBROBLAST GROWTH FACTORS

The FGF family comprises 23 members including acidic FGF (FGF1), basic FGF (bFGF, FGF2), and FGFs 3–9. Acidic and basic FGF are the best-characterized family members. Although they are not crucial for embryogenesis [49], both have been successfully used for therapeutic angiogenesis [50]. Because they lack a signaling sequence, acidic and basic FGF are nonsecreted, intracellular peptides that enter the extracellular space passively after cell damage; however, FGF4 and FGF5 are efficiently secreted and consequently, may have therapeutic advantages over the intracellular FGFs. FGFs bind with high affinity to four tyrosine kinase receptors. Upon binding, the FGF/receptor complex is rapidly removed from the circulation and localized to cells or to the extracellular matrix.

The biological activity of FGF is not well understood. Although FGF proteins are potent mitogens, their activity is not limited to ECs, and they induce mitogenesis in other cell types, including vascular smooth muscle cells and fibroblasts. Like VEGF, secreted FGF stimulates the synthesis of proteases such as plasminogen activator and metalloproteinase. Proteases contribute to angiogenesis by digesting the extracellular matrix, thereby loosening intercellular structure and liberating sequestered angiogenic factors [51]. Basic FGF enhances the proliferative activity of ECs in response to hypoxia [52], and hypoxia also induces formation of an HIF1 α -dependent autocrine loop in FGF2, which subsequently drives angiogenesis [53]. However, since the most well-characterized forms of FGF lack a secretory signal sequence, FGF gene transfer requires either genetic modification of the common FGFs or the use of less-common FGF genes that contain a signal sequence [54–56].

46.3.3 OTHER GENETIC TARGETS

Numerous pro-angiogenic proteins, growth factors, cytokines, and regulatory factors have been the focus of angiogenic research. The following discussion includes the more well-characterized therapeutic candidates.

46.3.3.1 Hypoxia-Related Transcription Factors

As an alternative to the transfer of genes that encode a single angiogenic growth factor, investigations have begun to assess the utility of upstream transcription factors that regulate multiple angiogenic genes. The metabolic stimuli associated with hypoxia and ischemia (e.g., hypoglycemia and low pH) induce expression of a variety of transcription factors that stimulate angiogenesis. Hypoxia-inducible factors (HIFs) and hypoxia-response elements (HREs) can function as master switches for an “angiogenesis program” that upregulates the expression of a number of growth factors and cytokines simultaneously, thereby mimicking a natural angiogenic response. On the cellular level, the detection of hypoxia is mediated by HIF1 α [57]; HIF1 α is degraded under normoxic conditions, but it accumulates during hypoxia and binds to HREs located in the promoter region of hypoxia-regulated genes. During postischemic vasculogenesis, the mobilization and trafficking of progenitor cells is critically dependent on HIF1 α , and the effects are directly related to HIF1 α regulation of SDF-1 expression [58]. However, HIF1 α may also induce cell death [59], so its potential for vascular gene therapy must be carefully investigated, and HIF1 α may be a significantly less potent angiogenic agent than VEGF [10].

46.3.3.2 Platelet-Derived Growth Factors

The role of PDGFs in the recruitment of pericytes to growing vessels [60] suggests that PDGFs could be added to growth-factor therapy to enhance angiogenesis. The combined application of PDGF and VEGF₁₆₅ via a polymeric system for growth factor delivery rapidly produced a mature and stable vascular network in mice [61], and a PDGF–FGF2 combination induced the formation of stable, long-term vessels in the corneas of rodents [62]. Recombinant PDGFC has been shown to mobilize EPCs, induce bone marrow cell differentiation, and boost neovascularization of ischemic tissue in mice [63].

46.3.3.3 Hepatocyte Growth Factor

HGF, the ligand of the receptor encoded by the c-met proto-oncogene, is an endothelium-specific growth factor with potent mitogenic activity in ECs. Its angiogenic capacity has been demonstrated in cell cultures, and gene transfer of human HGF improved perfusion in ischemic animal myocardium by activating the transcription factor ets, which is essential for angiogenesis [64].

46.3.3.4 Angiopoietins

Two members of this group, angiopoietin-1 (Ang1) and angiopoietin-2 (Ang2), modulate the maturation of blood vessels through agonist–antagonist interactions at the Tie2 receptor. By binding to the Tie2 receptor without activation, Ang2 antagonizes the activity of Ang1 and impairs angiogenesis [65]. The anti-inflammatory agonist Ang1 stabilizes mature vessels; although the mechanism is not known, it seems to prevent

VEGF-induced vessel leakage [66]. Overall, there is evidence that a number of these pro-angiogenic factors influence angiogenesis, at least in part, by induction of VEGF [34].

46.3.4 EMERGING GENETIC TARGETS

46.3.4.1 Stromal Cell-Derived Factor 1

Stromal cell-derived factor 1 (CXCL12) is a 68-amino acid cytokine of the CXC superfamily. Since its identification, its activity as a growth factor has been primarily linked to lymphopoiesis and myelopoiesis [67]. Two isoforms, SDF-1 α and SDF-1 β , are encoded as splice variants of a single gene. The two are nearly identical, but SDF-1 α is four amino-acids shorter [68]. It is expressed by both ECs and stem cells.

Although most investigations of the SDF-1/CXCR4 axis have focused on cell trafficking [69], it also mediates other biological functions, including vascular organogenesis [70]. Endothelial stem cells recruited by SDF-1 contribute to tumor vascularization [71], and SDF-1 α is essential for post-ischemic recruitment and homing of stem and progenitor cells [28]; cell traffic to ischemic tissue follows an HIF1-induced SDF-1 gradient [58]. Results in our laboratory indicate that EPC integration after limb ischemia is augmented by local SDF-1 α administration [26], and Grunewald et al. demonstrated the need for SDF-1 α in close perivascular proximity during VEGF-induced postnatal neovascularization [72]. Because SDF-1 α is essential for cell trafficking and maintenance during vasculogenesis, it is a promising candidate for gene therapy.

46.3.4.2 Sonic Hedgehog

Nearly three decades ago, the hedgehog (Hh) gene family was identified as a crucial regulator of cell-fate determination during embryogenesis [73], and it was subsequently shown to modify cell survival and proliferation [74]. Hh genes act as morphogens in various tissues during embryonic development, but most investigations have focused on their involvement in neurogenesis [75,76]. The secreted glycoprotein Shh is a vertebrate homologue of the *Drosophila* segment polarity gene Hh. Although its precise role remains unclear, the trophic or mitogenic activity of Shh seems to be required continuously during embryogenesis [73].

Our laboratory has demonstrated that recombinant Shh protein induces a robust angiogenic effect by upregulating multiple angiogenic factors, including VEGF, in interstitial mesenchymal cells [29]. This observation suggests that the embryonic pathway of vascular development could be reactivated postnatally to combat pathological conditions. Intramyocardial Shh gene transfer enhances the regeneration of ischemic myocardium by inducing expression of trophic factors such as SDF-1 and, consequently, by increasing the recruitment and incorporation of bone marrow-derived EPCs during neovascularization [25].

Because it appears to be capable of triggering a cascade of proangiogenic factors, Shh likely possesses considerable potential for vascular regeneration and is an appealing candidate

for future research in cardiovascular gene therapy. In addition, Shh has recently been shown to accelerate wound healing in diabetic mice by enhancing EPC-mediated microvascular remodeling [77].

46.4 BASICS AND LIMITATIONS

In addition to the detailed information provided in the specific sections of this chapter, some general aspects of gene therapy with special relevance for cardiovascular applications must be addressed (Figure 46.1).

In general, the presence of each genetic component can be modified directly by delivering recombinant proteins or indirectly by transferring genes that are then overexpressed. To date, combined therapy that includes both recombinant protein delivery and gene transfer has also been tolerated by cardiovascular patients with multiple morbidities, but the preparation, delivery strategy, and dosage of each agent must be optimized with consideration for each individual patient's fragility.

Direct protein delivery enables the dose to be delivered more precisely, with well-defined dynamics, kinetics, and safety profiles. Some investigators also advocate direct protein delivery for practical reasons; it is particularly suitable for administration to the limb. However, recombinant protein is often administered systemically, which is subject to at least

three limitations. First, adequate tissue uptake requires high plasma concentrations, with a consequently higher risk for adverse effects. Second, administered proteins do not produce a sustained effect because they are rapidly degraded by circulating proteinases [78,79]. Third, the production of recombinant human protein is complex and may be prohibitively expensive.

Gene transfer enables the attainment of high, sustained levels of gene expression accompanied by a lower probability of adverse reactions and lower costs. The effectiveness of gene transfer depends on the efficiency of transfection, which depends, in turn, on insertion of the transgene into the target tissue and the magnitude and endurance of its subsequent expression. The cellular penetration and intracellular trafficking of the transgene is facilitated by vectors.

There are two categories of vectors: viral and nonviral. Early attempts at cardiovascular gene therapy relied on nonviral, plasmid DNA because it was considered safe and easy to produce, and striated and cardiac muscle, the primary tissues of interest in cardiovascular medicine, had been shown to effectively take up and express naked plasmid DNA as well as transgenes encoded by viral vectors. However, later randomized, controlled trials did not support the use of plasmid DNA because of low gene transfer efficiency [80,81], and transfer efficiency was not improved by advancements in engineering (e.g., liposome polymers) or techniques designed

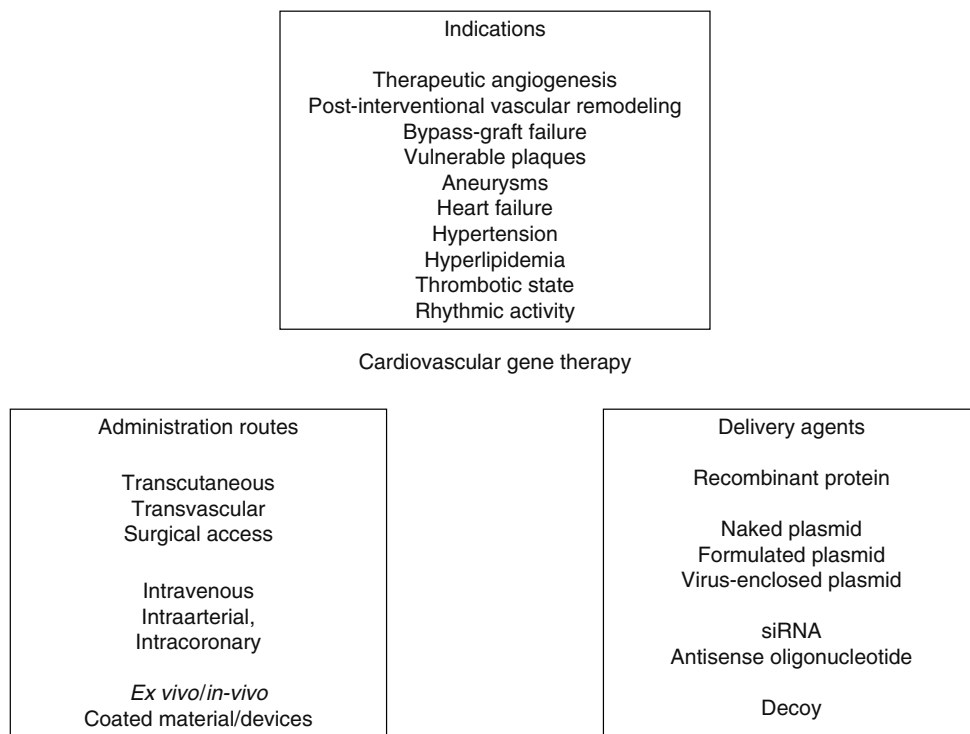

FIGURE 46.1 Efficiency or failure of cardiovascular gene therapy is determined by the targeted disease, route of administration, delivery vector/agents, and gene of therapeutic interest (Table 46.1).

to improve cell penetration (e.g., electroporation and ultrasound) [82–84]. Unlike viral transfer, naked DNA often fails to produce a dose-dependent response [85,86], and although naked plasmid DNA is generally safe, it may cause infarction in peripheral muscle and myocardium [87,88].

Adenoviruses (Ads), adeno-associated viruses (AAVs), and retroviruses are the most frequently used vectors for cardiovascular gene therapy. Both achieve high transduction efficiency in vessel walls and in heart and skeletal muscle [82]. AD seems particularly effective for gene transfer to cardiomyocytes and skeletal myocytes [89], and the safety of Ads has been very good in cardiovascular clinical trials [80,90]. Natural tropisms that favor vascular smooth muscle cells, cardiomyocytes, and skeletal myocytes are among the more useful characteristics of AAVs, and the expression of AAV-transfected genes can endure for months.

Although retroviral vectors were among the first used for cardiovascular gene therapy, their popularity has declined because of safety issues. Lentiviral vectors have emerged more recently and appear to efficiently transduce blood vessels [91,92], but additional engineering is needed to optimize their efficiency. Small interfering RNA (siRNA) has begun to replace antisense oligonucleotides for inhibition studies and may soon provide a new option for nonviral gene modulation. Very high transfection efficiency may be achievable by administration of decoy receptors or antibodies that circumvent blocking factors in cardiovascular tissue.

In addition to receptor binding, angiogenic efficiency is influenced by two other variables. Local growth factor concentration is a key determinant of vascular growth [93] and growth factor spread is influenced by the binding properties of the matrix and the volume and number of injections [85]. Transfection efficiency is fivefold greater when genes are transferred into ischemic, rather than healthy, muscle [94,95]. Intramuscular gene transfer yields higher efficiency and angiogenesis with less ectopic gene expression than intravascular injection [96], but it is more feasible for peripheral muscle than for the heart.

The successful use of gene therapy in the clinical setting will require practical delivery systems and techniques that are specific to the most commonly targeted tissues: myocardium, skeletal muscle, and blood vessel tissue. Gene transfer can be performed by direct organ injection (local delivery), intravascular application, and *ex vivo* gene transfer. Local delivery is easily applied to peripheral tissue; intramyocardial and intramuscular injection is an efficient strategy for inducing robust gene expression. Local delivery to the heart initially required open-chest surgery or thoracoscopy, but the recent development of ultrasound-guided, catheter-based delivery systems (e.g., navigation and catheter mapping technology [NOGA]) made local transvascular delivery to the myocardium much more feasible [85]. The transvascular approach bypasses open operative procedures and enables selective delivery to the targeted organ; however, preclinical studies have suggested that intra-arterial transvascular delivery is insufficient unless the permeability of the endothelium is modified or gradient methods are applied [96,97].

Intravenous gene infusion is practical and inexpensive, can be administered to most patients, can be done repetitively, and does not require a unique set of skills, but the vector is widely distributed throughout the body, which may be a critical safety limitation, and the amount needed is unreasonably high. Genes can be transferred to vascular grafts with high efficiency via *in situ* incubation or *ex vivo* immersion in the gene transfer solution, and a gene-eluting stent has recently been introduced for intravascular administration of gene therapy [98].

46.5 CLINICAL AND PRECLINICAL EVIDENCE

Recent investigations have assessed the therapeutic potential of vascular gene therapy for preventing postinterventional vascular remodeling (restenosis, in-stent restenosis) and bypass-graft failure, for stabilizing vulnerable plaques and aneurysms, for modulating rhythmic activity, and for managing heart failure, hypertension, hyperlipidemia, and thrombotic states [10,99]. However, the bulk of investigative work has studied its use for therapeutic angiogenesis, which remains the most clinically advanced application of vascular gene therapy. For these reasons, most of the studies discussed below focused on the therapeutic potential of vascular gene therapy for angiogenesis.

46.5.1 THERAPEUTIC ANGIOGENESIS—CAD

Chronic heart failure is associated with the highest morbidity and mortality rates in the cardiovascular field and generates obvious socioeconomic consequences. As medical treatment of acute events has advanced, long-term survival after myocardial infarction has become a significant contributing factor to chronic heart failure. Therefore, strategies to prevent myocardial ischemia as well as to improve cardiac function after an ischemic event are urgently needed. In addition, patients with refractory angina sometimes require multiple procedures to achieve sufficient symptomatic relief, and because of the diffuse nature of CAD, more invasive techniques may not be suitable for a considerable number of patients (Tables 46.1 and 46.2).

46.5.1.1 VEGF

Recombinant VEGF₁₆₅ protein has been administered via a variety of routes to induce angiogenesis in ischemic myocardium. Phase 1 studies of both intracoronary and intravenous VEGF₁₆₅ protein injection in patients with symptomatic, inoperable CAD found encouraging improvements in anginal status and nuclear perfusion both at rest and when under stress [100–102].

The phase 2 VIVA trial tested the effect of recombinant VEGF protein in patients with CAD, angina, and viable myocardial tissue who were not candidates for revascularization. In this double-blind, placebo-controlled, multicenter, dose-escalation study, patients were randomized to one intracoronary injection or

three dose-escalating intravenous infusions. Patients were followed for up to 1 year. Although the increase in exercise time did not differ significantly between the placebo group and either treated group after 60 days, there was a trend toward a lower angina class in VEGF-treated patients that could not be explained by differences in clinical status and diagnostic parameters. Angiographic and single photon emission computed tomography (SPECT) imaging were similar at follow-up [100,103]. Safety results indicated that hypotension was a significant, dose-limiting side effect among patients who received intravascular infusions. Hypotension had been previously observed in animal experiments with recombinant VEGF and may have been caused by VEGF-induced release of nitric oxide [104,105].

Because some delivery routes (e.g., intravenous, perid-ventitial) cannot produce sufficient plasma levels of the VEGF protein [106,107], the ineffectiveness of VEGF in some studies can likely be attributed to the method of administration. This assertion is supported by results from the phase 2 KAT trial. Here, 103 patients with CAD and angina (Canadian Cardiovascular Society [CCS] class II or III) were treated with a VEGF Ad vector, a VEGF liposome plasmid, or placebo via intracoronary injection while undergoing angioplasty and stenting. After 6 months, myocardial perfusion increased significantly in only the AdVEGF-treated group; the distribution of restenosis was similar in all three groups [80].

In some animal models of CAD, VEGF gene therapy has been successfully administered via naked plasmid DNA and viral vectors. Direct intramyocardial injection of AdVEGF₁₂₁ through a thoracoscopic access improved collateralization, tissue perfusion, and cardiac function after infarction in large animals [108,109], and intracoronary Ad-vector gene delivery yielded efficient gene transfer and VEGF expression in the myocardium [108]. However, local pericardial delivery of AdVEGF failed to improve collateral myocardial perfusion [79].

The first clinical study to transfer naked VEGF plasmid directly to targeted tissue was a phase 1, open-label, dose-escalating study initiated by our center that focused on safety and bioactivity. Preliminary results suggested that VEGF gene therapy administered by this method was safely and successfully transfected and yielded favorable clinical effects. Patients with refractory, stable angina when under exertion and with multivessel occlusive CAD and hibernating myocardium (determined via perfusion scanning) were selected. By using transesophageal echocardiographic control and a cardiac stabilizer, gene delivery was accomplished with no periprocedural complications. All patients experienced marked symptomatic improvement, including lower angina frequency and severity, reduced nitrate use, and improved exercise tolerance over a 1-year follow-up period. The clinical benefits were accompanied by enhanced perfusion in the ischemic area and recovery of wall motion abnormalities 60 days after gene transfer [110–113]. We observed similar results with VEGF2 plasmid DNA in an open-label, dose-escalating, multicenter, clinical trial in 30 patients with CAD and refractory class III–IV angina. All individuals had previously undergone bypass surgery, had sustained one to two episodes of acute ischemia, and were using more than two anti-anginal drugs. Gene transfer was performed safely and without complication. Twelve months later, anginal episode frequency and nitrate consumption were significantly lower, and mean exercise duration (determined by a standard treadmill protocol) increased by more than 2 minutes [114].

A number of other studies investigated direct myocardial VEGF gene transfer via an AdVEGF construct. The REVASC phase 2 trial was the largest investigation of AdVEGF₁₂₁ gene therapy in patients with ischemic CAD. Sixty-seven patients with CCS angina class II–IV were randomized to continue with optimal medical management or to receive intramyocardial AdVEGF₁₂₁ injection through a limited thoracotomy [115]. After 26 weeks, symptoms of ischemia occurred significantly later during treadmill testing in the AdVEGF₁₂₁-treatment group. Angina status and several domains of the Seattle Angina Questionnaire were also improved among patients who received VEGF₁₂₁ therapy; however, four patients experienced complications from the thoracotomy. Myocardial injection of AdVEGF₁₂₁ improved symptoms and exercise duration when administered to patients undergoing bypass surgery for advanced CAD and when administered without bypass surgery via minithoracotomy. Stress-induced nuclear perfusion images remained unchanged, and the vector was well-tolerated.

All of these early VEGF gene therapy studies in patients with myocardial ischemia were limited by the need for thoracotomy access. This procedure is associated with a small but relevant risk that can include substantial morbidity, and also precludes placebo-controlled investigations. More recent investigations have used a less invasive, catheter-based delivery system. The system integrates the NOGA mapping technique with a working catheter (Biosense-Webster, Warren, NJ). The distal catheter tip incorporates a 27-gauge needle used for injections into the myocardium. The mapping capabilities of the NOGA system are accompanied by three additional advantages when compared to an operative approach. First, the transgene can be delivered precisely to predetermined zones of ischemia, including sites that are less accessible via minithoracotomy; this, in turn, prevents accidental gene delivery to a myocardial scar. Second, catheter-based delivery eliminates the need for general anesthesia and operative dissection, so placebo-controlled, double-blind studies can be initiated. Third, the intervention can be performed as an outpatient procedure and repeated if necessary. Proof-of-concept, preclinical experiments confirmed the safety, reliability, reproducibility, and local accuracy of this approach [116,117].

We conducted a pilot study of percutaneous, catheter-based VEGF2 DNA gene transfer guided by the NOGA mapping system in six patients with symptomatic myocardial perfusion who were not candidates for revascularization. Twelve months after gene transfer, patients reported significant reductions in angina frequency and nitrate consumption, and improved myocardial perfusion was observed by both SPECT perfusion scanning and electromechanical mapping. After witnessing these encouraging results, we designed a double-blind, randomized, placebo-controlled, multicenter trial to evaluate catheter-based, VEGF2 gene transfer in patients with chronic myocardial ischemia not amenable to revascularization. Patients were randomized to receive six injections of VEGF2 plasmid (phVEGF2) or placebo. Gene transfer was well-tolerated and no relevant complications were reported. Twelve weeks later, the phVEGF2-treated group experienced significant improvement in angina severity class and other endpoints, such as exercise duration, functional improvement, and the Seattle Angina Questionnaire, exhibited strong trends favoring phVEGF2 over placebo treatment [118]. The study was closed by the U.S. Food and Drug Administration after 19 of the planned 27 patients had been enrolled, and larger, phase 2/3 trials were encouraged.

Only a few phase 2/3 trials have been initiated to date. In the Euroinject One phase 2 trial, 80 patients with CCS class III–IV CAD who lacked any other treatment options were randomly assigned to receive percutaneous, intramyocardial injection of naked VEGF₁₆₅ plasmid or placebo. Three months after plasmid delivery, myocardial perfusion (as assessed by SPECT) was similar in both groups, but regional wall motion (assessed both by NOGA and contrast ventriculography) was significantly better in VEGF-treated patients than in patients administered placebo [81]. The ongoing phase 2/3 Northern trial employed

AdVEGF₁₂₁ to therapeutically induce angiogenesis in no-option patients with CCS class III–IV angina. Change in myocardial perfusion was assessed 12 weeks after percutaneous, intramyocardial vector application. Results from 120 patients who have completed the trial are pending (ClinicalTrials.gov, NCT00143585). Patient recruitment for the phase 2/3 NOVA trial was recently halted because of substantial similarities with the Northern trial; the study design used percutaneous, intramyocardial application of AdVEGF₁₂₁ in patients with CAD and CCS class II–IV angina (ClinicalTrials.gov, NCT00215696). Finally, the GENASIS phase 2 study was designed to investigate the effect of naked VEGF2 plasmid applied by percutaneous, intramyocardial gene transfer on exercise tolerance in patients with CCS class II–IV CAD. The study was interrupted after 295 of the planned 404 patients had been enrolled because of complications stemming from the intramyocardial injection catheter (D. Losordo, unpublished data).

Taken together, clinical investigations of VEGF gene transfer for therapeutic angiogenesis are encouraging. Direct gene transfer into the myocardium is superior to intravascular applications and development of a catheter-based delivery system has revolutionized myocardial gene therapy.

46.5.1.2 FGF

Preclinical investigations in animal models of myocardial ischemia demonstrated that local FGF application improved myocardial perfusion and function and increased collateral blood flow [119–122]. Subsequent, small-scale phase 1 studies established the safety of recombinant FGF1 and FGF2 in patients with myocardial ischemia [123–127], and reported some evidence of clinical improvement and functional cardiac recovery in patients with CAD. Interpretation of these results is limited, however, because direct FGF injection to the myocardium was performed during coronary artery bypass graft surgery. Less invasive intravenous and intracoronary administration of recombinant FGF2 has been performed in phase 1 studies of patients with symptomatic CAD, but the results were mixed. Intravenous (but not intracoronary) injection alleviated angina, extended exercise time, and improved left ventricular function, but several patients experienced transient hypotension, conduction system disturbances, thrombocytopenia, or proteinuria [128–130].

The FIRST trial was an early phase 2 trial in 337 patients with inoperable CAD; patients received placebo or one of three doses of recombinant FGF2 by intracoronary injection. There were no significant differences between placebo and FGF2 treatment in any endpoint, including exercise duration and stress nuclear perfusion 90 days after treatment; however, there was a trend toward reduced anginal complaints in patients treated with FGF2, particularly among those who were older and more symptomatic [131].

Although the results achieved with recombinant FGF protein have been disappointing, FGF gene therapy remains promising. The Angiogenic Gene Therapy (AGENT) trial, conducted by Grines et al., was the first clinical investigation of FGF gene therapy for CAD. Patients with chronic stable

angina were randomized to receive placebo or escalating doses of AdFGF4 by intracoronary injection. The AdFGF4 infusion was well-tolerated, with few periprocedural adverse events (e.g., early transient fever, minor and self-limited liver enzyme elevation) and no significant difference in adverse event occurrence between AdFGF4- and placebo-treated individuals [132]. Four weeks after therapy, patients receiving AdFGF4 tended to exercise longer before manifestation of angina, and the difference between FGF4- and placebo-treated patients was significant in the subgroup of patients whose baseline exercise tolerance was less than 10 minutes. These results suggested that intracoronary infusion of AdFGF4 is safe and may exert favorable anti-ischemic effects in patients with severe myocardial ischemia.

In a subsequent double-blind, placebo-controlled study in 52 patients with stable angina and reversible ischemia (AGENT-2), AdFGF4 administered via intracoronary injection was associated with significantly smaller ischemic defect size (determined by SPECT) 8 weeks after treatment than was observed with placebo treatment [133]. However, the large-scale, multinational, double-blind AGENT-4 trial found no evidence of a robust effect on exercise tolerance among the 116 enrolled patients (ClinicalTrials.gov, NCT00185263). In the United States, patient enrollment in the AGENT-3 trial was terminated early because the primary endpoint was not achieved; however, a post hoc analysis of the AGENT-3 patients who were older (>55 years) and sicker found evidence of significant efficacy associated with FGF4 gene therapy, echoing the subgroup analyses performed in the FIRST trial. Recently, a pooled analysis of AGENT-3 and AGENT-4 patients revealed gender specificity in patient response to AdFGF4 gene therapy: men responded to placebo treatment but not to AdFGF4 therapy, and women experienced greater exercise time and reduced angina severity with FGF4 treatment but negligible response to placebo [134]. The therapeutic efficiency of FGF4 gene therapy in women is being investigated in the ongoing AWARE trial. This phase 3 multicenter study is designed to evaluate patient response to a one-time intracoronary FGF4 injection in 300 female patients with stable CAD (ClinicalTrials.gov, NCT00438867).

In summary, there is no evidence to support the use of intracoronary recombinant FGF protein for treatment of CAD, and the effectiveness of FGF gene therapy remains unknown. Further large-scale trials are needed to characterize the potential age- and sex-specific efficacy of FGF gene therapy.

46.5.2 THERAPEUTIC ANGIOGENESIS—PVD

In the consensus statement of the European Working Group on Critical Limb Ischemia, group members noted that no medical treatment has been shown to alter the course of critical limb ischemia. In a large proportion of patients with critical limb ischemia, the distribution and extent of arterial occlusion precludes proper revascularization. As a consequence, the quality of life for patients in later stages of the disease is comparable to that of patients with terminal cancer [135]. Ultimately, the chronic progression of critical limb ischemia

leads to limb loss, and of patients who undergo one amputation, 10% will undergo two or more [136–138]. Despite advances in conventional therapy, including interventional and operative techniques, there is an urgent need for treatment alternatives in patients with critical limb ischemia (Tables 46.1 and 46.3).

46.5.2.1 VEGF

The angiogenic efficiency of VEGF in critical limb ischemia was evident in early preclinical animal models. In rabbits, intra-arterial VEGF protein administration augmented collateral vessel and capillary development after severe, unilateral hind limb ischemia [139], and the angiogenic potency of VEGF protein was confirmed in a diverse set of other animal models [45,140]. However, clinical use was hampered by the same difficulties encountered with intravascular growth factor application. Cellular uptake of naked DNA after intravascular injection is poor, presumably because of prompt degradation by circulating nucleases, and the systemic distribution of intravascular gene transfer does not allow targeted treatment. Thoughtfully designed preclinical studies quickly established the feasibility and efficiency of site-specific, intramuscular VEGF gene transfer for treatment of critical limb ischemia. Meaningful biological outcomes were observed after direct injection of naked VEGF DNA into skeletal muscle, and blood pressure ratio and

Doppler-derived blood flow measurements correlated well with angiographic scores and capillary density [94,141].

The positive results of these and other preclinical studies encouraged the initiation of clinical studies. In a pilot clinical investigation, Jeffrey Isner, one of the pioneers of VEGF gene therapy in ischemic disease [142], found angiographic and histological evidence of angiogenesis after delivery of human VEGF₁₆₅ plasmid (phVEGF₁₆₅) in patients with ischemic peripheral arterial disease (PAD) [143]. In a small number of selected patients, transfer of naked phVEGF₁₆₅ (4000 μ g) successfully induced VEGF expression and was associated with improvements in a number of objective clinical parameters as well as subjective clinical benefit [144]. In a subsequent trial, 55 patients with ischemic pain at rest and ischemic ulcers were locally treated with phVEGF₁₆₅ injection. Over a follow-up period lasting up to 36 months, 65.5% of treated patients achieved a favorable clinical outcome, defined as improved ankle-brachial index, collateralization, peripheral blood flow, and limb salvage. Rest pain and an age of less than 50 years were independent predictors of a favorable clinical outcome (determined by multiple logistic regression), while classic risk factors and the magnitude of the phVEGF₁₆₅ dose were not [145,146]. Adverse effects were limited to self-limiting lower-extremity edema, which developed in one third of patients; prolonged edema resolved with short-term diuretic therapy [147].

In the recently published, placebo-controlled, phase 1/2 Groningen trial, the amputation rate at day 100 among 54 diabetic patients (27 in each group) with PAD and critical ischemia was lower (though not significantly) in patients who received naked VEGF₁₆₅ plasmid by intramuscular injection rather than placebo, and predetermined secondary endpoints, including clinical condition and ankle-brachial index, were significantly improved [148]. The VEGF for PVD phase 2 trial comprehensively compared plasmid-liposome and AdVEGF₁₆₅ gene transfer in 54 patients with PAD and intermittent claudication who were selected for percutaneous transluminal angioplasty (PTA). Catheter-based, local, intra-arterial delivery of both preparations led to improved clinical parameters after three months, including vascular growth distal to the injection sites. Both treatments were safe and well tolerated [90].

In addition to patients with classic PAD, those with Buerger's disease who were unresponsive to conventional treatments for critical limb ischemia benefited from intramuscular phVEGF₁₆₅ therapy. Nocturnal rest pain, ankle-brachial index, and collateralization determined by serial angiography improved with treatment. These findings were consistent with healing limb ulcers [149].

Adenoviral VEGF₁₂₁ gene therapy has been investigated in disabled patients with PAD by Rajagopalan et al. In their initial phase 1 trial with five patients, intramuscular injection at sites where collateral vessel formation was desired improved lower extremity endothelial function and flow reserve [150]; however, the subsequent double-blind, randomized, controlled, phase 2, RAVE trial failed to reproduce these benefits. Twelve and 26 weeks after treatment, there was no significant difference in quality of life or any clinical parameter between patients administered AdVEGF₁₂₁ and those who received placebo. Thus, the authors did not advocate the use of AdVEGF₁₂₁ for AGENT in patients with PAD [151]. Treatment with AdVEGF₁₂₁ also resulted in transient edema, as we observed with the intramuscular injection of AdVEGF₁₆₅, but severe adverse effects were not reported.

Overall, local gene transfer of VEGF₁₆₅ appears to exhibit potential for treatment of patients with PAD accompanied by intermittent claudication and critical ischemia. Intravascular injection is not appropriate, however, because of striking limits in the methodology. The therapeutic application of VEGF₁₂₁ and VEGF2 has not been supported by clinical evidence, but only a few properly designed trials have been attempted thus far, so these constructs may still prove to be effective.

46.5.2.2 FGF

After preclinical studies demonstrated the improvement of ischemic hind limb perfusion by recombinant FGF2 application [152–154], an initial phase 1 study in patients with atherosclerotic PVD and claudication tested the feasibility, safety, and tolerability of intra-arterial FGF2 administration. In this double blind, placebo-controlled, dose-escalation trial, blood flow in the calf was greater in FGF2-treated patients than in

the control group, and the authors recommended the initiation of phase 2 trials [155]. The TRAFFIC trial evaluated the administration of recombinant FGF2 in patients with moderate-to-severe, intermittent claudication from PVD. A total of 190 patients were randomized to receive placebo, one dose (30 µg/kg), or two doses (30 µg/kg each, one month apart) of FGF2. After 90 days, the increase in peak walking time was higher in patients who received either FGF2 dosing regimen than in placebo-treated patients ($p = 0.034$ when all 190 patients were analyzed), but the second FGF2 dose provided no additional benefit. Serious adverse events were similarly distributed in all groups [156].

Gene therapy with FGF was initially performed in a small number of patients with ischemic rest pain or tissue necrosis due to end-stage peripheral arterial occlusive disease for whom mechanical revascularization was unsuitable. In this phase 1 study, naked plasmid DNA encoding for FGF1 was administered to the ischemic thigh or calf muscle by intramuscular injection in either escalating single or escalating repeated doses. Overall, the treatment was well tolerated and there were no FGF1-related adverse events. Plasmid biodistribution was limited with no increase in FGF1 serum level and none present in the urine, presumably because of metabolism by endogenous endonucleases. Administration of FGF1 gene therapy was associated with significant reductions in pain and ulcer size as well as increased oxygen pressure and ankle-brachial index at follow-up, but response was not dose-dependent [157]. Results from subsequent, unpublished, phase 2 trials that employed intramuscular injection of naked FGF plasmid were less encouraging. In the PM 202 trial in patients with critical limb ischemia, FGF therapy was not associated with significant improvement in the primary endpoint (ulcer healing) or in transcutaneous pO₂ [10], and there was no relevant difference in the primary endpoint (ulcer healing) of the TALISMAN 201 trial, although FGF therapy was associated with a significant reduction in amputation rate [10].

The findings described above suggest that recombinant FGF2 may be effective for therapeutic angiogenesis [156], but the scarce number of FGF gene therapy trials do not provide convincing support for administering the FGF gene to patients with PVD. Because conclusive evidence is lacking, additional large-scale studies are needed.

46.5.2.3 Other Factors

In addition to VEGF and FGF, a small number of other potential gene therapies are beginning to reach the clinical stage of investigation. Intramuscular injection of a Del-1 (developmentally regulated endothelial locus 1) plasmid formulated with poloxamer 188 in 157 patients with PAD and claudication did not substantially change the peak walking time after 3 months (DELTA-1 phase 2b trial, unpublished) [10]. Intramuscular application of AdHIF1 α /VP16 is being investigated in the ongoing, phase 2, WALK trial; the primary study endpoint is peak walking time 6 months after treatment and the planned enrollment is 300 patients with severe intermittent claudication (ClinicalTrials.gov, NCT00117650). The effect of naked HGF plasmid injection into

the skeletal musculature in patients with PAD and critical ischemia is being evaluated in the ongoing HGF-STAT trial [158]; wound healing, amputation rate, rest pain, and ankle-brachial index reflecting tissue perfusion are the designated study endpoints, and the planned enrollment is 100.

46.5.3 PREVENTION OF POSTINTERVENTIONAL REMODELING

One of the primary challenges remaining in cardiovascular medicine is postinterventional vascular remodeling, which can lead to acute thrombosis, restenosis, or in-stent stenosis. Even the most recent technical inventions often fail to overcome this shortcoming (Tables 46.1 and 46.4).

46.5.3.1 Coronary Artery System

Although drug-eluting stents dramatically reduce the occurrence of in-stent restenosis they also delay postinterventional endothelial recovery and increase the risk of fatality due to stent thrombosis. Brachytherapy has not provided a clinical breakthrough to date.

Acceleration of endothelial tissue formation (re-endothelialization) is known to attenuate the risk of restenosis after coronary stenting. Because VEGF is a potent stimulator of EC recovery, a VEGF-coated stent may reduce the risk of restenosis. In a pre-clinical model, rabbits were treated with uncoated or phVEGF2-coated stents. After 3 months, the coated stents were associated with significantly larger lumen cross-sectional areas and less cross-sectional narrowing; the underlying EC recovery was related to the greater EPC recruitment associated with VEGF gene-coated stenting [98]. A phase 1 clinical trial evaluating the safety of phVEGF2-coated stents has been initiated.

An alternative strategy for preventing restenosis that uses a specialized infiltration catheter to directly pre-infuse VEGF plasmid into the coronary plaque before stenting has been proposed. A technically similar approach was investigated in the *Italics* trial. Antisense oligonucleotides against c-myc were locally administered after stenting, but the neointimal vessel obstruction was similar in oligonucleotide- and saline-treated patients 6 months later [159].

46.5.3.2 Peripheral Arterial Vasculature

PTA is a successful therapy for alleviating arterial obstructions; however, the diffuse nature of arteriosclerosis and the increased

risk of postinterventional restenosis make procedures performed in the peripheral vasculature more challenging and generally less effective than coronary procedures. This observation has not been satisfactorily explained, and limb vasculature in the adductor canal seems particularly prone to stenosis and restenosis. Whereas the success rate for standard PTA is up to 90%, restenosis may complicate the clinical course for as many as 60% of patients undergoing PTA of the superficial femoral artery [136–138]. Because efforts to limit the development of restenosis by nonmechanical means have not been effective, newer strategies attempt to speed restoration of endothelial integrity after the intervention. Results in our laboratory indicated that the administration of mitogens such as VEGF accelerates re-endothelialization in animals by promoting EC migration and/or proliferation, thereby reducing intimal thickening [160–163]. Other preclinical studies of re-endothelialization in different vascular beds after VEGF overexpression have yielded conflicting results [164–166].

In an unblinded, single-center, phase 1 pilot trial, we investigated whether VEGF gene therapy reduces restenosis after PTA-induced endothelial disruption by enhancing re-endothelialization. Gene transfer was intra-arterial, and transfer efficiency was established by a rise in plasma VEGF levels. Duration of exercise before claudication increased and Rutherford class improved with VEGF gene therapy, and there was a sustained improvement in ankle-brachial index, but the effect on the PAD severity score was unstable. During invasive follow-up with intravascular ultrasound, restenosis was less in patients administered VEGF gene therapy than in patients who did not receive the gene or in historical controls who had undergone brachytherapy. These results suggested that VEGF gene therapy could safely prevent restenosis by enhancing re-endothelialization [167].

Other target genes with vasoprotective potential, such as nitric oxide synthase (NOS) or prostacyclin synthase, have been successful in animal models [168,169], but these findings have yet to be confirmed in patients. Combining targeted gene therapy with drug-eluting stents may help overcome the clinical drawbacks of antiproliferative drug activity on the endothelium, and the costs of extended antithrombotic drug therapy may also be reduced. Gene-eluting stents have been engineered and tested in animal models [98], but stents that elute both drugs and genes are not yet available.

TABLE 46.4

Randomized Controlled Phase II/III Clinical Trials—Further Cardiovascular Indications

Trial	Entity	Agent	Route	Primary Endpoint	n	Follow-up	Outcome	Reference
ISIS	Familial hypercholesterolemia	apoB antisense oligonucleotide	Intravenous, followed by subcutaneous maintaining dose	LDL-cholesterol	36	12 weeks	Positive	[182]

46.5.4 PREVENTION OF GRAFT FAILURE

Because of the absence of established treatments and a desire for easier techniques, gene therapy could be a valuable option for prevention of graft alteration and subsequent occlusion (Tables 46.1 and 46.4). The concept is supported by promising results in animal models, and *ex vivo* gene transfer may be an attractive option before coronary, peripheral, and arteriovenous graft implantation [170–172]. To some extent, VEGF activity is vasculoprotective, and blockade of the VEGF cascade has been linked to cardiovascular events [173]. Animal studies suggest VEGF may exert a pro-arteriogenic effect [166,174], but adenoviral overexpression of VEGF in multiple clinical studies does not support this notion [34]. Because of its vasodilative, antithrombotic, and antiproliferative properties, NOS may be a suitable candidate gene for this application [175], and Ang1 could also serve as a target to reduce graft vasculopathy [176]. However, clinical attempts to reduce graft failure with any of these agents are rare.

After the *in situ* transfer of genes to grafts was demonstrated feasible and safe in a clinical pilot study [177], some large-scale trials were initiated to test the clinical relevance of this concept. In the PREVENT IV, phase 3 trial, 2400 patients who were undergoing coronary artery bypass surgery were implanted with venous grafts that had been treated with edifoligide (an E2F transcription factor decoy) or placebo. After 12 to 18 months, the failure rate of venous grafts (defined as $\geq 75\%$ vein graft stenosis) was similar in both groups; longer-term responses were not evaluated [178]. Similar venous grafts were used during bypass surgery for PAD in the phase 3 PREVENT III trial. In 1404 patients with critical limb ischemia who underwent infrainguinal revascularization, there was no significant difference in primary graft patency or limb salvage between patients who received treated or untreated grafts; however, there was significantly better secondary graft patency within 1 year [179]. These results indicate that graft pretreatment with antisense oligonucleotides may not be sufficiently effective to justify routine clinical use, although pretreatment with alternative agents (e.g., siRNA) may still prove beneficial.

46.5.5 THERAPY FOR HYPERLIPIDEMIA, HYPERTENSION, AND THROMBOSIS

Although the effectiveness of conventional therapy has improved substantially in recent decades, the cardiovascular burden of arteriosclerosis continues to rise. Among the many patients who have this disease, those with familial hypercholesterolemia or hypertension refractory to drug therapy may be particularly good candidates for targeted gene therapy (Tables 46.1 and 46.4).

In an early study, Grossman et al. injected autologous hepatocytes transfected to overexpress a functional LDL receptor (LDLr) into the portal vein of five patients with homozygous familial hypercholesterolemia. Although the therapy appeared safe and feasible, LDL levels were only modestly reduced, perhaps because the number of transfected

cells was small [180]. Subsequent animal studies demonstrated that excessive and unregulated AdLDLr overexpression created an imbalance between LDL uptake and metabolism, resulting in lipid accumulation in the liver [181]. In the first and only clinical study to use an antisense oligonucleotide inhibitor of apoB, 36 volunteers with mild dyslipidemia were treated by injection with a multiple-dosing regimen of inhibitor or placebo. Twelve weeks later, LDL-cholesterol and apolipoprotein B levels were significantly reduced by up to 35% and 50%, respectively. Injection-site erythema was common, but the therapy was otherwise safe [182].

Despite promising results in animal models [183–186], there have been no clinical investigations of gene therapy for treatment of hypertension and thrombosis. Hypertension could potentially be controlled by inhibiting the implicated genes or by overexpressing vasodilative genes; stable regulation of chronic hypertension might be accomplished with vectors that enable long-term gene expression. Experimental data suggest that thrombosis might be prevented by targeting antithrombotic genes such as tissue plasminogen activator and thrombomodulin.

46.5.6 THERAPY FOR HEART FAILURE AND MODULATION OF ELECTRICAL ACTIVITY

Long-term survival after myocardial infarction is now the most common cause of chronic heart failure, and despite significant medical advances, postischemic heart failure remains a primary cause of morbidity and mortality in the western world [187]. As available knowledge about the molecular mechanisms that lead to heart failure increases, gene therapy that targets these mechanisms could become a valuable therapeutic option. To improve contractile function, gene therapies will likely be designed to enhance tissue perfusion, increase Ca^{2+} transients, attenuate ventricular remodeling, and modulate electrical activity (Tables 46.1 and 46.4).

Gene therapy with VEGF has been shown to improve left-ventricular function in animal models of ischemic [34] and pacing-induced heart failure [188], and many other genes are potential candidates for treatment of heart failure. Genetic modification of Ca^{2+} -handling factors could be a viable treatment approach, because myocardial contractility is dependent on ventricular Ca^{2+} handling, and factors that are involved in myocyte apoptosis, survival, and proliferation could also be targeted to preserve cardiac function. In addition to treating acute damage, cardiac function could be preserved by reducing chronic remodeling after infarction; heme oxygenase-1 markedly reduced fibrosis and ventricular remodeling in an animal model of myocardial infarction [189]. However, despite the wide range of potential approaches and genetic targets, clinical investigations of gene therapy for treatment of heart failure have yet to be completed.

As the genetic factors influencing arrhythmia are identified, it may be possible to generate impulses in bradyarrhythmic individuals, negatively modulate activity in tachyarrhythmic patients [190], or suppress malignant arrhythmias like Brugada

syndrome with long-term gene therapy. Reliable genetic modulation could replace rhythmic therapy devices and reduce the treatment costs associated with pacemakers and defibrillators. To date, these approaches have not been attempted in the clinical setting.

46.6 SAFETY

Results from numerous studies indicate that the transfer of proteins and genes to the human system is safe and feasible [8–10,34]; however, long-term safety data from ongoing large-scale studies on cardiovascular gene therapy are not available. For this reason, a number of safety concerns are yet to be addressed, including the potential for angiogenesis-triggered malignancies, the impact of angiogenesis on physiologic or pathologic processes, and the toxic effects of specific growth factors.

Because anti-angiogenic therapies are proven effective for treating tumors, there is concern that pro-angiogenic growth factors may promote tumor development. To date, preclinical and clinical experiences with different growth factors have not identified an increased risk for malignancies, although long-term follow-up periods are rare. Two of the 88 patients at our institution who received VEGF gene transfer therapy for critical limb ischemia have been diagnosed with cancer [191], and in the VIVA trial, tumor incidence was higher in the placebo group than in VEGF-treated patients [103]. Speculation about the risk for angiomata has been common, but this complication has never been reported in clinical studies nor in animal studies that involved transducing myoblasts or applying supraphysiologic DNA doses via plasmid or adenoviral vectors [192,193]. Consensus opinion suggests that the risk of malignancy is primarily determined by the age of the patients who are eligible for gene therapy.

Because high VEGF levels in ocular fluid levels have been observed in patients with active proliferative diabetic retinopathy and endangered vision, there were theoretical concerns that VEGF gene therapy would increase the risk of proliferative and/or hemorrhagic retinopathy in these patients [194]. This potential problem has not been observed in clinical studies or in more than 100 patients treated at our institution, one-third of whom had diabetes or remote retinopathy. Treatment with naked plasmid VEGF1 or VEGF2 DNA did not affect visual acuity or eye fundus (as assessed by serial funduscopic examinations) over a 4-year follow-up period.

The potential of VEGF and other pro-angiogenic factors to promote atherosclerotic plaque growth or destabilization has been debated [122,195–197]. This concern is based, in part, on the angiogenic potential of FGF2 and VEGF on vasa vasorum [198] and on a study by Moulton et al., who demonstrated that plaque area and intimal neovascularization were significantly reduced after treatment with angiogenesis inhibitors (e.g., endostatin, TNP-470) in hypercholesterolemic and apolipoprotein E-deficient mice [199]. Results from both preclinical and clinical studies indicate that angiogenic cytokines are not likely to accelerate atherosclerosis [160–163,200]. Instead, VEGF administration significantly reduced intimal thickening by promoting

re-endothelialization, which refutes speculation that VEGF therapy may hasten the progression of atherosclerosis.

When gene therapy is administered via a viral vector, the vector itself could lead to side effects in the patient. Earlier generations of Ad vectors were shown to induce cell-cycle dysregulation [201], and Ad-vector-related death has been discussed in the past [202], although one fatality appears to have been caused by overdosing an immunocompromised patient [203]. Adenoviral vectors are used extensively in cardiovascular trials, and apart from occasional inflammation related to vector persistence [204], they have a very good safety profile. Nevertheless, continued awareness and further development of optimized vectors are warranted.

Angiogenic factors are accompanied by their own potential toxicities. Hypotension is associated with FGF2 [205] and may be more severe with recombinant VEGF proteins, especially when administered systemically or at higher doses [206,207]. Mechanistically, VEGF could induce hypotension by upregulating nitric oxide synthesis and subsequent nitric oxide-dependent arteriolar vasodilation. Hypotension has never been confirmed with VEGF gene transfer in animal or human studies [208,209], but the hypotensive effect has been dose-limiting in phase 1 trials that use both FGF2 and VEGF. Exposure to FGF2 has also been associated with renal insufficiency due to membranous nephropathy accompanied by proteinuria [210]; protein deposition in the glomerular membrane is the most likely underlying cause. Co-application of PDGFC or PDGFD and FGF may lead to tissue fibrosis and heart failure [211].

In transgenic mice, VEGF overexpression induced lethal vascular leakage, but the leakage was attenuated by co-overexpression of both VEGF and Ang1 [212]. Other reports have linked transient tissue edema to VEGFA and VEGFD as well as FGF4 gene transfer [85,96,213,214]; fluid accumulation was dose-dependent, correlated with capillary size, and coincided with maximal perfusion increase 5 to 6 days after transfer. Clinically, patients treated with VEGF for critical limb ischemia have experienced local, pedal edema that responded well to diuretics [147]; however, edema in limb muscle and (especially) in the myocardium can be hazardous, so strategies must be employed to minimize this risk [108]. When administered in moderate doses, long-lasting VEGF stabilizes growing vessels and appears to reduce, but not eliminate, edema [215]. Corticosteroids can counteract VEGF-mediated vascular permeability but also inhibit angiogenesis (Korpisalo, unpublished data) [10].

Overall, adverse effects in phase 1 trials of cardiovascular gene therapy were rare and mild; however, long-term safety data are lacking, so clinicians who perform this experimental therapy must remain aware of potential risks. The recent death of a young woman who received gene therapy for rheumatoid arthritis emphasizes the need for continued vigilance [216], although her death has not been attributed to gene therapy [217].

46.7 FUTURE PERSPECTIVES

New studies designed to advance the field of gene therapy continue to be initiated. In addition to refining techniques for therapeutic angiogenesis, which is currently the most advanced

application of gene therapy, strategies to prevent postinterventional vascular remodeling and bypass-graft failure, stabilize vulnerable plaques and aneurysms, manage heart failure, hypertension, hyperlipidemia, and thrombotic states, and modulate rhythmic activity are being pursued. The identification of new genetic targets will proceed in parallel.

As the characterization of individual gene therapies becomes more complete, researchers can logically speculate about the effectiveness of treatment that combines two or more gene therapies. Preclinical investigations designed to identify the potential complementary or synergistic effects achieved with combinations of gene therapies are under way. The effectiveness of this strategy will be determined by the same variables that influence single-gene therapy, including (but not limited to) the model species, the delivery vector, the organ and disease treated, and the genes delivered.

Although cell therapy has produced promising results in small clinical studies of cardiovascular disease, methodological uncertainties, technical difficulties, and an inadequate understanding of the therapeutic mechanisms have limited its application [218,219]. Because gene and cell therapies appear to have mechanistic commonalities, it may be possible to increase the effectiveness of cell therapy by genetically modifying stem cells to improve the survival, differentiation, and functional integration of both transplanted and endogenous cells. Combined gene-cell therapy may also produce equivalent or greater benefit with a smaller dose than either individual therapy, thereby improving patient safety. This concept is supported by evidence that the paracrine effects of bone marrow cells can be augmented by overexpression of trophic factors in mesenchymal stem cells [220], and results from our laboratory indicate that a combination of VEGF2 gene transfer and EPC administration reduced cell apoptosis (through Akt activation) and infarct size, enhanced capillary development, and improved functional recovery after acute myocardial infarction in rats [221]. Shh and SDF-1 α are likely candidates for future studies that combine gene and cell therapy because they have been shown to regulate the recruitment and incorporation of bone marrow-derived EPCs.

Gene and cell therapy can be combined in three ways: (1) gene therapy supplemented with drug-induced stem or progenitor cell mobilization, (2) combined administration of both gene therapy and *ex vivo* expanded cells, and (3) administration of genetically modified cells during cell therapy. In a large-animal study performed in our laboratory, cytokine-induced bone marrow cell mobilization combined with local VEGF gene transfer boosted myocardial recovery after infarction by enhancing bone marrow cell recruitment, retention, and incorporation; increased myocardial function and perfusion were accompanied by more dense capillary development [222]. However, intramyocardial injection of VEGF₁₆₅ plasmid combined with granulocyte-colony stimulating factor induced cell mobilization did not improve myocardial performance in patients with severe chronic ischemic heart disease in one report [223]. This latter result is surprising, and additional trials are needed to assess the potential of VEGF gene therapy combined with drug-induced cell mobilization for the

treatment of ischemic heart disease. The ischemic blood supply may not be sufficient to ensure the survival of incorporated cells, thus, in an ongoing study at our institution, gene transfer is performed before cell transplantation, thereby initiating angiogenesis in the cardiac tissue before cell mobilization and homing (ClinicalTrials.gov, NCT00279539). Combined gene and cell therapy also produced unexpected results in a sheep model of myocardial infarction; simultaneous injection of VEGF protein and myoblast cells was no more effective than treatment with VEGF protein alone [224], which might be explained by rapid degradation of the VEGF protein.

Genetic modification of cells before administration may enable enhancement of cell survival and proliferation after incorporation [225,226], thereby improving the effectiveness of cell therapy. Genetic modifications can also change intercellular communication and electrical properties [227,228] and could potentially be used to treat or prevent arrhythmia or to eliminate arrhythmic risks that may be associated with certain cell lines.

46.8 CONCLUSIONS

The safety and feasibility of gene therapy have been demonstrated repeatedly in well-designed, randomized, controlled studies with large numbers of patients, and there is convincing clinical evidence to support the efficacy of VEGF gene transfer for therapeutic angiogenesis. However, conflicting efficacy results from recent phase 2 and 3 studies make the utility of gene therapy for cardiovascular disease somewhat uncertain. The effectiveness of gene therapy is influenced by a large number of complex factors, so identifying methods to optimize gene therapy in cardiovascular medicine will require detailed analyses of the clinical data. For studies that combine the delivery of recombinant protein or gene therapy with conventional revascularization procedures, it may be difficult to determine the relative contributions of the angiogenic agent and the surgical procedure.

Vector-delivered gene therapy appears to be safer and more effective than the administration of recombinant proteins. The disappointing results observed with intravascular administration of recombinant protein likely arise, at least in part, because the concentration of protein in the target organ fails to reach therapeutic levels. Methodological improvement of gene therapy requires large-scale, double-blind, randomized, controlled trials of adequate detection power to enable optimization of vector choice and delivery techniques. Because clinical choices are initially extrapolated from preclinical studies, the potential implications of species-specific variation must be considered. Development of the catheter-based NOGA delivery system has made gene delivery more attractive for myocardial applications because the therapy can now be administered without open-chest surgery or thoracotomy.

Gene therapy is most advanced for applications that involve therapeutic angiogenesis. Until recently, this application of gene therapy for treatment of myocardial and

limb ischemia was restricted to highly symptomatic patients for whom conventional treatments had failed or were poorly suited. Recently, gene therapy for therapeutic angiogenesis has been made available to patients who are symptomatic but more stable, such as CAD patients with CCS class II/III angina. With continued advancement, cardiovascular gene therapy could become a routine treatment tool. The development of gene therapy for other indications has lagged, but numerous targets for genetic modification have been identified, so the expanded use of gene therapy seems almost inevitable. As more genetic modifications are characterized, combinations of factors will be investigated in an attempt to identify complementary or synergistic actions between them, and recent progress in cell therapy, administered both alone and in combination with gene therapy, provides more options for enhancing patient response and improving patient safety.

47.1 STRATEGIES OF GENE TRANSFER FOR THE TREATMENT OF CANCER

Since the 1970s, a multidisciplinary approach combining surgery, chemotherapy, and radiation has led to a dramatic improvement in survival for patients affected by malignant diseases. Cellular therapies, such as stem cell transplantation, have also made a significant contribution. Nonetheless, many patients are still resistant to standard therapies, which also have high and often unacceptable acute and chronic organ toxicity and an increased risk for secondary malignancies. Therefore, new strategies are needed to improve overall survival and decrease treatment-associated morbidity.

Gene transfer may be a component of these new approaches against cancer and may be used in a number of different ways:

1. *Modification of tumor cells:* By repairing genetic defects believed to be responsible for tumoral proliferation, for example, by restoring genes controlling cellular division or that induce programmed cell death (apoptosis).
2. *Sensitization of normal tissues or tumor cells in order to modify the therapeutic index of cytotoxic drugs:* Genes encoding enzymes that can transform a nontoxic prodrug into an active drug can be introduced into cancer cells, or we can modify normal tissues with genes that can protect them against cytotoxic agents.
3. *Modulation of tumor invasiveness:* By delivering genes that can inhibit the growth of new blood vessels to impede nutrient supply to the tumor cells (inhibition of neoangiogenesis).

4. *Enhancement of the antitumor immune response:* Either by inducing the recognition of tumor cells by the host's immune system or by enhancing the cytotoxic function of immune effector cells.
5. *Gene marking:* Even though gene marking is not a therapeutic intervention per se, this approach has helped investigators to understand the behavior and outcome of transduced cells once returned to the patient. This strategy is discussed elsewhere in this book (see Chapter 44).

47.2 MODIFICATION OF TUMOR CELLS

Progress made in identifying and understanding molecular aberrations has allowed much better characterization of the steps leading to cancer. Many of these aberrations alter key regulatory, survival, and differentiation processes in the normal cell cycle. Other aberrations lead to the production of abnormal fusion products, with subsequent gain or loss of critical functions in cell life and death.

Currently, the most widely used strategy is to insert a complementary DNA (cDNA) that encodes a functional protein to compensate for loss of function mutations. For example, p53 gene mutations generating inactive forms of the protein have been identified in numerous tumors and likely play a crucial role in the abnormal cell proliferation associated with malignant diseases. Transfer of wild-type p53 in p53-mutated or -deficient tumors reduces uncontrolled cell growth [1] and can induce apoptosis [2], and adenoviral [3], retroviral [4], or nonviral [5] p53 gene transfer have been explored in preclinical models [6], and subsequent clinical trials. Despite low rates of gene transfer, apparent clinical benefits are observed following p53 gene transfer in patients with ovarian cancer [7], head and neck tumors [8,9], and non-small cell lung carcinomas [10]. Indeed an adenoviral p53 formulation has been licensed as a drug in China and details are described elsewhere in this book (see Chapter 38). Likewise, alterations of p16 have been described in squamous head and neck carcinomas, and gene replacement approaches similar to those developed for p53 mutations are being explored [11].

In other tumors, the transformation event is caused by oncogenic fusion transcripts [12] or aberrant expression of antiapoptotic genes [13] determined by specific chromosomal translocations or by aberrant activation of oncogenes such as genes of the *ras* family (*H-ras*, *N-ras*, and *K-ras*) by a simple point mutation [14]. Gene transfer can help reverse these gain of function mutations by knocking-down oncogene activity. Knock-down of the mRNA from a mutated *K-ras* gene can be achieved by antisense RNA, thereby reducing production of the altered protein and delaying tumor cell growth *in vitro* and *in vivo* [15,16]. *Fos* oncogene has been similarly targeted in a murine model of mammary tumor [17]. Several other knock-down approaches using ribozymes [18] (see Chapter 18), antisense RNA [19] (see Chapter 19), or intracellular antibodies [20] have all shown promising results, but are not yet evaluated clinically. The recent discovery that double-stranded small interfering RNAs (siRNAs) can knockdown the expression

of a target gene very efficiently and with high specificity [21,22] has increased interest in this general approach. Systemic delivery or gene transfer of siRNAs can specifically downregulate oncogenes in tumor cells [23] or inhibitory molecules [24] or death signals in cells of the immune system, thereby improving the activity of the latter [25].

Numerous difficulties must be overcome before tumor correction strategies can be successful in a clinical trial. For example, the corrective gene must enter an extremely high proportion of malignant cells, unless there is a potent "bystander" effect on nontransduced tumor (postulated but unproven for p53 gene therapy). Secondly, targeting metastatic disease will usually be necessary and will require adequate distribution by blood stream and perhaps by replication competence of the therapeutic vector. Thirdly, correction of a single defect may be inadequate to eradicate the tumor cells, leaving instead a collection of "*n*-1 cells" (where *n* is the number of mutations required for malignancy to occur) capable of undergoing another mutation to restart the malignant process.

Another possible complication has recently come to light. Investigators have identified a subset of tumor cells that possess self-renewal capability and can generate more differentiated tumor cells. These cells have been dubbed "cancer stem cells" and have been isolated from a variety of cancers of the blood, breast, central nervous system, pancreas, skin, head and neck, colon, and prostate [26]. This concept may have profound implications for the design of approaches that specifically target these cells and thereby permanently eradicate the tumor.

Overall, exploitation of tumor correction strategies will require significant improvements in vector efficiency and targeting, and until these come to pass, the development of novel rationally targeted small molecules will likely dominate this "corrective" approach.

47.3 SENSITIZATION OF NORMAL TISSUES OR TUMOR CELLS

47.3.1 PRODRUG-METABOLIZING ENZYME

Introduction of a gene encoding an enzyme that metabolizes an otherwise inert molecule into a cytotoxic agent has frequently been used in tumor gene therapy. Although the herpes simplex virus thymidine kinase (HSV-Tk)-ganciclovir system has been the most widely applied, there are more than 20 such prodrug-metabolizing enzyme (PDME) systems currently in various stages of development or clinical trials [27,28]. For almost all of these, the concept is that the gene encoding the PDME is expressed in the cancer cell and metabolizes a small molecule to an active moiety, which then kills the tumor cell directly. The molecule may also diffuse either through intercellular gap junctions or in the extracellular space and destroy adjacent tumor cells. In this way, transduction of even a small proportion of tumor cells can produce a large "bystander" effect on adjacent tumor tissue. As discussed later in this section, bystander effects may also result from recruitment of components

of the immune system, which are triggered by the products of dead and dying cells. Irrespective of the mechanisms, the bystander effect compensates for the low efficiency of transduction achieved by currently available vectors and may help to destroy a large tumor burden.

Brain tumors were an attractive initial target for PDME gene therapy. Because the tumors seldom metastasize, the goal of the therapy is the local eradication of the tumor. Hence, the major limitation of PDME, that it requires local inoculation of a tumor with the vector encoding the gene, does not represent a major disadvantage. In the mid-1990s, phase I/II studies in patients with malignant glioma used intratumoral injection of retroviral vector-producing packaging cell lines (VPC) generating particles encoding HSV-Tk. These injections were followed by systemic administration of ganciclovir [29–31]. Because of initial promising results, a phase III study was conducted in patients with previously untreated glioblastoma [32]. In this study, 248 patients were randomized to conventional treatment (usually resection and radiotherapy) or conventional therapy plus adjuvant injection of VPC-HSV-Tk [32]. Unfortunately, this study failed to show improved progression or disease free survival in the patients receiving the study drug and currently this approach has been discontinued for this disease.

PDME does, however, continue to be studied in other cancers. Retinoblastoma is a localized tumor that is conventionally treated by enucleation or chemoradiotherapy [33]. Enucleation is obviously disabling and deforming, and if the tumor is bilateral it leads to blindness. The alternatives to chemotherapy and radiotherapy are less mutilating but are both associated with secondary malignancies. Hurwitz and colleagues enrolled eight patients with bilateral retinoblastoma in a phase I clinical trial [33]. These patients received bilateral intratumoral injection of adenovirus (Ad) type 5 encoding the thymidine kinase gene followed by administration of ganciclovir. This dose escalation study showed mild ocular toxicity at 10^{11} vp. and resolution of the vitreous tumor seeds in seven patients who received 10^{10} vp. One of these patients remained tumor-free 38 months after therapy and a second, modified study is planned.

The accessibility of locally recurrent prostate cancer means that these patients can receive multiple intratumoral injections of TK-encoding adenovectors [34–37]. Several studies have independently confirmed the safety of the procedure and suggested efficacy by showing prolongation of the median serum prostate-specific antigen (PSA) doubling time. The combination of this suicide gene approach with delivery of transgenes encoding immunomodulatory molecules such as IL-12 may further improve benefit by favoring an active antitumor immune response following the tumor destruction mediated by the PDME.

Other suicide gene therapies are being evaluated. Among the most developed of them is the cytosine deaminase system, which converts fluorocytosine to fluorouracil [38]. There are, however, concerns that this suicide system may be less potent than the Tk-ganciclovir prodrug system. Other molecules that metabolize drugs or trigger apoptotic pathways within tumor

cells are also being considered. Perhaps the most important future trend is to attempt to enhance the bystander effect. At present, this is mediated predominantly by transfer of the small molecule cytotoxic drug from cell to cell. However, it is apparent that at least part of the bystander effect is dependent on an immune response generated to the lysed tumor. Hence, the bystander effect in immunocompromised animals has been observed to be substantially less than in those with intact immune systems. Investigators are now attempting to combine PDME genes with sequences encoding a variety of immunostimulatory molecules (see Section 47.5.5.1), including, but not limited, to interleukin 2 (IL-2), IL-12, and granulocyte-macrophage colony-stimulating factor (GM-CSF) [39–41]. Data from these studies are yet to be evaluated. Efforts are also being made to generate vectors, which can selectively divide in malignant cells (conditionally replication-competent vectors; see Chapters 3 and 38) and may therefore spread their encoded PDME genes throughout the tumor bed [42].

PDME has also effectively been used as a means of controlling T cell therapies. For example, graft versus host disease (GvHD) may occur when donor T cells are given to patients after allogeneic stem cell transplantation in an effort to treat tumor relapse (graft versus tumor effect) or posttransplant infections. Several groups have infused donor T cells transduced with the HSV-Tk gene and reported successful abrogation of GvHD after treatment with ganciclovir [43,44]. However, the main limitation of this strategy is the high immunogenicity of the viral-derived TK protein that can eliminate transgenic T cells. The substitution of human-derived proteins should reduce the immunogenicity of the transgene. For example, the Fas receptor [45] is one of the most potent inducer of apoptosis. Fas has been modified to incorporate a specific endodomain that induces its dimerization and activation after exposure to a specific chemical inducer of dimerization (CID), analogs of which have been safely tested in a phase I study [46]. Recently, our group extended this concept by constructing a suicide gene based on an inducible caspase-9 molecule [47]. This gene has advantages over Fas attributable to higher potency, since recruitment of few molecules is sufficient to induce apoptosis. We are currently implementing a phase I clinical trial to test the safety and efficacy of this approach in patients receiving haploidentical transplantation [48].

As T cell therapies for cancer become more widespread, these suicide mechanisms will become extremely important in ensuring that the regimens are acceptably safe.

47.3.2 CYTOTOXIC DRUG-RESISTANCE GENE TRANSFER

The concept of dose intensification has long been current in modern oncology. In other words, it is believed that giving more of a cytotoxic drug over a longer period will cure a higher proportion of patients. Although there are many obvious exceptions to this rule, for many pediatric malignancies in particular, it is clear that failure to tolerate chemotherapy in the intended doses correlates well with an increased risk

of relapse. For that reason, there is an interest in using genes, which will protect normal tissues from cytotoxic drugs while leaving malignant cells vulnerable to destruction. By increasing the therapeutic index in this way, it is hoped that more drug can be administered and a higher percentage of patients cured.

There are many different candidate drug-resistance genes that can be transferred, but perhaps the most widely studied is the human multidrug resistance-1 (MDR-1) gene. The gene product acts as a drug efflux pump and prevents accumulation of toxic small molecules, including a range of cytotoxic drugs such as mitoxantrone and daunorubicin. The primary toxicity of many of these cytotoxic drugs is on hematopoietic progenitor cells. Retroviral-mediated gene transfer of drug-resistance genes into hematopoietic stem cells has until recently been difficult to accomplish. The incorporation of fibronectin together with hematopoietic growth factors into the transduction regimen, together with repeated cycles of gene transfer, has allowed a significant proportion of hematopoietic cells to be protected with expression levels adequate to reduce the sensitivity of these stem cells to chemotherapeutic agents [49]. Other molecules extensively validated in preclinical studies include dihydrofolate reductase (DHFR), which confers resistance to antifolates, and O⁶-methylguanine-DNA-methyltransferase (MGMT), which confers resistance to the cytotoxic effects of alkylating agents.

Clinical trials have been reported using HSC-expressing MDR1 [49–53]. Although appealing in concept, several problems have progressively reduced enthusiasm for this general approach, including the limited levels of transgene expression and hence drug protection *in vivo*, and toxicities to other unprotected organ systems once drug dosages are escalated. Moreover, the development of myeloproliferative/leukemic disorders in some animal studies in which MDR transporter proteins are expressed in HSC has raised concerns about the oncogenic potential of these transgenes [54]. Despite these limitations, a number of additional clinical studies are planned. These studies hope to benefit from the higher levels of gene transfer to human HSC that can now be obtained using lentiviral vectors, which may also have lower oncogenic genotoxicity compared to oncoretroviral vectors [55].

47.4 ANTIANGIOGENESIS GENE THERAPY

Because angiogenesis is a prerequisite for the development of metastatic disease for solid tumors, and probably also for leukemias and lymphomas, an attack on newly formed blood vessels may help to impede the spread of disease. Recombinant endostatin is currently the most clinically studied inhibitor of angiogenesis. Although administration of the recombinant protein has proven safe, the clinical benefits were minimal [56,57]. One explanation for this failure is that sustained effective concentrations of endostatin might not be achieved because of the short half-life of the (recombinant) protein [58]. By contrast, intramuscular injection of an adeno-associated Ad encoding for the endostatin gene

[59] makes product continuously, and the more favorable pharmacokinetics may be a reason to reevaluate the contribution of endostatin to tumor control.

A number of other different large and small molecule inhibitors of vasculogenesis are currently under study and some of them are suitable for a gene therapy approach [60]. Much remains to be learned about the most appropriate route and cell delivery of angiogenesis inhibition, but as with any protein-based therapeutic, gene transfer should allow a continual delivery of the drug rather than the peak-and-trough concentrations that result from most forms of injection, and may thereby produce a more sustained and effective response.

47.5 GENE MODIFICATION OF THE IMMUNE RESPONSE

The specificity of the immune system affords many opportunities for targeted cancer therapy. Identification of antigens expressed on tumor cells (Table 47.1) and the improvements made in gene transfer techniques, together with a better understanding of the molecular and cellular mechanisms involved in the immune response against cancer, have given investigators tools to manipulate the immune system to induce an efficient immune response in the tumor-bearing host.

47.5.1 TUMOR ESCAPE

Even though many *in vitro* cancer gene and immunotherapy studies have been published since the early 1980s, and despite impressive improvements in gene transfer technology and techniques for immune manipulation, clinical efficacy is still poor. Interest now focuses on a better understanding of the mechanisms by which tumors can escape immunosurveillance *in vivo* (Table 47.2), perhaps the greatest impediment to successful application of immunotherapy strategies.

47.5.2 ANTIGEN PRESENTATION DEFECTS

An appropriate pattern of T helper and T cytotoxic cell stimulation has been proved to be essential in mounting an efficient immune response. Many tumors prevent the recruitment of T cell immune response by downregulation of major histocompatibility (MHC) molecules or of costimulatory and adhesion molecules.

Several immunotherapy strategies have been conceived to overcome these defects. Introduction of MHC molecules into tumors was one of the first strategies adopted clinically in the 1990s. Earlier murine models had shown that an increased expression of MHC class I molecules decreased tumorigenicity due to enhanced antigen presentation to CD8⁺ cytotoxic T lymphocytes (CTLs) [61]. Tumor immunogenicity has also been increased by gene transfer of both allogeneic MHC class I and II molecules [62], thus demonstrating the relevance of both CD8 cytotoxic and CD4 helper T cells in enhancing systemic immunity against cancer. Increased expression of MHC molecules can also be obtained indirectly by transducing

TABLE 47.1
Tumor Antigens Recognized by T Lymphocytes

Antigen	Primary Tumor ^a	Normal Tissues
<i>Differentiation antigens</i>		
Tyrosinase	Melanoma	Melanocytes
ACE	Colon, digestive tumors	Colon
Immunoglobulin (idiotype)	B lymphomas	B lymphocytes
gp100	Melanoma	Melanocytes, retina ^b

tumor cells with cytokines able to induce MHC molecule upregulation on the cell surface. Examples of cytokines with this property are interferon- γ (IFN- γ) [63], IL-4, and tumor necrosis factor- α (TNF- α) [64].

Once the T cell receptor (TCR) has specifically interacted with the epitope, costimulatory signals induce a T cell response and prevent anergy [65]. A number of such signals have been identified of which the B7 family members, such as B7.1 (CD80) and B7.2 (CD86), are among the best known. These molecules are expressed on the antigen-presenting cell (APC) surface and bind to their cognate receptor, CD28, on the responding T cell [66]. Other costimulatory molecules, such as intercellular adhesion molecules (ICAM) and leukocyte function-associated antigens, are also important. The absence of costimulatory molecules on the tumor cell surface is one of the explanations for the unresponsiveness of CD8⁺T cells in the tumor-bearing host. This important role of CD80/86-CD28 interaction in T cell activation made B7 genes an appealing target for gene transfer into tumor cells [67].

CD40 ligand (CD40L) also represents a possible candidate for gene transfer because it can enhance antigen presentation by tumor cells and induce maturation of professional APCs [68]. This molecule (normally expressed only by activated CD4⁺ T lymphocytes) interacts with the specific receptor CD40 and increases antigen presentation by malignant cells by upregulating costimulatory molecules (e.g., B7-1 and B7-2), adhesion molecules (e.g., ICAM-1 and ICAM-3), and MHC molecules. CD40L also increases antigen uptake by dendritic cells (DCs) and allows them to bypass CD4⁺ T helper cells in recruiting specific CTL [69]. Hence, CD40L gene transfer has been widely used in multiple preclinical and several clinical studies (described later in this chapter) with promising results [70–76].

Failure to take up tumor antigens or to present them adequately on APCs (mainly DCs) is commonly observed in tumors. Many immunotherapy strategies therefore aim to increase the efficiency of antigen presentation. In this context, GM-CSF has been widely used for transducing

autologous or allogeneic cancer cells and proved to be one of the most potent molecules *in vivo*, mainly acting as a critical factor for promoting maturation of DCs at the site of vaccine injection and thereby enhancing tumor antigen uptake and presentation [77].

47.5.3 T CELL DEFECTS

T lymphocytes in the tumor-bearing host may be decreased in number or fail to home to tumor infiltrates. They may also be anergic and show increased apoptosis, impaired cytokine secretion, inhibition of proliferation, decreased cytotoxic capacity, defects in helper function, and absence of memory T cells. In part, these diverse deficits are attributable to an increased production of immunosuppressive factors expressed by the tumor itself or by regulatory T cells (Treg). Transforming growth factor- β (TGF- β) and IL-10 [78] and proapoptotic molecules such as Fas-ligand (Fas-L) that inhibit T cell functions or contribute to an early death of cytotoxic T cells that express high levels of Fas receptor [25,79,80] are commonly implicated.

Multiple strategies have been used to overcome the above T cell defects. Most commonly, tumor cells are transduced with genes encoding cytokines able to recreate an optimal microenvironment for T cells recruitment, activation, and expansion. Several cytokines can be used alone or in various combinations to enhance antitumor T cell-mediated immunity. Recruitment of cytotoxic CD8⁺ T cells able to

recognize tumor-specific antigens is observed with IL-4 [81], whereas CD4⁺ T cell recruitment is favored by TNF [82] and IL-7 [83].

Systemic administration of IL-2 increases the *in vivo* expansion of adoptively transferred antitumor CTLs [84]. However, the systemic toxicity [84] and the expansion of unwanted cells, including Treg [85], limit the clinical value of this strategy. Transgenic expression of IL-2 and IL-15 in tumor-specific CTLs increased the expansion of these cells in the tumor microenvironment [86–88] and enhanced antitumor activity [88]. Moreover, the coexpression of an efficient suicide gene allowed efficient elimination of transgenic CTLs, thereby increasing the safety and feasibility of this approach for clinical application [89,90].

Expression of class I antigens is enhanced by IFN- γ [91], which in turn increases tumor immunogenicity. A combination of these effects may also be obtained. For example, IL-2 can recruit both cytotoxic T and natural killer (NK) cells directly [92] and can also induce release of the secondary cytokine IFN- γ [93]. NK cells may also be important in generating an effective antitumor immune response [94]. These cells exert cytotoxic activity through the granzyme–perforin system and release inflammatory cytokines (including IFN- γ , IL-5, TNF- α , and GM-CSF). NK cells, unlike T lymphocytes, recognize and destroy target cells that lack MHC antigens, so they can be effective against tumors with downregulated surface expression of these molecules. IL-2 can also induce lymphokine-activated killer cells from both

T and NK cells [92], which have enhanced cytolytic activity against a broad range of tumor cells and act in an MHC-unrestricted manner.

The cytokine IL-12 also increases antitumor activity, by recruitment of cytotoxic T cells and NK cells [95]. Unfortunately, early clinical trials of recombinant IL-12 in cancer were rapidly discontinued due to lethal toxicity [96]. Transfer of the IL-12 gene to a restricted cell population, such as the tumor cells themselves, may retain the benefits of IL-12 in the local tumor environment whilst reducing its adverse systemic consequences by limiting peak levels [97]. Similarly, transgenic production of IL-12 by DCs increases the potency of antitumor vaccines [98]. Finally, in experimental systems, tumor-specific CTLs that are genetically manipulated to express IL-12 are resistant to the inhibitory effects of the Th2 tumor environment [99].

Costimulatory surface molecules such as B7.1 or CD40L may serve as accessory signals in the T cell activation process and prevent/overcome the T cell anergy induced by tumors [68,69]. Finally, chemokines (such as the T cell specific lymphotactin [LTN]) [100] may be used to attract immune-effector cells to the vaccination site, thereby enhancing the probability of adequate immune activation.

47.5.4 MICROENVIRONMENT ABNORMALITIES

Tumors can secrete substances able to induce immunosuppression. The best characterized of these are TGF- β , IL-10, vascular endothelial growth factor (VEGF), and Fas-L. TGF- β affects CTL function, inhibiting production of Th1 cytokines

(especially IL-12), downregulating surface expression of IL-2 receptors on T cells, inhibiting antigen presentation on MHC class II molecules, and decreasing surface expression of costimulatory and adhesion molecules [78]. IL-10 shares many immune-inhibitory properties with TGF- β , reducing Th1 cytokine synthesis and making tumor cells insensitive to CTL-mediated lysis. IL-10 antisense gene transduction can restore immunogenicity when tumor cells produce high amounts of IL-10 [101]. VEGF serves to promote tumor angiogenesis and inhibit DC differentiation. Antisense gene transduction or gene therapy with soluble inhibitory receptors represents a promising strategy to block these VEGF effects [102]. The Fas/Fas-L pathway is crucial for the T cell contraction that follows elimination of infectious agents [103,104]. Many tumors can aberrantly express Fas-L and create an unfavorable environment for tumor specific Fas positive CTLs, inducing premature apoptosis [80]. As we describe in the following sections, T lymphocytes can be genetically modified to overcome some of these tumor immune escape mechanisms.

47.5.5 CLINICAL APPLICATIONS OF IMMUNOGENE THERAPIES

Gene transfer can be used in several ways to manipulate the immune system (Table 47.3). Passive immunotherapy consists of the adoptive transfer either of specific antitumor immune effectors, gene modified or not, or of specific antibodies (generated *ex vivo*) to the cancer patient. The use of cancer vaccines in active immunotherapy aims to induce efficient and long-lasting immune responses by direct stimulation

TABLE 47.3
Strategies in Cancer Immunotherapy

Passive Immunotherapy "Adoptive Immunotherapy"

Transfer of effector cells

- Sensitized *ex vivo*
- Pulsed APCs^a
- Transduced effectors
- Restricted/nonrestricted Epitopes

- Expanded *ex vivo*
- Bulk
- Cloned population

Transfer of specific monoclonal antibodies

- Induce ADCC^b
- Coupled with toxin or radioisotope

Active Immunotherapy "Cancer Vaccines"

In vivo immunization with

- Purified antigen
- Immunodominant peptide
- "Naked" DNA encoding tumor antigen
- Recombinant viruses encoding tumor antigen
- Whole tumor cells
- Used as APCs
- Modified to attract host APCs (cross-priming)

Adjuvant therapies

- IL-2, IFN- γ : systemic administration
- IL-2, GM-CSF,^c LTN^d
- IL-12: in situ administration

^a APC, antigen-presenting cell.

^b ADCC, antibody-dependent cell-dependent cytotoxicity.

^c GM-CSF, granulocyte-macrophage colony-stimulating factor.

^d LTN, lymphotactin.

(with gene-modified cells or cell components) of the patient immune system.

47.5.5.1 Gene-Modified Autologous and Allogeneic Tumor Cells

Several clinical applications in humans have been reported using manipulated autologous cancer cells [105]. When transduced autologous tumor cell lines cannot be obtained (because the tumor is not accessible, the tumor cells do not grow *ex vivo*, or gene delivery is difficult), an immunogenic allogeneic tumor cell line can be a valid alternative. This approach unfortunately has several limitations: (1) The tumor antigens present on the autologous tumor population may be absent in the tumor cell line; (2) the antigen may be presented on a mismatched MHC molecule and, in the absence of cross-priming of host APCs/lymphocytes, may fail to be recognized by host T cells; (3) the tumor antigen may not contain peptides capable of being presented by host APC so an immunogenic allogeneic tumor in one individual may be nonimmunogenic in a second patient with a different human leucocyte antigen (HLA) type.

Among the many immunomodulatory gene products tested to date, vaccination with irradiated cancer cells engineered to secrete GM-CSF induced the most efficient, specific, and long-lasting immunity in several murine tumor models [77]. This approach, often referred as “GVAX cancer immunotherapy,” has been translated in numerous phase I/II clinical trials for therapy of several types of malignancies, including renal cell carcinoma [106,107], metastatic melanoma [108,109], prostate cancer [110], and nonsmall cell lung cancer [111]. In early studies, tumor cells were collected from the patients and engineered to produce GM-CSF using retroviral vectors. However, the transduction system was rapidly switched to Ads, as these vectors can transduce both dividing and nondividing tumor cells and guarantee higher expression of the transgene. The number of patients enrolled in each phase I/II studies ranged from 10 to 100 and single or multiple doses (from two to eight) of the vaccine were administered to the patients. Overall, treatments were well-tolerated with the most common reported toxicities being inflammation at the injection site and modest flu-like symptoms. In the great majority of the studies, the immunologic response to the vaccine was evaluated as delayed-type hypersensitivity (DTH) skin responses against irradiated autologous cancer cells and in some cases against specific tumor-associated peptides. The proportion of patients with immune responses ranged from 20% to 80% depending on the tumor type, cell dose, and number of vaccinations. The clinical activity of this approach was modest, with mixed tumor responses or tumor regression for more than 3 years in just 5% to 8% of patients.

In addition to its limited efficacy, the above approach is hindered by the complexity of the vaccine preparation. For this reason, an alternative GVAX immunotherapy has been developed in which unmanipulated autologous tumor cells are coinjected with an allogeneic bystander GM-CSF producer

cell line that functions as “universal vaccine” [112]. The cell line chosen (K562) lacks HLA class I or II antigens, so reduces the probability of inducing an allogeneic T cell-mediated response. In addition, the cell line produces large amounts of GM-CSF, so that few modified cells need to be given together with autologous unmodified tumor cells. This greatly increases the feasibility of the approach for clinical application. Two clinical trials evaluated this approach in patients with multiple myeloma [113] and nonsmall cell lung cancer [114]. Although these trials confirmed feasibility and showed the induction of immune responses, the clinical impact has remained marginal.

Other clinical trials directly use GM-CSF secreting allogeneic tumor cells alone. This approach is the simplest to scale-up clinically, since it uses an “off-the-shelf” product that can be manufactured, certified, and distributed as a drug. The rationale is that common tumor antigens will be cross-presented after uptake of tumor apoptotic bodies by local professional APCs. The most advanced clinical application of allogeneic GVAX is in patients with prostate cancer using two GM-CSF modified prostate cancer cell lines. Approximately 200 patients with recurrent prostate cancer [115] received the vaccines, which were well tolerated. Activity was demonstrated by reduction of PSA levels and by production of antibodies binding the allogeneic vaccine. Allogeneic vaccination increased the survival of metastatic patients to 20 months. Based on these studies, two phase III clinical trials including almost 600 patients have been initiated [115].

IL-2 has also emerged as a potential immunomodulatory molecule alone or in combination with other cytokines or chemokines, such as LTN. Clinical trials conducted by our group at St. Jude Children’s Research Hospital and Baylor College of Medicine (BCM) used neuroblastoma cells transduced with retroviral vectors so that they expressed the IL-2 gene. Both autologous and allogeneic studies were instituted. In the autologous trial, patients received up to eight injections of their own tumor cells subcutaneously. More than half the patients produced specific antibody and a specific cytotoxic T cell response directed against the autologous neuroblasts. Of 10 patients, five had clinical tumor responses including one complete and one very good partial response [116]. In the study using allogeneic vaccine, however, the immunizing cell line induced no evident specific immunity and only one patient showed a partial response [116]. Of note, in both studies a significant number of children showed good tumor responses on subsequent treatment with low-dose oral etoposide. This interaction between genetic immunotherapy and low-dose chemotherapy has subsequently been observed in a number of tumor vaccine studies [117,118], and likely represents a genuine interactivity between these treatment modalities that may usefully be exploited for therapeutic benefit in the future.

A subsequent clinical study in neuroblastoma was based on animal data showing that the combination of LTN a T cell chemokine, and IL-2, the T cell growth factor, accelerated, and augmented the immune response to a tumor cell line [100]. Patients with relapsed or refractory neuroblastoma

received either an autologous or allogeneic vaccine engineered to release IL-2 and LTN. In the allogeneic group, it was possible to observe specific antitumor immune responses to the immunizing cell line, and four patients entered complete remission, which was durable in three [119]. In the autologous study, the clinical results did not appear to be measurably superior to IL-2 alone [120]. Hence, in the allogeneic setting, the combination of two agents acting at different phases of the immune response may be superior to a single agent. Confirmation will be sought in larger studies.

Tumor vaccines with engineered autologous or allogeneic tumor cells are also used in patients with acute leukemia [121]. In one study, acute myelogenous leukemia (AML) blast cells are collected at diagnosis and then patients are vaccinated with tumor cells mixed with the K562 cell line producing GM-CSF. These vaccines can be given before and after autologous stem cell transplantation, with the intent of priming the antileukemic response during immune reconstitution after stem cell transplant, followed by additional vaccination to boost the immune response. Interim analysis suggested improved clearance of minimal residual disease in vaccinated patients [121].

The CD40/CD40L pathway plays a crucial role in enhancing the APC capacity of CD40⁺ malignant B lymphocytes [70,71,73] and is a key molecule for activation of professional APCs. We and others are producing leukemia-vaccines engineered to express CD40L alone or in combination with IL-2. We completed a phase I study in patients with acute lymphoblastic leukemia using autologous tumor cells expressing CD40L/IL-2 [75]. Ten patients received up to six vaccine injections without adverse events, and immunological evidence of antileukemia T-cell response was detected in more than half of the patients, even when the vaccines were given in the immediate posttransplant period [75]. The great majority of patients were in clinical remission at the time of vaccination, so the clinical impact of this adjuvant treatment is unknown. The manufacturing complexities of these autologous vaccines are considerable so feasibility of large-scale studies using this approach is questionable [122]. Once again, allogeneic gene modified tumor cells may be preferable, and will be evaluated.

Chronic lymphocytic leukemia (B-CLL) is an indolent leukemia, with plentiful availability of tumor cells, and may be a better target for autologous vaccination than an acute leukemic illness. We therefore used CD40L/IL-2 gene transfer into autologous cells, to examine the immunological and clinical responses to subcutaneous injections [74,76]. Vaccination induced a specific immunologic antitumor response *in vivo* as measured by specific IFN γ release by T cells in response to autologous tumor cells and also by the production of antibodies-binding tumor cells. The clinical benefit of this approach consisted in transient reduction of the lymphadenopathy and stabilization of the disease in some patients. Of note, the immunologic effects of the vaccine were sustained during the vaccination period (from two to eight vaccinations), but ceased rapidly after the suspension of the vaccine, suggesting that prolonged vaccination schedule is likely required to produce a

prolonged immune response and to generate clinical benefits [74]. In another study, B-CLL patients received autologous tumor vaccines expressing murine CD40L: this vaccine was administered *i.v.* [76]. A proportion of treated patients had reduced tumor burden and disease stabilization, but it is likely that these antitumor effects were mediated by direct apoptosis of the endogenous B-CLL cells due to the engagement of CD40L [123] rather than to indirect induction of an anti-B-CLL immune response.

In summary, genetic modification of tumor cells appears safe and is capable of generating specific humoral and cellular antitumor cytotoxic responses. There have been at least some tumor regressions and the approach is now being evaluated in a wider range of tumors and in a larger number of patients.

47.5.5.2 Cancer Therapy with Gene-Modified T Cells

Several studies have suggested the feasibility and apparent clinical efficacy of adoptive transfer of CTLs directed at tumor antigens [84,124,125]. By using gene-marked cells in these studies, it has not only been possible to determine the survival and homing of the infused T cells, but also to determine if they mediate adverse effects such as GvHD [124,126,127]. Clinical studies and their results are described elsewhere in this book (see Chapter 44), and include Epstein-Barr virus (EBV)-associated posttransplant lymphoproliferative disorder (PTLD) [128-132], Hodgkin's disease (HD) [133,134], and nasopharyngeal carcinoma (NPC) [135-137].

Protecting T cells against tumor-induced downregulation. Clinical studies using CTL against EBV-related malignancies including PTLD, HD, and nasopharyngeal cancer NPC are promising and there have been complete and sustained tumor responses, particularly in patients with PTLD. Nonetheless, a significant fraction of patients with HD or NPC have incomplete responses after T cell therapy. This may be due to a lack of specificity of the EBV-specific CTL for the immunosubdominant LMP1 and LMP2 antigens that are all present on the HD/NPC tumor cells. In addition, these tumors secrete immunosuppressive cytokines and chemokines, which affect CTL function [138].

Gene transfer can be used to overcome both types of problems. By using DCs transduced with adenoviral vectors encoding either LMP2 or a mutated LMP1, it is possible to generate CTL that have high cytolytic activity *in vitro* to LMP2- or LMP1-positive targets when compared with conventional EBV-CTL [139,140]. We recently completed a clinical trial in which DCs were genetically modified to overexpress the weak tumor associated antigen LMP-2. Coculture of these gene-modified DC with patient T cells produced a high proportion of CTLs with specificity for the LMP-2 antigen [141]. Following adoptive transfer, these LMP-2-enriched CTL lines were safe, and 9/10 patients treated in remission of high-risk disease remained in remission, while 5/6 with active relapsed disease had a tumor response, which was complete in four and sustained >9 months [141].

Although LMP2- or LMP1-specific CTL may be more effective, there is a concern that they will remain vulnerable to the immunosuppressive factors secreted by the Hodgkin's Reed–Sternberg cell. The cytokine that has the most devastating effects on CTL proliferation and function is TGF- β [138]. This cytokine is secreted by a wide variety of tumors and allows the tumor to escape the immune response [138]. To overcome this capacity to inhibit the EBV-CTL, our group transduced CTL from patients with relapsed EBV-positive HD with a retrovirus vector expressing a dominant-negative TGF- β type II receptor (DNR). This prevents formation of the functional trimeric receptor. Cytotoxicity, proliferation, and cytokine release assays showed that exogenous TGF- β had minimal inhibitory effects on DNR-transduced CTLs [142]. This approach will be tested in a phase I clinical trial that has been recently approved by Food and Drug Administration.

Hodgkin's lymphoma uses multiple mechanisms to escape the immune recognition. Hence a combination of strategies will likely be required to overcome the tumor resistance. For example, Reed-Stenberg cells not only have abnormally high expression of Fas-L [143], which induces premature apoptosis of CTLs, they also secrete the chemokine Thymus- and activation-regulated chemokine (TARC) [144], which attracts T lymphocytes with Th2 properties [138] and Treg [145]. Transfer of a specific siRNA that knocks-down the Fas receptor in CTLs makes them resistant to Fas-L-mediated apoptosis [25], while transgenic IL-12 makes them resistant to the hostile Th2 environment [99]. Moreover, enhanced CTL proliferation in the tumor microenvironment through the autocrine production of cytokine (IL-2 or IL-15) further augments their antitumor effect [86–88], suggesting that transfer of these cytokine genes may overcome multiple mechanisms of resistance.

$\alpha\beta$ TCR transfer for tumor therapy. The generation of CTLs recognizing a broad spectrum of viral-derived-tumor associated antigens is feasible and can be scaled up to obtain sufficient cell numbers for adoptive T cell transfer in patients. In contrast, the reactivation and expansion *ex vivo* of CTLs specific for epitopes derived from the great majority of tumor-associated antigens, including cancer testis antigens and epitopes derived from fusion oncogenic proteins, is suboptimal for translation in clinical trials.

We can overcome this limitation by transferring the TCR genes ($\alpha\beta$ TCR) that recognize a specific tumor-associated epitope [146–148]. The proof-of-principle for this technology has been recently demonstrated by Rosenberg et al. in patients with metastatic melanoma. In this trial, polyclonal T cells were genetically modified to express an $\alpha\beta$ TCR specific for MART-1. The adoptive transfer of these cells induced objective tumor regression in 20% of the patients [149]. Currently, this technology has several limitations: (1) MHC restriction of transgenic $\alpha\beta$ TCR means the approach is feasible only in patients with a specific HLA type; (2) tumor cells that downregulate MHC will escape lysis; (3) cross-pairing of the transgenic $\alpha\beta$ TCR with the

native $\alpha\beta$ TCR produces chimeric T cells with unknown specificity; (4) escape mutants rapidly emerge since the T cells target just one antigenic epitope.

Several strategies have been proposed to overcome these limitations. For example, $\alpha\beta$ TCR crosspairing can be minimized by modifications in $\alpha\beta$ TCR construction [150]. In addition, the selection of tumor-antigens crucial for tumor survival, and the combination of adoptive immunotherapy with other conventional treatments, may limit the possibility of tumor escape [151].

Chimeric T cells for tumor therapy. T lymphocytes can also be modified to express chimeric antigen receptors (CARs) derived from antibodies. If these CAR are specific for tumor antigens expressed on the cell surface, they may have considerable therapeutic potential [152–154]. CARs allow us to extend the recognition specificity of T lymphocytes beyond classical T cell epitopes by transducing cells with genes that encode the variable domain of an antigen-specific monoclonal antibody (MAb) single-chain fragment (ScFv) joined to a cytoplasmic signaling domain such as ζ - or γ -chain of the CD3 $\alpha\beta$ TCR complex. This strategy can therefore be applied to every malignancy that expresses a tumor-associated antigen for which an MAb exists. CAR-transduced T cells potentially have numerous advantages over immunotherapies based on monoclonal antibodies or T lymphocytes alone: (i) Because there is no need to select and expand tumor-specific antigens from scanty precursors, large populations of antigen-redirected T lymphocytes can be obtained in a matter of weeks. (ii) Since CARs are MHC unrestricted, tumor escape by downregulation of HLA class I molecules or defects in antigen processing are bypassed. (iii) Because both CD4⁺ and CD8⁺ T cells can express the same CAR, the full network of T cell function is directed against tumor cells [155]. (iv) The presence of CAR-mediated effector function may be more likely to produce tumor cell lysis than humoral immune responses alone since the perforin/granzyme killing mechanism may be effective against cells that are relatively resistant to antibody and complement, whereas cytokine secretion upon T cell activation by tumor antigen recruits additional components of the immune system, amplifying the antitumor immune response. (v) Unlike intact antibodies, T cells can migrate through microvascular walls, and extravasate and penetrate the core of solid tumors to exert their cytolytic activity. (vi) Finally, a single T lymphocyte can sequentially kill a multiplicity of target cells.

Human T lymphocytes genetically engineered to express these CAR genes have exhibited specific lysis via the perforin/granzyme pathways, as well as cytokine secretion upon exposure to tumor cells expressing the cognate target antigen [156]. Examples of clinical applications to tumor treatment are given in Table 47.4 [155–160].

Although adoptively transferred chimeric receptor-transduced cells are protective in murine tumor models [155,156,161–163], few clinical trials have yet been reported. In human immunodeficiency virus (HIV) patients, T cells

TABLE 47.4
Examples of Different Targets of Chimeric TCR Constructed with scFvs

Target	Comment
GD ₂	GD ₂ expressed on melanomas and neuroblastomas
GD ₃	GD ₃ expressed on melanoma cells
HMW-MAA	High-molecular-weight melanoma-associated antigen
CII	Directed against type II collagen—use T cells as gene carriers in rheumatoid arthritis
EGP40	Colon cancer-associated antigen
EGP-2	Derived from MAb GA733.2, which binds the epithelial glycoprotein 2 protein, which is overexpressed on a variety of human carcinomas
CD30	Malignant cell population in Hodgkin's lymphoma expresses high amounts of this cell surface antigen
CEA	Anti-CEA chimeric TCR with scFv derived from the MAb BW431/26
ErbB2	ErbB2 is a type I growth factor receptor overexpressed in a high percentage of human adenocarcinomas
FR	Folate receptor is expressed on most ovarian carcinomas and some types of brain tumors
Neu/HER2	Human adenocarcinoma-associated growth factor receptor
κ-light chain of immunoglobulins	Directed against mature B-cell derived malignancies

were transduced to express a CAR binding the HIVgp120 envelop protein in order to kill HIV-infected cells [164]. CAR-T cells homed to the HIV infected tissues after adoptive transfer, but the antiviral benefits of this treatment are limited [164]. Recently, phase I studies have been conducted in cancer patients with neuroblastoma [165] and ovarian cancer [166], showing the feasibility of the approach, but also the lack of objective antitumor effects. These trials also suggested that the limited effects may be attributable to lack of persistence of the transgenic T cells.

Costimulatory signals are crucial for T cell function, since $\alpha\beta$ TCR stimulation in absence of costimulation induces T cell anergy. To enhance function and persistence, the second generation of CARs contains costimulatory endodomains (CD28, OX40, or 4-1BB), to ensure the transgenic T cells are fully activated after their encounter with their specific target [155,167–170]. In preclinical studies, T cells expressing CARs encoding costimulatory endodomains exhibit potent antitumor activity and secrete significant amounts of IL-2, enhancing their persistence *in vivo* [155,171]. Clinical studies have begun.

An alternative strategy is to incorporate the CAR in CTLs with well-defined specificity in their native antigen receptor [163,172,173]. These (usually) viral-specific CTLs can be repeatedly boosted and activated *in vivo* by the engagement of their native $\alpha\beta$ TCR with viral epitopes on professional APCs. By providing all necessary costimulatory signals, this strategy should maintain the pool of transgenic

CTLs, allowing the CAR to redirect the activated cells to tumor cells (Figure 47.1). This principle has been tested in preclinical studies [163,172,173]. A current clinical trial at BCM gives patients with relapsed neuroblastoma both polyclonal T cells and EBV-specific CTLs that are genetically modified to express two distinguishable but functionally identical CARs that target the G(D2a) antigen. This trial will show whether costimulation of G(D2) + EBV-specific CTL by latently infected B-lymphocytes in EBV-seropositive patients can increase their persistence compared to polyclonal G(D2) + T cells. If this hypothesis is confirmed, the potential use of an “EBV-based vaccine” to boost *in vivo* the CTLs may further enhance their persistence. Other investigators have evaluated similar approaches using CMV-specific [174] or allo-specific CTL [175].

47.5.6 CLINICAL VACCINES USING DENDRITIC CELLS

To overcome the antigen presentation defects of tumor cells, DCs can themselves be manipulated *ex vivo* and used as cancer vaccines, mainly acting by priming naive T cells [176]. Several clinically applicable methods are now available to isolate and expand DCs from peripheral blood and bone marrow. Once isolated, DCs can be induced to present tumor antigens by several strategies, including feeding with tumor cell lysates and apoptotic bodies or by using tumor-derived RNA or making DC–tumor cell hybrids. Specific tumor

FIGURE 47.1 Strategies to express functional CARs in T cells. (A) Polyclonal T cells modified to express CAR incorporating a costimulatory endodomain (CD28) to provide full activation after engagement with the antigen. (B) CARs engrafted on antigen specific CTLs. CAR provides the antitumor effects and the native $\alpha\beta$ TCR provides appropriate costimulation by engagement with specific antigens expressed on professional APCs.

antigen gene transfer into DC using viral or nonviral vectors is also possible [177].

Several clinical studies using active immunization with DCs have been completed in patients with metastatic melanoma, metastatic renal cell carcinoma, and B cell lymphoma. Most of them have used antigen-pulsed DC [178,179], but some investigators have reported induction of immune responses using gene-modified DC [180].

In the past few years, genetic modification of DC has been directed not only to load these cells with specific antigens but also to manipulate specific pathways that can increase their effects after vaccination. In particular the down regulation of inhibitory molecules such as SOCS-1 [24] or the prolonged activation of the CD40 pathway [181] significantly improved the antitumor effects of DC vaccine in mouse models. Both these strategies are now approaching clinical validation.

47.5.7 NUCLEIC ACID VACCINES

Nucleic acid vaccines induce an immune response targeted against a protein expressed *in vivo* subsequent to the administration of its encoding DNA or RNA. Investigators demonstrated that the intradermal and intramuscular injections of polynucleotide products generate long-lasting T cell and humoral immunity [182].

Nucleotide-based vaccines have several advantages over proteins and peptides. They provide prolonged antigen expression that can continuously stimulate the immune system, probably through an intracellular antigenic reservoir, resistant to antibody-mediated clearance. This may favor induction of immune memory even in the absence of booster immunization. Codelivery with plasmids encoding

cytokines or costimulatory molecules can further enhance the immune response [183]. Moreover, nucleotide vaccination leads to antigen processing through both the endogenous and exogenous pathways, so that specific CTL and helper T cells can be recruited.

In a murine model of B cell lymphoma, mice immunized with DNA constructs encoding the idiotype had specific antibody responses and were protected against tumor challenge. Use of DNA encoding a fusion protein of idiotype and GM-CSF greatly improved vaccine efficacy [178]. Improvement of vaccine efficacy was also observed when the idiotypic DNA was fused to the C fragment of tetanus toxoid [184]. These preliminary results indicate that DNA may be a simple and efficacious system of inducing immune responses against a weak tumor antigen, provided that additional stimuli are included with the DNA (e.g., GM-CSF or tetanus toxoid).

47.5.8 FUTURE PERSPECTIVES FOR GENETIC IMMUNOTHERAPY IN CANCERS

Tumors possess multiple and powerful strategies to escape immune surveillance and can develop new immune evasion mechanisms during disease progression. Many of these strategies have been elucidated, and counterattack can now be planned thanks to major improvements in protein engineering, gene transfer, and cell therapy technologies. Why then have few major clinical success yet been reported? Two centuries past, in 1893, William Coley reported regression of tissue sarcoma in 10% of patients after they had been infected with live or heat-inactivated bacteria. Since then, clinical response rates after immunotherapy have not convincingly

changed. Hence, our nightmare is that this is as good as it ever gets. But the reality is that, despite lack of concrete clinical progress, our increasing knowledge and skills offer a real promise of improved results in the near future. It is also clear that immunotherapy by itself is unlikely to be sufficient to eradicate tumors because human malignancies are too heterogeneous in terms of the antigens they express and their susceptibility to immune-mediated killing. Only integration with standard treatments will likely be successful. Active immunization will be used as adjuvant therapy to eradicate minimal residual disease in patients previously debulked of their tumor by surgery, chemoradiotherapy, or stem cell transplantation. Patients receiving allogeneic stem cell transplant represent an obvious paradigm. After transplantation, when a new immune system is reconstituting, cancer vaccines could induce the formation of potent and long-lasting immunity. Specific cytotoxic lymphocytes from the donor could also be expanded *ex vivo* in the presence of host malignant cells and administered after transplant should malignancy recur.

Although no “breakthrough” clinical success has been reported, a better understanding of immune evasion strategies and the availability of improved technologies of immune manipulation have opened the way for real immunotherapies of cancer that should ultimately deliver on the dreams of the nineteenth and twentieth centuries.

47.6 CONCLUSION

We have far to go before gene therapy of malignancy can truly be said to have made a major impact on these diseases. Nonetheless, over the past decade, new techniques including gene transfer and immunotherapy have produced unequivocal tumor responses even in advanced disease. Improvement of gene transfer for the treatment of cancer certainly relies on four major steps: (1) simplification of gene transfer protocols, still too complex to implement in a clinical environment; (2) controllable, tissue-specific regulation of transgene expression; (3) progress in the understanding of carcinogenesis mechanisms to improve therapeutic strategies; (4) improvement in the methodology of clinical trials, including optimal choice of the patient population, and monitoring of tumor and immune responses, within the tight frame of regulatory and cost-related issues. As we continue to make incremental advances in the application of these approaches, we can expect to see gene therapy increasingly supplement probably long before they can eventually supplant conventional cancer therapeutics.

48.1 INTRODUCTION

The tumor suppressor p53 is one of the most important and intensively studied molecules in biomedical research. Since its discovery 28 years ago, more than 43,000 articles have been published about p53. These studies cover nearly all aspects of biomedical research, encompassing biochemistry, biophysics, molecular biology, cellular biology, genetics, pharmacology, toxicology, metabolism, immunology, bioinformatics, as well as clinical research. Tremendous effort has been spent elucidating the mechanisms underlying p53's tumor suppressive function and how it is regulated. Still, there is much ground to cover before p53 and its signaling pathways are fully understood. However, this fact does not prevent the application of our current knowledge to the development of strategies for treating cancer patients using the p53 pathway as a therapeutic target. Indeed, a number of strategies, such as introduction of functional wild-type p53 into cancer cells and inhibition of MDM2-mediated p53 suppression, have been investigated in recent years. In this chapter, we will review p53's properties and functions, as well as its regulation in response to diverse cellular stressors. We will also briefly describe recent progress in the development of anticancer therapies that target the MDM2–p53 feedback loop. p53 gene delivery-based gene therapy will be discussed in Chapter 49.

The p53 protein is a stress-activated transcription factor; therefore activated p53 can either induce or repress the transcription of many target genes. The proteins encoded by these target genes are involved in the regulation of multiple biological functions, including cell cycle, apoptosis, cell senescence, differentiation, angiogenesis, cell migration, and DNA repair [1]. Diverse stressors, including DNA damage, oncogene activation, hypoxia/anoxia, ribonucleotide depletion, and loss of

support/survival signals, stabilize the p53 protein and enhance its activity [2]. The importance of p53 in tumor suppression is highlighted by the fact that more than half of all types of human tumors harbor mutations or deletions in the p53 gene, and the remainder often have impaired function of the p53 pathway through the involvement of direct or indirect p53 regulators [3–6]. Germ-line mutations of p53 have been identified in individuals with the cancer-prone Li-Fraumeni syndrome [7,8]. Similar to human cancers, mice homozygous for inactivated p53 are highly susceptible to spontaneous tumorigenesis [9], and transgenic mice expressing hot-spot gain-of-function p53 mutations develop tumors in various tissues [10,11]. These studies establish p53 as a principal “guardian of the genome” and demonstrate that p53 plays an essential role in protecting the organism from tumorigenesis.

The p53 protein possesses the typical structural domains of a transcription factor, as well as several unique domains. These features include the DNA-binding domain, the transactivation domain, the oligomerization domain, the basic regulatory region, and the proline-rich domain. These features of the p53 protein allow for the dynamic regulation of p53's stability and activity in response to various external and internal cellular stressors. The central DNA-binding domain mediates sequence-specific binding to chromatin [12–14]. The majority of p53 gene mutations, which are found in human cancers occur in this domain, emphasizing the importance of this region for p53's function [15]. These mutations alter the conformation of p53 and affect the folding of the DNA-binding domain, therefore disrupting the capacity of p53 to bind to its DNA target, rendering it inactive. This domain has also been shown to interact with the ASPP (Ankyrin repeat, SH3 domain, and proline-rich domain containing) family proteins ASPP1 and ASPP2, allowing p53 to preferably activate transcription of proapoptotic genes such as *Bax* and *PIG3* [16].

The N-terminal, bipartite acidic transactivation domain makes contacts with basal transcription factors and coactivators, thus initiating transcriptional activation of target genes [17,18]. The C-terminal oligomerization domain allows p53 to form a tetramer and is required for its transcriptional activity [12]. The basic regulatory region at the extreme C-terminus is thought to regulate the sequence-specific binding activity of the central core DNA-binding domain and contributes to p53's ability to recognize several forms of DNA that resemble structures caused by DNA-damaging agents [12,19–24]. Finally, the p53 N-terminal proline-rich domain, containing five copies of the sequence PXXP, has been shown to be important for the p53-induced apoptotic response to DNA-damaging agents [25–30].

48.2 BIOLOGICAL FUNCTIONS OF p53

Upon activation, p53 binds to its cognate DNA response elements (p53RE) in the genome and activates or represses the transcription of genes residing in the vicinity of these binding sites. There are over 4000 putative p53-binding sites existing in the human genome [31]. More than 150 p53 target genes have been described and many more will be revealed with the development of advanced molecular technology. The proteins encoded by these genes contribute to diverse biological functions of p53 in multiple ways, including inducing cell cycle arrest, apoptosis, senescence, and angiogenesis [1]. In addition, p53 may facilitate DNA repair directly or indirectly through the induction of genes associated with DNA repair. These cellular responses to p53 activation can be variable and highly dependent on both cell type and the nature of the sustained damage.

Proper cell cycle checkpoints ensure that genomic integrity is maintained throughout cell division. p53 plays a role in both the G1 and the G2 checkpoints of the cell cycle, in part by induction of its target genes *p21^{WAF1/CIP1}* (p21 will be used hereafter), *14-3-3- σ* , and *GADD45*. The p21 protein inhibits cyclin D-dependent kinases (CDK). CDKs phosphorylate Rb, thereby causing the dissociation of Rb from E2F, allowing E2F to activate the expression of proteins important for the progression of the cell cycle [32]. As a result, p21 maintains the Rb–E2F complex and indirectly inhibits E2F activity, preventing the G1–S transition [15,33]. The 14-3-3- σ and GADD45 proteins inhibit cyclin B–CDC2 kinase activity, which is essential for the G2–M transition. In response to DNA damage, 14-3-3 σ binds to phosphorylated Cdc25, a tyrosine protein phosphatase for CDC2, and sequesters Cdc25 in the cytoplasm where it cannot activate CDC2. Then the GADD45 protein dissociates CDC2 from cyclin B, blocking the G2–M phase transition [34,35]. Thus, p53 also mediates the G2 cell cycle arrest [36,37].

Depending on the type and duration of the stress and the cellular growth conditions, p53 can activate different subsets of target genes with proapoptotic activity [1,38]. These genes encode the cell membrane proteins Fas/CD95, KILLER/DR5, and PERP [39–43], the cytoplasmic proteins PIDD and PIG (p53-inducible gene family), and mitochondrial proteins, such

as BAX, NOXA [44], PUMA [45], p53AIP1 [46], BID, and others. These proteins trigger the death-receptor-mediated [47,48] and mitochondrial-mediated apoptotic pathways [49,50]. In addition, p53 can interact directly with antiapoptotic proteins, such as Bcl-XL and Bcl-2, to exert its apoptotic function in the mitochondria, independent of its transcription activity [51–53]. Also, activation of autophagy by the p53-induced protein DRAM has been described as an important contribution to the apoptotic response [54]. Therefore, primarily by inducing cell cycle arrest or apoptosis, p53 provides a crucial surveillance mechanism for allowing cells to either recover from stress or to be eliminated from the replicative pool, thus preventing growing cells from undergoing malignant transformation.

In addition, p53 plays an important role in maintenance of genomic stability by mediating DNA repair [55–57]. It has been shown that p53 is involved in various types of DNA repair, including nucleotide excision repair (NER), base excision repair (BER), nonhomologous end-joining (NHEJ) and homologous recombination (HR) [58–62]. For example, p53-dependent transcriptional activity is important for regulation of NER by p53 [61]. p53 binds to the NER-associated helicases XPB and XPD and modulates their activities [63,64]. It also regulates the expression of the DDB2 and XPC [65–67], and serves as a chromatin accessibility factor for NER of DNA damage [68]. Further, p53 also binds to RAD51 and RAD54, major components of the HR machinery, and controls the level of HR [69,70]. Therefore, p53 regulates DNA repair as well as the DNA damage response.

In addition to its role in gene maintenance, p53 stimulates the expression of genes important for suppression of blood vessel formation (angiogenesis). Angiogenesis is critical for tumor progression [71]. At least three mechanisms account for this inhibitory effect of p53 on angiogenesis: Interference with the central regulators of hypoxia that mediate angiogenesis, inhibition of the production of proangiogenic factors, and direct increase of the production of endogenous angiogenesis inhibitors. These mechanisms license p53 to shut down the angiogenic potential of cancer cells and prevent tumor growth, progression, and metastasis [71]. Recently, p53 has been shown to inhibit hypoxia-inducible factor-1 (HIF-1) activity; HIF-1 induces angiogenic factors in response to hypoxia and impairs cardiac angiogenesis in response to pressure overload. As a consequence, p53 prevents the development of cardiac hypertrophy and induces systolic dysfunction in response to sustained pressure overload, therefore fulfilling a crucial function in the transition from cardiac hypertrophy to heart failure [72].

Of further interest, p53 also can activate the transcription of some noncoding RNAs, resulting in cell growth inhibition and apoptosis. For example, p53 induces the expression of miRNA-34a, which also contributes to p53-mediated cell cycle arrest and apoptosis [73–76]. Moreover, p53 represses RNA polymerase (Pol I)-mediated transcription of precursor rRNAs and Pol III-mediated transcription of tRNAs and 5S rRNA, leading to inhibition of ribosomal biogenesis [77].

p53 has been shown to repress the Pol II-mediated transcription of U1 snRNA [78] and Pol III-mediated transcription of U6 snRNA [79,80]. Therefore, there are many layers to p53's role in cell growth.

The tumor suppressive function of p53 is validated concretely by several *in vivo* mouse models. It is firmly established that p53 knockout mice die within 10 months due to a variety of spontaneous tumors [9]. Remarkably, restoration of endogenous p53 expression in p53-deficient tumors leads to complete regression of these tumors due to cell cycle arrest, apoptosis, senescence, and initiation of an innate immune response [81,82]. These studies place important emphasis on the fact that, although cancer arises from a combination of mutations in oncogenes and tumor suppressor genes, p53 deficiency is required for maintenance of aggressive tumors. Also, these *in vivo* studies provide an incredibly solid foundation for cancer therapeutic strategies aimed at reintroduction of p53's function.

48.3 MDM2: A FEEDBACK INHIBITOR OF p53

The ability of p53 to induce apoptosis or cell cycle arrest can be detrimental to normal cell growth if left uncontrolled. Therefore, it is essential for a cell to tightly control p53 activity during normal development and cell growth. Under physiological conditions, p53 is maintained at an extremely low and inert level with a half-life of approximately 30 min. This rapid turnover of p53 is due to its ubiquitylation-mediated proteasomal degradation. Although a number of ubiquitin ligases, such as Pirh2, COP1, and alternative reading frame (ARF)-BP1, have been shown to ubiquitylate p53 [83], the central and most extensively studied ubiquitin ligase is the oncoprotein MDM2. The *mdm2* gene was originally identified on a mouse double minute chromosome in the 3T3DM cell line [84]. It can immortalize and, in cooperation with Ras, transform rat embryonic fibroblasts [85]. Consistent with this study, overexpression or gene amplification of *mdm2* has been shown in a variety of human tumors, particularly in soft tissue sarcomas, carcinomas, leukemias, lymphomas, breast and lung cancers [86–91]. More recent data have shown that a naturally occurring polymorphism (SNP309) within the *mdm2* promoter leads to an increase in *mdm2* mRNA and protein in human populations [92], which may be related to higher incidence of cancers.

MDM2 is a nuclear phosphoprotein, which possesses several important functional domains, including the p53-binding domain, a central acidic region with a C4 zinc finger, and a C-terminal RING domain, which confers MDM2's E3 ligase activity. MDM2's N-terminal p53-interacting domain mediates MDM2's binding to the N-terminal transcriptional activation domain of p53, thus interfering with p53's ability to interact with the transcription machinery [93,94]. The central acidic domain of MDM2 is pivotal for MDM2-mediated p53 degradation, but not p53's ubiquitylation [95,96]. A number of proteins, such as the ribosomal proteins L5 and L23, and ARF, bind to this domain, leading to inhibition of MDM2-mediated p53 degradation. The C-terminal side of the acidic

domain contains a C4 zinc finger domain, which has recently been shown to mediate the binding of MDM2 to ribosomal protein L11. Mutation of residue Cys 305 to either Phe or Ser resulted in the loss of L11 binding to MDM2 and stabilization of p53, indicating this region may also play an important role in controlling p53 degradation [97]. The C-terminal RING finger domain is required for the E3 ligase activity of MDM2 [98]. MDM2 also contains a nuclear localization signal (NLS) and a nuclear export signal (NES), which mediates the shuttling of MDM2 between the cytoplasm and the nucleus and also provides a mechanism to regulate p53's activity [99,100]. Further, within the RING domain, amino acids 464–471 can function as a nucleolar localization signal (NoLS) [101]. All of these domains in MDM2 are crucial for regulating p53's stability and activity.

MDM2 inhibits p53's function through several mechanisms. MDM2 binds p53 specifically, linking their N-terminal domains. This binding conceals the N-terminal transcription activation domain of p53 at its target promoters, preventing the interaction of p53 with the basal transcription machinery. Also, by occupying at p53's target promoters with p53, MDM2 can also interact with histones and promote monoubiquitylation of histone H2B in the vicinity of a p53-binding site [102–105]. These actions lead to the inhibition of p53's transcriptional activity [94,106]. In addition, this binding initiates the ubiquitylation of p53 at several C-terminal lysine residues, catalyzed by the C-terminal RING-finger domain of MDM2; this ubiquitylation results in p53's degradation by the 26S proteasome [98,107]. MDM2 was recently found to differentially catalyze monoubiquitylation and polyubiquitylation of p53 in a dosage-dependent manner [108]. As a consequence, low levels of MDM2 activity induce monoubiquitylation and nuclear export of p53, whereas high levels promote polyubiquitylation and nuclear degradation of p53. It seems likely that these distinct mechanisms are employed under different physiological settings. For example, MDM2-mediated polyubiquitylation and nuclear degradation may play a critical role in suppressing p53's function during the later stages of a DNA damage response, or when MDM2 is malignantly overexpressed [109,110]. On the other hand, MDM2-mediated monoubiquitylation and subsequent cytoplasmic translocation of p53 may represent an important means of p53 regulation in unstressed cell, where MDM2 is maintained at low levels [111–114]. Moreover, MDM2 was also reported to promote NEDD8 conjugation of p53. The C-terminal glycine residue of the ubiquitin-like protein NEDD8 can be covalently linked to Lys 370, 372, or 373 of p53. This modification inhibits p53's transcriptional activity without affecting p53's protein stability [115]. The lysine residues modified by neddylation are three of the six lysines also targeted by ubiquitylation. Whether neddylation augments ubiquitylation is not yet clear. Interestingly, the *mdm2* gene is a downstream target gene of p53 [116,117], thus forming a negative feedback loop [118,119]. Indeed, genetic disruption of *p53* rescues the lethal phenotype of *mdm2* knockout mice [120,121], firmly validating that MDM2 is a critical inhibitor of p53.

48.4 p53 STRESS RESPONSE

To activate p53, cells must overcome the MDM2-p53 negative feedback circuit. Multiple pathways can lead to activation of p53 in response to a wide variety of cellular stressors, including DNA damage, oncogenic stress, ribosomal stress, and others, such as those induced by hypoxia, reactive oxygen species, telomere erosion, and the loss of survival signals [122,123]. All of these stressors lead to disruption of the negative control of p53 imposed by MDM2 through shared or distinct pathways or cellular components.

DNA damage triggers an Ataxia telangiectasia mutated kinase (ATM) or ataxia telangiectasia RAD3-related kinase (ATR) kinase-dependent phosphorylation cascade and results in p53 activation. In response to ionizing radiation (IR), p53 is phosphorylated at Ser 15 by ATM kinase [124–127] and at Ser 20 by Chk2, which is phosphorylated by ATM [128–130]. In response to UV damage, p53 is phosphorylated at Ser 15 by ATR kinase [131,132] and at Ser 20 by Chk1, which is phosphorylated and activated by ATR [133]. Although phosphorylation of Ser 15 and Ser 20 did not diminish the binding of an N-terminal p53 peptide to MDM2, subsequent phosphorylation of Thr 18 drastically reduced p53-MDM2 binding [134]. Since phosphorylation of Thr 18 requires prior phosphorylation on Ser 20, DNA damage-induced phosphorylation of p53 at the N-terminal residues within the MDM2 binding region impairs the binding of MDM2 to p53 and blocks its inhibitory effect on p53. Similar to p53, phosphorylation of MDM2 also plays a role in p53's activation during a DNA damage response. Most MDM2 phosphorylation sites are clustered within MDM2's N-terminal p53-binding domain and the central acidic domain. For example, MDM2 is phosphorylated by DNA-PK at Ser 17. This phosphorylation might play a role in blocking the MDM2-p53 interaction [135]. ATM phosphorylates MDM2 at Ser 395 and impairs MDM2's ability to promote p53 degradation, possibly through phosphorylation-dependent inhibition of p53's nuclear export by MDM2 [136–138]. In addition to the regulation of p53's stability upon DNA damage, phosphorylation also regulates the recruitment of transcriptional coactivators such as p300/CBP to p53, thus enhancing p53's transcriptional activity [139]. Taken together, DNA damage triggers the activation of p53 through phosphorylation of both p53 and MDM2, impairing MDM2's ability to bind to p53, therefore relieving its inhibitory effect on p53.

The MDM2-p53 feedback loop is also subjected to regulation through protein-protein interaction. One critical player of this regulatory mechanism is ARF (p14^{ARF} in human, p19^{ARF} in mouse) that is encoded by the INK4a locus and translated in an ARF, when compared to the reading frame for the CDK inhibitor p16 [140]. ARF activates p53 in response to aberrant growth and proliferation signals, such as those induced by the overexpression of the oncogenes Ras [141], c-Myc [142], E2F [143], E1A [144], or β -catenin [145]. It binds to the central acidic domain of MDM2 and directly inhibits MDM2 ubiquitin ligase activity, both *in vitro* and in cells [146], thus leading to stabilization and activation of p53

[146–150]. Because of this function, ARF also acts as an important tumor suppressor [137,151,152].

Another group of proteins, which activate p53 through direct interaction with MDM2 and suppression of MDM2's activity, are ribosomal proteins. Recently, at least four ribosomal proteins, including L11, L5, L23, and S7 [83,153–158], have been shown to interact with MDM2 in response to ribosomal stress caused by perturbation of ribosomal biogenesis.

The ribosome is a fine-tuned cellular machine that translates cellular mRNA through a static, higher-ordered cellular process, into proteins [159,160]. To produce a ribosome, eukaryotic cells must assemble about 79 ribosomal proteins with four different ribosomal RNA (rRNA) species (28S, 18S, 5.8S, and 5S) into ribosomal subunits in the nucleolus [161,162]. Notably, all three RNA polymerases (I, II and III) are involved in this process and are coordinated to ensure the high efficiency and accuracy of ribosome production. Together, these complex processes are called ribosomal biogenesis and of fundamental importance for normal cell growth and proliferation. Therefore, it is also perfectly coupled with cell growth and proliferation. Illustrating this point are studies showing that interference with ribosome production severely retards animal growth and development, at both the cellular level and the organism level.

Since ribosomal biogenesis occurs primarily in the nucleolus and many external and internal stimuli lead to the disruption of the nucleolus, it is understandable that perturbation of the nucleolus or nucleolar protein production would be linked to p53 activity along with other types of stress [163]. This specific type of stress is often referred to ribosomal (or nucleolar) stress, and can be triggered by actinomycin D or 5-fluorouracil (5-FU) treatment [164–166], serum starvation [167], the expression of dominant-negative Bop1 [168], or the genetic disruption of ribosomal protein S6 and TIF-IA [169,170]. In response to ribosomal stress, free L5, L11, L23, and S7 may be released to the nucleus or the cytoplasm where they bind to MDM2 and inhibit MDM2-mediated p53 suppression [83,153–158]. These studies suggest that p53-dependent cell cycle checkpoints monitor the malfunction ribosomal biogenesis. Interestingly, like ARF, these individual ribosomal proteins are small basic proteins. They also bring up several important questions. Why do so many basic nucleolar proteins bind to and inhibit MDM2's function? Do these nucleolar proteins collaborate to produce an optimal stress response? Would they play a role in response to different nucleolar stressors? Finally, how might the regulation of ribosomal proteins play a role in preventing tumorigenesis? All of these questions and others remain.

48.5 OTHER REGULATORS OF THE MDM2-p53 FEEDBACK LOOP

Besides the aforementioned proteins, the MDM2-p53 feedback loop is also subjected to regulation by many other proteins. The transcriptional coactivators p300 and CBP appear to exert a dual function on this loop [171]. p300/CBP acetylates

p53 and stimulates its activity. This acetylation can be inhibited by MDM2 [172,173]. Additionally, p300/CBP interacts with MDM2 in nuclear body-like structures, where MDM2 might be protected from proteasomal degradation [174] and cooperates with MDM2 to degrade p53 [171,175,176]. Consistently, MDM2 mutants lacking the p300/CBP-binding domain within MDM2's central acidic domain failed to degrade p53, but still promoted monoubiquitylation of p53 [177,178]. More recently, p300/CBP was shown to act as an E4 enzyme to assist MDM2 in polyubiquitylation of p53 [179]. It is yet unclear what physiological conditions may cause p300 to regulate this portion of the feedback loop and if the overall outcome of this stimulus would be the positive or negative regulation of p53.

Another key regulator of MDM2 is its homolog, MDMX, which assists MDM2 in downregulating p53's function [180]. MDMX shares significant homology with MDM2 in its N-terminal p53-binding domain and its C-terminal RING-finger domain [181]. Like MDM2, MDMX binds p53 and inhibits its function [182–184]. As in the case of MDM2, genetically targeting the p53 gene also rescues the lethal phenotype of *mdmx* knockout mice, suggesting that MDMX is critical for MDM2-p53 feedback regulation as well [185–187]. Increased expression of MDMX is frequently observed in human tumors [188–190]. However, unlike MDM2, the expression of MDMX is not regulated by p53 [180], and MDMX alone does not ubiquitylate p53 [182,186,191,192]. Also distinct from MDM2, MDMX appears to reside mostly in the cytoplasm [186,193], but can be recruited to the nucleus by MDM2 [186,194]. The nuclear import of MDMX is also induced by DNA damage signals, such as γ irradiation [195]. In the absence of MDMX, MDM2 is relatively ineffective at downregulating p53 because of its extremely short half-life. MDMX aids MDM2 through an interaction between MDM2 and MDMX's RING-finger domains. This interaction sufficiently stabilizes MDM2 and enables it to degrade p53 at its optimal turnover rate [194].

MDMX is also degraded by MDM2 [196,197]. Moreover, ARF prevents MDM2 from degrading p53 and shifts MDM2 activity to degrade MDMX instead [197]. Therefore, MDM2 and MDMX may have different roles in inhibiting p53. MDMX is thought to enhance MDM2-mediated p53 ubiquitylation and degradation [198,199], consequently repressing p53's function. Interestingly, in response to ionizing or UV irradiation, MDMX is phosphorylated at Ser 376 by ChK2 or ChK1 and this phosphorylation leads to the interaction of MDMX with 14-3-3 proteins. As a result, MDMX loses its ability to suppress p53, thus leading to p53 activation [200,201]. Therefore, to activate p53, stress signals must turn on cellular mechanisms that surmount the negative control by MDM2 and MDMX.

Finally, the MDM2-p53 feedback loop is regulated by deubiquitylation. Herpes virus-associated ubiquitin-specific protease (HAUSP), an ubiquitin hydrolase, was shown to be a direct antagonist of MDM2 activity and acts by specifically deubiquitylating p53 after stimulation by DNA damage, thus protecting p53 from MDM2-mediated degradation [202]. However, HAUSP was also shown to bind and to deubiquitylate MDM2 and MDMX, thus stabilizing both proteins [203,204]. This effect appears to be more dominant, as knockdown or knockout of HAUSP activates p53 function [203]. In contrast to HAUSP, another deubiquitylation enzyme called USP2a has recently been shown to specifically bind to and deubiquitylate MDM2, but not p53, thus enhancing MDM2-mediated p53 degradation. Consistently, reduction of USP2a levels destabilizes MDM2 and causes the accumulation and activation of p53 [205]. These studies suggest that deubiquitylation also regulates the MDM2-p53 feedback loop. Whether these deubiquitylases play a role in tumorigenesis would be an interesting and critical question for future investigation.

The above-discussed and other p53 regulators not discussed are listed in Table 48.1, highlighting the extreme complexity of p53 regulation in cells.

48.6 STRATEGIES FOR TARGETING p53 IN CANCER THERAPY

The understanding of p53's biological function and its regulation provides a basis for targeting p53 for anticancer drug development. Over the past decade, a number of attempts have been made to develop drugs that either rescue p53's activity by overexpressing its wild-type form in cancers, or enhance p53's activity by interfering with the MDM2–p53 interaction or MDM2's ubiquitin ligase activity (Table 48.2).

Some of the approaches currently explored to activate or rescue the wild-type function of p53 are the small molecules cp-31398, PRIMA-1, and MIRA-1, and the recombinant adenoviral

p53, known as Genticine. CP-31398, PRIMA-1, and MIRA-1 were developed as chaperone molecules to aid in refolding of mutant p53 in cancer tissue so that it can assume a proper wild-type conformation. CP-31398 had the disadvantage in that it could only chaperone the newly translated p53 protein. However, recent tests with PRIMA-1 and MIRA-1 are very promising and demonstrate that these compounds can not only chaperone the folding of the newly produced p53 but also refold the mutant p53 already present in the cells [206–208]. The description of Genticine, a recombinant adenovirus encoding the human p53 tumor suppressor gene (rAd-p53), and its clinical studies are discussed by Dr. Zhaohui Peng and his

RITA	Small molecule	Disruption of p53/MDM2 interaction	Cells, mouse	[208,286]

colleagues in Chapter 49, and represents a paradigm for clinical application p53 as an anticancer agent.

Since aberrant overexpression of MDM2 occurs in subset of tumors with wild-type p53, it is also necessary to overcome MDM2's inhibition of p53 by downregulating its expression, either by directly inhibiting its ubiquitin ligase activity or compromising its interaction with p53 to restore p53 function in some tumors. Over past years, several strategies that target MDM2 for inhibition have been explored: (1) Inhibition of MDM2 expression by antisense oligonucleotides has been shown to activate p53 in various wild-type p53-containing tumor cell lines and has antitumor activity in xenograft tumor models in nude mice [209–211]. These antisense oligonucleotides synergistically enhance the antitumor effect of chemotherapeutics and radiation therapy [212–214]. Interestingly, the antisense MDM2 inhibitors also have antitumor activities in human cancers with p53 deficiency, reflecting their inhibitory effect on p53-independent function of MDM2 [210,213].

As noted above, MDM2 is the central negative regulator of p53, acting as an ubiquitin ligase to target p53 for proteasome-mediated degradation. Thus inhibition of MDM2's E3 ligase activity would stabilize p53 for activation. Recently, small molecule inhibitors have been identified to possess such an inhibitory effect on MDM2. One of such compounds, named HLI98, inhibits MDM2-mediated p53 ubiquitylation and induces p53-dependent apoptosis in cancer cells [215]. The major drawback for this class of compounds is their low selectivity and potency. To screen more selective small molecules for the desired specificity would increase the feasibility of using them in cancer therapy.

Finally, a potential way to activate p53 is through inhibition of the MDM–p53 binding. MDM2 contains a well-defined, relatively deep hydrophobic pocket in its the N-terminus (residues 25–109) where the transactivational domain of p53 binds, thereby concealing p53 from interacting with the transcriptional machinery [216]. The minimal MDM2-binding site on p53 was subsequently mapped to residues 18–26 [93,217,218]. This pocket is filled by three primary side chains (Phe 19,

Trp 23, and Leu 26) from the helical region of the p53 peptide [216,217]. Therefore, it is possible to design small molecules to mimic p53's binding to MDM2. A number of such molecules have been investigated, including chalcone derivatives, chlorofusin, nutlin, and reactivation of p53 and induction of tumor cell apoptosis (RITA). Chalcone derivatives are present in many antioxidant-rich foods and are intermediates in the production of flavanoids. They were the first found inhibitors of the MDM–p53 interaction, as was chlorofusin, a fungal metabolite [208, 219,220]. However, their activity and cell and animal models are currently unconfirmed. The small molecule inhibitors nutlin and RITA are potent and selective MDM2 antagonists, which bind to MDM2, blocking its suppression of p53 [221,222] *in vitro* and *in vivo* tumor models and are promising for future study [223].

In summary, p53 and the MDM2–p53 feedback loop are highly relevant to cancer formation and progression. Hence, using p53 as an anticancer gene therapy or targeting this loop for anticancer therapy presents a very promising approach. Other alternative strategies could be designed by either disrupting MDMX–p53 binding or screening compounds that target the central domain of MDM2 or MDMX, thus inhibiting their ability to inactivate p53. Although we have a long path to march in order to develop strategies stemmed from these concepts for effective cancer treatment, such a triumphant day is within reach, given that tremendous effort will continually be spent expanding upon the wealth of knowledge already established in this exciting and advancing arena.

49.1 INTRODUCTION

Over the past decade, gene therapy has been increasingly applied in clinical studies as a new mode of medical intervention. According to data published by the *Journal of Gene Medicine* (<http://www.wiley.co.uk/genetherapy/clinical/>), there were a total of 1309 approved clinical trials for gene therapy across the world at the end of July of 2007. Among these clinical trials, 66.5% were for the treatment of cancer.

Of these cancer gene therapy trials, 62 used recombinant adenovirus encoding the p53 tumor suppressor (rAd-p53). More than 20 kinds of cancer indications have been treated with the rAd-p53 agent, such as head and neck squamous cell carcinoma (HNSCC), lung cancer, breast cancer, and liver cancers. A number of clinical treatment regimens have been evaluated, including administration of rAd-p53 agent alone, or in combination with conventional therapies, such as radiotherapy, chemotherapy, and surgery.

Encouraging clinical responses have been reported by a number of study groups. Lang et al. (2003) reported the results of a phase I clinical trial study in which rAd-p53 was administered to 15 patients with recurrent glioma. rAd-p53 was injected intratumorally at doses between 3×10^{10} and 3×10^{12} viral particles (VP). Three days after rAd-p53 injection the tumor was resected and more rAd-p53 was injected into the tumor bed. Of the 15 patients treated, one survived more than 3 years without evidence of recurrence, four patients experienced no recurrence for more than 6 months after treatment, and two of these four patients survived for more than 1 year. In a multicenter phase II trial involving 25 patients with nonsmall cell lung cancer, 7.5×10^{12} VP of rAd-p53 was injected intratumorally in combination with cisplatin and vinorelbine. No significant difference in tumor response was observed from rAd-p53-injected lesions and noninjected lesions (52% versus 48%, respectively), yet the rAd-p53-treated lesions appeared to be smaller than the nontreated controls (Schuler et al., 2001). In a separate clinical study of 24 patients with nonsmall cell lung cancer (Nemunaitis et al., 2000), rAd-p53 was injected intratumorally at doses between 1×10^6 and 1×10^{11} plaque-forming units (PFU)/injection in combination with cisplatin. Seventeen patients achieved stable disease, two patients achieved partial response (PR), and four patients had progressive disease. Intratumoral injection of rAd-p53 in combination with cisplatin was well tolerated and there was evidence of clinical efficacy. rAd-p53 was also used for nonsmall cell lung cancer treatment in combination with radiation therapy (Swisher et al., 2003). The rAd-p53 dose ranged from 3×10^{11} to 3×10^{12} VP/injection. Radiation was given concurrently over 6 weeks to a total of 60 Gy. Of the 19 patients treated, 1 showed complete regression (CR) (5%), 11 demonstrated partial regression (PR) (58%), 3 showed stable disease (16%), 2 showed progressive disease (11%), and 2 were unable to be evaluated (11%). In a bladder carcinoma trial, 12 patients received either intratumoral or intravascular injections of rAdp53 at doses of 7.5×10^{11} to 7.5×10^{13} VP (Kuball et al., 2002). Higher transduction efficiency was observed when using the intravascular delivery method. Seven of the 11 patients who could be evaluated had evidence of p53 expression by reverse transcription-polymerase chain reaction (RT-PCR) analysis. Nine of the 12 patients were alive at a median follow-up of 30 months. Pagliaro et al. (2003) reported a similar phase I study in which rAd-p53 was instilled intravascularly at 1×10^{12} VP/dose in 13 patients with locally advanced transitional cell carcinoma of the bladder. A preliminary antitumorigenic effect was observed at a treatment dose of 1×10^{12} VP on days 1 and 4. Clayman et al. (1998) reported the results of a clinical study in which rAd-p53 was applied as a single agent to treat advanced recurrent HNSCC. Thirty-three patients received an intratumoral injection of rAd-p53 at doses up to 1×10^{11} PFU/injection. Of the 17 patients who could be evaluated, 2 patients showed objective tumor regression of greater than 50%, 6 patients presented stable disease for up to 3.5 months, and 9 patients showed progressive disease. Cristofanilli et al. (2006) reported a prospective, open-label, phase II trial. Thirteen patients with locally advanced

breast cancer (LABC) were treated with six 3-week cycles of primary systemic therapy (PST), which consisted of intratumoral injections of Ad5CMV-p53 for 2 consecutive days, plus docetaxel and doxorubicin followed by surgery. p53 status was determined at baseline and was assessed immediately after the first injection (up to 48 h). Clinical response was assessed by clinical and radiologic methods. Serial biopsies showed an increase in p53 messenger RNA (mRNA) and p21^{WAF1/Cip1} mRNA. All 12 patients who could be evaluated achieved an objective clinical response. The surgical specimens revealed scattered tumor cells with extensive leukocytes infiltration into the tumor (predominantly T-lymphocytes). At a median follow-up of 37 months (range, 30–41 months), four patients (30%) developed systemic recurrence and two patients died. The estimated breast cancer-specific survival rate at 3 years was 84% (95% confidence interval, 65.7%–100%). There was no increase in systemic toxicity. Cristofanilli et al. (2003) reported another clinical study with Adp53 combined with chemotherapy in the treatment of LABC. Twelve patients were enrolled. Patients received up to six cycles of the combination of Adp53, docetaxel, and doxorubicin. A total of nine patients had completed induction chemotherapy, seven patients had surgery. Clinical response (CR + PR): 8 (90%); partial regression (PR) 1 (10%); stable disease (SD) or progressive disease (PD) 0 (0%). A phase I, pharmacokinetic, and pharmacodynamic study of intravenously administered adp53 in patients with advanced cancer was studied by another group (Tolcher et al., 2006). Seventeen patients were treated with escalating doses of Adp53, ranging from 3×10^{10} to 3×10^{12} VP, intravenously over 30 min on days 1, 2, and 3, every 28 days. No severe toxicity was observed during the treatment operation. Adenovirus was observed in the circulation 24 h after administration and the p53 transgene was detected in tumor tissue distant from the site of administration. Thus it was feasible to systemically deliver Adp53 for cancer treatment.

In all the reported clinical studies, the most common side effects were pain at the injection site, fatigue, and development of self-limited fever. Overall, rAd-p53 treatment was well-tolerated by patients without serious side effects. To commercialize Adp53 for cancer treatment, Introgen Therapeutics (Austin, TX) is currently pursuing a number of late-phase clinical studies using rAd-p53 for the treatment of cancers, of which treatment for HNSCC is in phase III clinical study. There has been an active clinical gene therapy program using rAd-p53 for the treatment of HNSCC in China since 1998. After extensive multiyear and multicenter clinical studies, a recombinant human adenoviral-p53 injection (trademarked as Gendicine) (Figure 49.1), developed by Shenzhen SiBiono GeneTech (SiBiono; Shenzhen, China), was approved by the State Food and Drug Administration of China (SFDA) on October 16, 2003 for the treatment of HNSCC. The product was formally launched in the market in April 2004. Gendicine became the world's first gene therapy product approved by a government agency for the treatment of cancer indications and set a new milestone in the history of gene therapy.

This chapter presents a general description of the clinical research and applications of Gendicine and its antitumorigenic

Gendicine (recombinant human Ad-p53 injection)

1×10^{12} viral particles/vial

Made by SiBiono GeneTech Co., Ltd. China

mechanisms. The p53 tumor suppressor gene and its biological function and regulation are also briefly outlined, while the detailed p53 regulation and the recent progress in p53 research are reviewed by Hua Lu and his colleagues in a separate chapter (Chapter 48). In addition, an overview about the manufacturing process, quality control, and quality assurance of Gendicine is provided.

49.2 GENDICINE AND ITS ANTITUMORIGENIC MECHANISMS

Gendicine is a recombinant human serotype 5 adenovirus in which the E1 region is replaced by a human wild-type p53 expression cassette. The p53 gene is driven by a Rous sarcoma virus (RSV) promoter with a bovine growth hormone (BGH) poly (A) tail. The recombinant adenovirus (rAd) is produced in the SBN-Cel producer cells grown in a bioreactor. The SBN-Cel producer cell is a propriety cell line subcloned from the human embryonic kidney (HEK) 293 cells. Virus produced from the bioreactor is further processed and chromatographically purified to produce the recombinant human Ad-p53 injection product. After more than two decades of study, the p53 gene is now widely regarded as the “guardian of the genome.” It has been estimated that at least half of all human malignancies are related to a mutation of the p53 gene (Shiraishi et al., 2004). p53’s ever-increasing research knowledge base facilitated the application of its pathways to the clinic, of which

p53 gene therapy is a very promising treatment. It is expected that the clinical application will, in turn, help us to a greater understanding of p53’s function.

The active pharmaceutical ingredient in Gendicine is the recombinant adenoviral vector encoding the p53 gene. The adenoviral vector functions as a delivery vehicle for the therapeutic p53 gene. After Gendicine administration, the adenoviral particle infects the targeted tumor cells and delivers the adenoviral genome, carrying the therapeutic p53 gene, to the cytoplasm and the nucleus for transcription and translation. p53 then exerts its antitumorigenic activities by one or more of the following mechanisms:

- Simultaneously triggering apoptotic pathways in tumor cells by a transcription-dependent mechanism in the nucleus (Muller et al., 1998; Bouvard et al., 2000; Matsuda et al., 2002; Taha et al., 2004), and by a transcription-independent mechanism in the mitochondria (Chipuk et al., 2004; Leu et al., 2004) and Golgi apparatus (Bennett et al., 1998; Ding et al., 2000)
- Activation of immune response factors such as natural killer (NK) cells (Yen et al., 2000; Cerwenka and Lanier, 2003; Rosenblum et al., 2004) to exert “bystander effects”
- Inhibition of DNA repair and antiapoptotic functions in tumor cells (Sah et al., 2003)
- Downregulation of the expression of (1) multidrug resistance genes (Krishna and Mayer, 2000) to

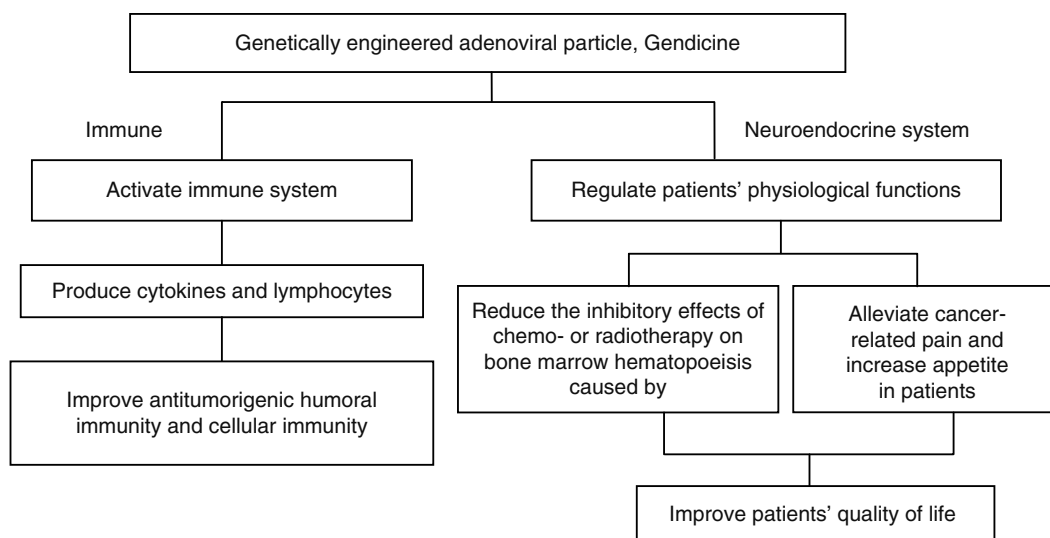

FIGURE 49.2 Proposed therapeutic mechanisms of Gendicine adenovirus particle.

revert the resistance of tumor cells against radio- and chemotherapies, (2) the vascular endothelial growth factor (VEGF) gene (Dameron et al., 1994; Pal et al., 2001) to block the blood supply to the tumor tissue, and (3) matrix metalloproteinase (MMP) (Toschi et al., 2000; Ala-aho et al., 2002; Sun et al., 2004) to suppress tumor cell adhesion, infiltration, and metastasis

- Blockage of the transcription of survival signals in tumor cells (Singh et al., 2002; Yin et al., 2003; Rother et al., 2004) to inhibit the growth of tumor cells in any stage of the cell cycle
- Limitation of the uptake of glucose (Schwartzberg-Bar-Yoseph et al., 2004) and the production of ATP (Brasseur et al., 1997; Iizumi et al., 2002) in tumor cells

After intratumoral injection of Gendicine, we observed marked lymphocytic infiltration and obvious inhibition of VEGF activity in biopsies of tumor lesions of patients enrolled in clinical trials of Gendicine.

We believe, in addition to the therapeutic *p53* gene, that the adenoviral particle component of Gendicine also plays an important role in Gendicine's therapeutic effect. The adenoviral delivery vehicle is well known in triggering a strong immune response in patients. It may also induce various hormones and cytokines, thereby affecting the endocrine and immune systems in the body. The triggering of these systems may increase humoral immunity, cellular immunity, and stimulate NK cells to target tumor cells more effectively. Evidence is found for these increased immune activities in the development of grade I/II self-limited fevers in approximately 32% of treated patients. Fever is usually regarded as a side effect in clinical practice; however, in the case of Gendicine treatment, it may reflect the effectiveness of Gendicine in mobilizing the body's immune system. An enhanced immune response in advanced or terminal stage cancer patients is likely to be beneficial for tumor containment.

In clinical studies, we also observed that Gendicine reduced the side effects caused by conventional chemo- and radiation therapies. A significant observation was that some patients showed improved appetite and general health status approximately 2 days after receiving Gendicine treatment. This result is a positive clinical development for cancer patients who suffer from severe side effects caused by radio- and chemotherapy. The mechanism leading to the improvement is not yet known. We suspect it is related to the rAd particle component of Gendicine, as shown in Figure 49.2. Further study is under way to better understand the clinical implications of these results.

49.3 SAFETY AND EFFICACY OF GENDICINE

49.3.1 SAFETY

Gendicine is an active rAd genetically engineered to express the human *p53* gene. The *p53* gene exists ubiquitously in normal cells and is one of the most widely studied tumor suppressor genes in the human body. Because of its importance in maintaining genome stability, the *p53* gene has been dubbed the "guardian of the genome." The adenoviral vector is a replication-incompetent serotype 5 adenovirus (Ad5) with a deletion in the E1 region, which limits the virus so that it is capable of only one infection cycle. Furthermore, the adenoviral genome does not integrate into the host's genomic DNA. Ad5 has one of the weakest pathogenicity levels in the adenovirus family. Wild-type Ad5 infection generally results in mild upper respiratory disease and fever. Although one fatality has been reported in a study of using adenoviral vector to treat a patient with ornithine transcarbamylase (OTC) deficiency syndrome, the death was later found to be caused by the patient's overwhelming immune reaction against a high systemic dose of adenoviral vector (Chen et al., 2003; Han et al., 2003; Zhang et al., 2003a,b). No fatalities have been reported in other cancer gene therapy trials using

adenoviral vectors. Data from our own clinical studies demonstrated that Gendicine is safe for clinical use.

In a phase I clinical study (Han et al., 2003) from 1998 to May 2000, 12 patients with advanced laryngeal cancer were given various doses of Gendicine before and after surgery. The study results showed that administration of Gendicine did not change the healing process of the surgical wound. No other side effects were observed besides self-limited grade I or II (below 40°C) fever. Results from extensive multicenter controlled and randomized clinical studies involving 135 patients (Zhang et al., 2003a) confirmed that grade I/II self-limited fever was the most commonly observed side effect, occurring in approximately 50%–60% of Gendicine treated patients (Table 49.1). In a few rare

cases, patient fever reached as high as 40°C. Development of fever was observed as soon as approximately 3 h after injection, lasted about 4 h, and then disappeared spontaneously. On some occasions, the fever lasted more than 10 h. A common antipyretic was used to effectively control the patient's temperature. It was also observed that Gendicine in combination with radiotherapy (GTRT) did not exacerbate side effects resulting from radiotherapy.

To date, Gendicine has been administered to more than 6000 patients with a variety of cancers from around 40 countries with distinct ethnic backgrounds. The route of administration included intratumoral injection (Figure 49.3), intrapleural and intraperitoneal infusion, intravenous injection, intervention administration, and endotracheal and

Intratumoral injection of Gendicine

(A) Injection of Gendicine under ultrasonic guidance

(B) Showing a strong echo after Gendicine injection

FIGURE 49.3 (See color insert following blank page 206.) Injection of Gendicine.

intravesicular instillation. Gencidine has been used in combination with other therapies including radiotherapy, chemotherapy, hyperthermia, surgery and biological therapies. Deterioration of the side effects associated with the traditional therapies was not observed in any of the combination treatments. GTRT or chemotherapy did not exacerbate any side effects.

Based on our clinical study experience, the recommended dose of Gencidine treatment is one vial (1×10^{12} VP) per injection, per week. An average treatment course involves eight injections for a total of 8 weeks. The maximum accumulative use of Gencidine in a single case was 85 doses (85×10^{12} VP) within a successive 40 weeks. No unexpected side effect was observed in the patients. Our extensive clinical experience showed that Gencidine is safe and well tolerated by treated patients.

49.3.2 THERAPEUTIC EFFECTS

The therapeutic *p53* gene carried by Gencidine exists ubiquitously in normal cells. The rAd can infect, with varying efficiency, almost all human cells, including dividing cells and resting cells. Those unique biological properties make Gencidine a wide-spectrum antitumorigenic agent. Its efficacy in treating cancer has been demonstrated in our clinical studies and the continued patient use after marketing approval. Furthermore, the clinical efficacy of Gencidine appears to be independent of the endogenous *p53* gene status of tumor cells. The published data on Gencidine clinical studies are presented below.

49.3.2.1 Advanced Head and Neck Squamous Cell Carcinoma

49.3.2.1.1 Gencidine in Combination with Surgery for Treatment of Laryngeal Carcinoma

From 1998 to 1999, Gencidine was used in a phase I study for the treatment of 12 patients (Han et al., 2003) with laryngeal carcinoma with an average clinical symptom for 41 months. Seven of the 12 patients did not receive any treatment prior to Gencidine administration and 5 of the 12 patients had a history of one or multiple tumor recurrences. One of the patients had received six laser surgeries because of frequent relapses averaging about 9 months. The patients were divided into three groups receiving escalating doses of Gencidine. Intratumoral injection was administered at doses of 1×10^{10} , 1×10^{11} , and 1×10^{12} VP every the other day for a total of 10 injections. According to 6 years of follow-up data, 11 of the 12 patients were still alive, and 9 remained tumor-free. The 6-year overall survival (OS) rate is 91.7%. This result compared very favorably to the data from the American Joint Committee on Cancers (2002) which showed that the 5-year survival rate for treatment of laryngeal carcinoma by conventional therapies was 68.6%–71.1% at stage I, 55.5%–59.9% at stage II, and 46.04%–50.1% at stage III, respectively. Therefore, Gencidine can effectively prevent tumor recurrence and prolong the lifespan of patients suffering from laryngeal carcinoma.

49.3.2.1.2 Gencidine in Combination with Radiation Therapy for Treatment of Head and Neck Squamous Cell Carcinoma

Significant synergetic effects have been demonstrated using GTRT, chemotherapy, surgery, and hyperthermia for treatment of cancers (Chen et al., 2003; Zhang et al., 2003 a,b). A multicenter, concurrently controlled, randomized clinical trial using Gencidine on 135 patients with HNSCC was conducted. Of the enrolled patients, 77% had late stage III to IV cancer and either failed radio-/chemotherapies or were not eligible for surgery. A majority (85%) of the patients had nasopharyngeal cancer. The patients were divided randomly into two groups: one group received GTRT and the other group received radiotherapy (RT) alone. A conventional or three-dimensional conformal radiotherapy was used at doses of 70 Gy/35 f/7–8 w for the RT treatment. In the GTRT group, Gencidine was given at a dose of 1×10^{12} VP three days prior to the radiotherapy per week for a total of 8 weeks. Radiotherapy in the GTRT group was kept the same as that used in the RT group. The objective tumor response was evaluated using computed tomography (CT) or magnetic resonance imaging (MRI), according to the World Health Organization (WHO) response criteria. Usually, it is somewhat misleading to use the total response rate in judging clinical efficacy because of the frequently observed high instance of relapse for patients with PR. Instead, we believe that it is more appropriate to use the CR rate to evaluate true clinical efficacy. The short-term efficacy data, shown in Table 49.1 below, showed that the response rate in the GTRT group was 93%, of which 64% was CR and 29% was PR. The response rate in the RT group was 79% of the patients, of which 19% was CR and 60% was PR. There is a significant difference ($P < 0.01$) between the two groups in either the CR rate or the PR rate. The CR rate in the GTRT group was threefold higher than in the RT group. Furthermore, it is very encouraging to note that 4 weeks after treatment, 65% of patients exhibited PR in the GTRT group whereas 40% of patients in the RT group showed PR and 57% showed SD (stable disease). GTRT showed obvious synergistic effects for cancer treatment (Figure 49.4).

Sun et al. (2005) reported the clinical outcome of combination of Gencidine with radiotherapy for treatment of refractory or recurrent cancers of the head and neck. Twenty-five patients were enrolled, 6 at stage III and 19 at stage IV (five of them with distant metastasis). Twelve patients had squamous cell carcinoma (SCC) (58%) and 13 had nonsquamous cell cancers (non-SCC) including 2 patients with adenocarcinoma, 3 with adenoid cystic carcinoma, 6 with sarcoma, 1 with melanoma, and 1 with basalioma. Gencidine was administered either by direct intratumoral injection or by ultrasound-guided percutaneous intratumoral injection at a dose of $1-2 \times 10^{12}$ VP once a week. The total doses of Gencidine ranged from 3×10^{12} to 20×10^{12} VP (median of 8×10^{12} VP). The radiotherapy dose for patients receiving Gencidine ranged from 40 to 76 Gy (median of 70 Gy). The mean follow-up for surviving patients was 15 months (ranged from 3 to 52 months). The median survival was 8 months. The 1- and 2-year survival

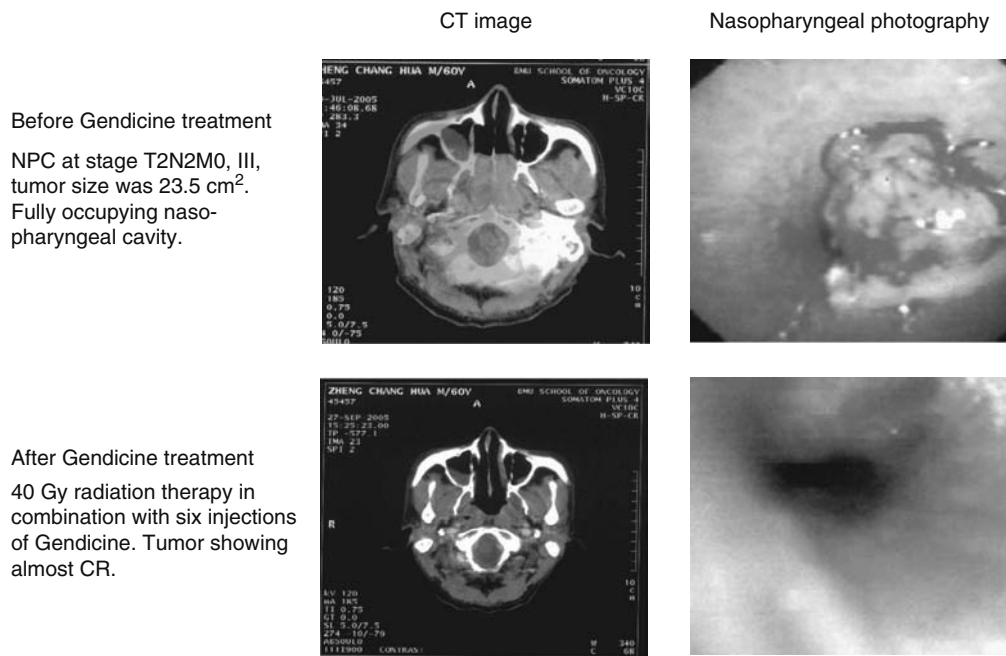

FIGURE 49.4 Efficacy of Gencidine in combination with radiation therapy for treatment of advanced nasopharyngeal carcinoma.

rates were 52.4% and 26.3%, respectively, with no significant differences between SCC and non-SCC. The 1-year tumor-free survival rate was 33.3% for all patients, 16.7% for those with SCC, and 55.5% for those with non-SCC. A higher local control rate was noted for patients with non-squamous tumors ($p = 0.0594$). The tumor response was evaluated at the end of the eighth week after beginning gene therapy. CR and PR were seen in 2 (8.0%) and 14 patients (56.0%), respectively. Nine patients (36.0%) had stable response. Patients with recurrent tumors had a poor tumor response rate ($p = 0.0060$). No significant difference between the tumor response rate and the histological type was noted.

49.3.2.1.3 Five-year Follow-Up for Patients with Nasopharyngeal Carcinoma Using Gencidine in Combination with Radiation Therapy

According to the 5-year follow-up results for the 49 patients (24 cases in the GTRT Group, 25 cases in the RT-only group) with stage II/III nasopharyngeal carcinoma (NPC) presented by the principal investigator (PI), Dr. Zhang Shanwen of Beijing Tumor Hospital, at the 10th National Conference of Tumor Hyperthermia, Gencidine showed noticeable improvement of the local-regional tumor control and prolonged the survival time for patients with NPC. The 5-year local regional failure of GTRT and RT groups is 4.4% and 47.6%, respectively. The local regional control rate of the GTRT group is 10 times higher than that of the RT group. The 5-year overall and tumor-free survival rates are 65.4% and 64.3% for the GTRT group versus 51.9% and 35.6% for the RT group, respectively. The 5-year overall and tumor-free survival rates of

the GTRT group are 13.5% and 36% higher than those of the RT group, respectively (Tables 49.2 through 49.4). The 5-year median time to recurrence is 43 months for the GTRT group and 38 months for the RT group. A new multicenter, concurrently controlled, randomized phase IV clinical study on 300 patients with NPC has been initiated and is in progress.

49.3.2.1.4 Gencidine in Combination with Chemotherapy for Treatment of Advanced Head and Neck Carcinoma

Li and Huang (2006) reported a clinical and biomolecular combination therapy study using subselective intra-arterial Gencidine infusion with induction chemotherapy for locally advanced head and neck carcinoma (Table 49.5). Eighty-eight patients with locoregionally advanced HNSCC or adenoid cystic carcinoma of head and neck (ACCHN) were randomly assigned

CR	5 (17)	0 (0)	0 (0)
PR	13 (43)	6 (33)	2 (50)
SD or PD	12 (40)	12 (67)	2 (50)

to three groups. The groups were (I) Gendicine in combination with chemotherapeutic agents ($n = 30$), (II) Gendicine alone ($n = 28$), and (III) chemotherapy alone ($n = 30$). Patients in groups I and II received 10 cycles of Gendicine infusion within 6 weeks. The selected dose of Gendicine was delivered in 20 min using 10 mL syringes once every day for 4 days as a treatment cycle. The Gendicine doses ranged from 1×10^{12} to 2×10^{12} VP for patients with unilateral and bilateral catheters, respectively. The Gendicine doses remained the same throughout the study. Patients were closely monitored for 4 h after each Gendicine administration. Patients in group I received two periods of combination chemotherapy, which was similar to those in group III. The first combination chemotherapy period began 2 days after the first Gendicine infusion. Between the two treatment periods there was a 7-day recovery break.

The chemotherapeutic agents used for treatment of squamous cell carcinoma were Carboplatin (CP), Bleomycin (BLM), and Methotrexate (MTX). The chemotherapeutic agents used for treatment of adenocarcinoma (including adenoid cystic carcinoma and mucoepidermoid carcinoma) were CP, 5-Fluorouracil (5-FU), and cyclophosphamide (CTX). The primary tumor lesion of 60 patients responded to the therapy (CR + PR), of which 21 patients showed CR and 39 patients showed PR. The CR rate (37%) of group I was significantly higher than those of group II and III (18% and 17%, respectively) ($p < 0.05$). No significant difference in therapeutic outcome was found between group II and III ($p > 0.05$). The primary tumor lesions of 28 patients did not respond to the treatment (SD or PD), of which 6 (20%) were in group I, 10 (36%) were in group II, and 12 (40%) were in group III.

Before Gendicine administration

2 Months after Gendicine treatment

Male, 67 years, suffering from SCC of lower lip, T4N2aM0, was enrolled into the group and treated with Gendicine in combination with chemotherapy (CP, BLM, and MTX). Ten injections of Gendicine (4×10^{12} VP/injection, one injection every 5 days) and two courses of chemotherapy. The tumor showed complete clinical recovery.

FIGURE 49.5 (See color insert following blank page 206.) Efficacy of Gendicine in combination with chemotherapy for treatment of advanced squamous cell carcinoma.

The rate of the nonresponders (SD and PD) in group I was significantly lower than those in group II and III ($p < 0.05$). Although we found promising therapeutic responses on cervical nodal metastasis and distant metastasis of patients in group I, statistical analysis was not performed because of the limited number of patients (Figure 49.5).

The CR rate of group I was statistically higher than that of the other two groups. Intraarterial infusion of Gendicine resulted in successful transfer of the exogenous wild-type *p53* gene and subsequent expression of functional *p53* protein. The expressed *p53* protein activated *Bcl-2*, inactivated *Bax*, and ultimately induced tumor cell apoptosis. As a result, Gendicine in combination with chemotherapy produced an additive therapeutic effect with no apparent added side effects.

49.3.2.1.5 Advanced Liver Cancer

Guan et al. (2005a), at West China Hospital, Sichuan University, China, reported the results of a study using Gendicine in combination with hepatic arterial chemoembolization (TACE) on patients with advanced hepatic cell carcinoma (HCC). A total of 150 patients were enrolled. Sixty-eight patients were treated using Gendicine-TACE (GT-TACE) combination by intra-tumoral injection of Gendicine under CT guidance or transcatheter perfusion at $1-4 \times 10^{12}$ VP per dose, one dose/week for 4 weeks. Gendicine was administered 2-5 days after a TACE

was carried out. Eighty-two patients were treated by TACE alone as the control group. For both the treatment and control groups, TACE was performed with 5-fluorouracil (5-Fu) 1 g, hydroxycamptothecin (HCPT), Adriamycin (ADM) 40 mg, and arterial embolization with iodized oil (10-30 mL).

Patient response rates were 67.6% and 51.2% in the GT-TACE group and the TACE alone group, respectively. The difference is statistically significant ($P < 0.05$) (Table 49.6). Compared with patients in the control group, patients in the GT-TACE group experienced better pain relief and improvement of Karnofsky performance status. It is important to point out that 1-year survival rate was 76.5% (52/68) in the GT-TACE group and only 23.2% (19/82) in the control group. The difference is statistically significant ($P < 0.01$) (Table 49.7). The results showed that Gendicine in combination with TACE is effective for treatment of HCC patients.

Zhu Zhibing (2004) at the Second People's Hospital of Shenzhen reported a clinical study on 38 patients with refractory, inoperable advanced HCC. Thirty of the 38 patients received Gendicine treatment alone and the other eight patients were treated with Gendicine in combination with hyperthermia. All patients received the same Gendicine treatment at a dose of $1-2 \times 10^{12}$ VP/wk (injection) for a total of 4 weeks, by intralesional injection via percutaneous hepatic paracentesis or hepatic arterial infusion. The preliminary

TABLE 49.6
Short-Term Efficacy of Gendicine in Combination with TACE for Treatment of HCC Patients

Groups	Case No.	CR	PR	NC	PD	CR + PR (%)
Gendicine-TACE	68	0	45	15	7	67.6

	3 Months	6 Months	12 Months
Gendicine-TACE	89.71%	76.13%	43.30%
TACE	68.15%	36.98%	24.02%

TABLE 49.8
Survival Time of the Patients with Advanced HCC Receiving Gendicine Treatment

Group	Case Numbers	Average Survival Time (days)	Range of Survival Time (days)
Gendicine + chemotherapy	14	238.1 ± 119.9	14 to 405
Chemotherapy	16	80.7 ± 35.9	18 to 167

TABLE 49.9
Karnofsky Scores of the Patients with Advanced HCC Receiving Gendicine Treatment

Group	Before Treatment	After Treatment	P Value
Gendicine + chemotherapy	54.3 ± 12.2	67.9 ± 23.3	<0.05
Chemotherapy	60.0 ± 12.6	50.6 ± 22.4	>0.05

clinical data for the 30 patients receiving Gendicine alone showed 2/30 of PR, 24/30 of SD, and 4/30 of PD. Twenty-six of the 30 patients showed an improvement of Karnofsky performance status from 55.79 ± 11.30 to 61.05 ± 21.64 . All the patients tolerated the Gendicine treatment well.

Chen Shixi (2007) at Cancer Hospital of Jiangsu Province reported a preliminary clinical study of Gendicine on 30 patients with advanced hepatocellular carcinoma (HCC). The 30 patients were divided into a treatment group (14 cases) and a control group (16 cases). For the treatment group, a dose of 10^{12} VP of Gendicine in combination with 20 mg of HCPT were infused into the hepatic artery once a week, for a total of 3 weeks as a treatment course. The 14 patients in the treatment group each received one to four courses of treatment. Only 20 mg of HCPT was used for the control group. Patients in the treatment group survived between 14 to 405 days with an average of 238.1 days. Patients in the control survived between 18 to 167 days with an average of 80.7 days. There was a significant difference in the average survival between these two groups ($P < 0.05$) (Table 49.8). The KPS score of the treatment group was also statistically higher than that of the control group (Table 49.9).

Zhang et al. (2004, 2007) at the Friendship Hospital of Dalian in China reported the preliminary clinical observation on interventional Gendicine injection guided by ultrasonography

(US) combined with sequential chemoembolization for cancerous embolization in portal vein, for treatment of HCC. 21G needle was inserted into portal vein tumor thrombi (PVTT) under US guide and Gendicine was injected slowly in the first day. On the third day, Chemoembolization will be finished in the same way. Results showed that in 16 cases of primary hepatocellular carcinoma (PHC) with PVTT treated by sequential therapy of Gendicine and Chemoembolization, the mass of tumor thrombus was decreased in all patients after two to three sequential therapies. Blood flow can be seen in the tumor thrombus under US. The clinical symptoms were partially relieved. There was no severe side effect related to therapy observed in all patients. It indicated that this measure is an effective, safe, and easy procedure.

49.3.2.1.6 Advanced Lung Cancer

Fifteen patients with stage IIIb–IV lung cancer were treated with Gendicine by intratumoral injection at a dose of 1×10^{12} VP (Weng et al., 2004). Gendicine was injected by percutaneous lung paracentesis under CT guidance once a week for 4 consecutive weeks as a treatment course. Clinical response was evaluated by CT image, tumor biopsy and a 2-month follow-up. The results were PR in 5 of the 15 (33.3%) patients, SD in 7 of the 15 (46.7%) patients, and PD in 3 of the 15 (20%) patients.

Tumor biopsy for 6 of the 12 patients having PR and SD revealed obvious tumor tissue necrosis and reduction in tumor cell number.

Fifteen patients with advanced lung cancer were treated with Gendicine in combination with conventional chemotherapy in Sichuan University (Guan et al., 2005b). Gendicine were infused into the bronchial artery via a catheter with a dose of $1-4 \times 10^{12}$ VP each week for 4 weeks. Two to five days after each Gendicine infusion, the patient was treated with cisplatin, 5-Fu, or etoposide (DDP 100mg, 5-FU 1.0g, and VP-16 100mg). Of all the 15 patients, the total response rate (CR + PR) was 46.7% (seven out of 15). Tumor lesion disappearance was seen in one case, significant tumor regression was seen in six cases, mediastinal lymph nodes shrinkage was seen in three cases, and regression of thoracic fluid was seen in one case. Fourteen out of 15 (93.3%) of the cases had alleviation of clinical symptoms. Results from this preliminary study showed that Gendicine in combination with BAI is safe and effective in lung cancer treatment. Eight of the 13 patients showed positive response after a 1-4 month follow-up, including 1 CR, 6 PR, and one patient with thoracic liquid reduction. Eleven of the 13 patients showed alleviation of clinical symptoms such as cough, thoracodynia, hemoptysis, and dyspnea.

49.3.2.1.7 Advanced Soft Tissue Sarcoma

Clinical application of Gendicine in combination with hyperthermia and radiotherapy for treatment of advanced

soft tissue sarcoma was studied by Xiao et al. (2007) (Figure 49.6). Thirteen patients with advanced soft tissue sarcoma were enrolled. All patients received intratumoral injection of Gendicine at 1×10^{12} VP once a week for a total of 8 weeks. Two days after Gendicine injection, all patients received additional hyperthermia treatment, once or twice a week for a total of 9 weeks. Twelve patients were concurrently treated with radiation therapy with the conventional fractionation of 2Gy/f, five fractions a week to a total dose of 16-70 Gy in 8-35 f spanning 2-8 w. The average total radiation was 56.3Gy. One patient was concurrently treated with DDP-based chemotherapy, once a month with a total two cycles. Patients were monitored for adverse events and tumor response. The response rate was assessed by CT analysis 2 months after treatment. Among the 13 patients CR was observed in two cases (15.4%), PR in four cases (30.8%), and SD in seven cases (53.8%). The 1-year, 2-year, and 3-year survival rates were 75%, 50%, and 33.3%, respectively. Intratumoral injection of Gendicine in combination with hyperthermia was found to be safe and effective for treatment of advanced soft tissue sarcoma.

49.3.2.1.8 Pancreatic Cancer

Chen Jie et al. (2007) at Department of Gastroenterology, Chang Hai Hospital of the Second Military Medical University, in Shanghai, treated eight patients with unresectable pancreatic cancer by intratumoral injection of Gendicine

FIGURE 49.6 (See color insert following blank page 206.) Efficacy of Gendicine in combination with radiation therapy for treatment of Eiomysarcoma.

with a paracentetic needle guided by endoscopic ultrasound (EUS) once a week for 4–5 weeks. Gemcitabine chemotherapy was used at the same time. The average treatment time was about 10 min. After treatment, one patient complained of a burning sensation in the stomach and a flushed face, and two patients felt febrile (37.5%). All these symptoms subsided spontaneously. One patient died of cancer during the course of the treatment. Significant relief of the pain caused by the cancer was observed in all the remaining seven patients. One patient experienced a complete relief from the pain and gained 2 kg weight in 2 months. Image scans showed stable tumor lesions in all patients. EUS-guided intratumoral injection of Gendicine appeared to be a safe and reliable approach for treatment of unresectable pancreatic cancer.

49.3.2.1.9 Esophageal carcinoma

Lu et al. (2007) at Xinxiang Medical University in China, observed intratumoral injection of Gendicine by endoscopy in combination with radiotherapy for treatment of 15 cases with esophageal carcinoma. A prospective randomized control method was adopted. Thirty patients with unresectable esophageal cancer were randomly divided into two groups. The 15 cases used in GTRT group, or radiotherapy alone. Gendicine was intratumorally injected once a week for a total of 6 weeks and radiotherapy was given 3 days after the first injection of Gendicine. Then the patients were followed up every 2 months. In combination group, 5/15 patients reached CR (33.3%) and 8/15 patients PR (53.3%). In radiation therapy group, 2/15 patients CR (13.3%) and 8/15 patients PR (53.3%). Compared to the efficacy rate between the two groups, $P > 0.05$ and CR was 2.5 times higher in combination group than in radiation therapy group. Eight of 30 patients presented with self-limited fever and 10/30 patients felt pain in the injection region; no other side effects were noted.

49.3.2.1.10 Other Advanced Solid Tumors

Ding et al. (2005) at the Cancer Center of the Sun Yat-Sen University reported the use of Gendicine for treatment of 24 patients with advanced solid tumors (comprising 13 distinct tumor types). All the patients failed conventional therapies, such as chemotherapy and radiation therapy. The treatment regimen was 1×10^{12} VP per week for a total of 4 weeks. Administration routes included intratumoral injection, intra-bronchial spray, intraperitoneal injection, artery infusion, and intravenous injection. Gendicine in combination with a variety of therapies was used, including 18 cases with chemotherapy, two cases with radiation therapy, one case with radio- and chemotherapies, one case with abdominal thermotherapy and Gefitinib, one case with immunotherapy, and one case with Gendicine treatment alone. One patient withdrew from the study due to early disease progression. Twenty patients received four injections of Gendicine, two patients received eight injections of Gendicine, and one patient received 20 injections of Gendicine. Results from the 21 of valuable cases showed PR in 5/21 (24%) cases, SD in 5/21 (24%) cases, and PD in 11 cases. Clinical responses were observed in 10/21 (48%) patients. A

common side effect was grade I–II self-limited fever, with two patients experiencing grade III fever. Other rare side effects were pain at the injection site, shivering, and muscle soreness.

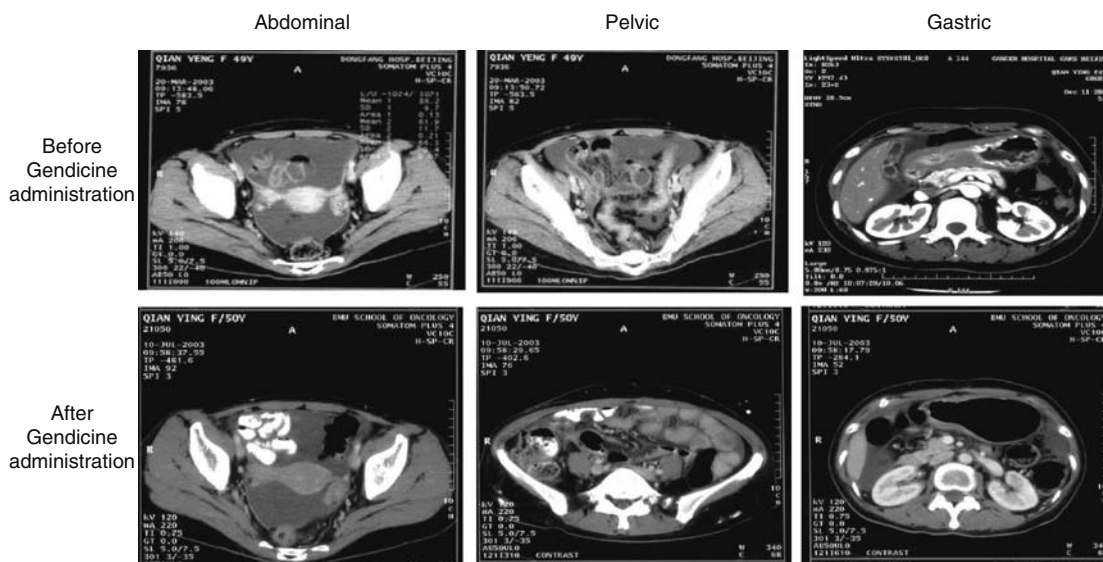

Zhang et al. (2003a) at the Department of Radiation Therapy of the Beijing Cancer Hospital reported a clinical study of Gendicine in combination with thermotherapy in seven patients with advanced malignant tumors. Gendicine was injected intratumorally at 1×10^{12} VP per week for a total of 4 weeks. On day 3 after Gendicine administration, hyperthermia was applied to advanced malignant tumors using either a 915 MHz microwave to warm tumor tissue up to 43°C–44°C or heating by a 40 MHz to increase the temperature to 42°C–43°C. The data showed one CR, two PR, and four SD at the end of eight doses of Gendicine treatment. Biopsy for CR and PR cases revealed tumor necrosis (Figure 49.7).

Zhang et al. (2005) reported a study on 21 patients with advanced malignant tumors receiving Gendicine treatment. As a treatment course, patient received weekly Gendicine injection for a total of 4 weeks. All patients were assessed for response and toxicity by clinical observation, CT or MRI and short-time follow-up. Significant reduction in tumor volume ($t = 2.04$, $P < 0.05$) and the Karnofsky score ($t = 2.66$, $P < 0.05$) (Tables 49.10 and 49.11) improved after Gendicine treatment.

Another study of Gendicine on malignant tumor patients was carried out by Qi et al. (2005) at Beijing Tongren Hospital. Twenty-three patients with advanced cancers were treated with Gendicine by intravenous drip and intratumoral injection. Ten patients were treated with Gendicine alone. Three of the 10 patients exhibited PR, 4 of the 10 patients had stable disease at the last time of follow-up, and 3 of the 10 patients showed progressive disease. Total clinical response was 70%. The other 13 patients were treated by Gendicine in combination with chemotherapy. Of the 13 patients, 6 showed PR (6 of 13 patients, 46.2%), 4 showed SD (4 of 13 patients, 30.8%), 3 showed PD (3 of 13 patients, 23.1%). On average, the Karnofsky Performance Score increased over 10 for both groups. Total clinical response was 76.9%.

49.3.2.1.11 Cancerous Ascites

A significant effect was reported using Gendicine to treat cancerous ascites (Zhu et al., 2005). Thirteen patients with advanced cancers (eight patients with gastric carcinomas, four with colon carcinoma, and one with carcinoma of the gall bladder) and having large amount of ascites were treated with Gendicine via peritoneal paracentesis and intraperitoneal infusion at a dose of $1-2 \times 10^{12}$ VP per week for a total of 4 weeks. Six of the 13 patients also had jaundice. Clinical response was evaluated through measurement of abdominal girth, CT, or MRI and 1 month of follow-up. After 3 weeks of treatment, 7 of the 13 patients showed significant reduction in ascites build-up, alleviation of disease symptoms, such as abdominal distention and shortness of breath, and improvement in Karnofsky performance status ($P < 0.05$). Except for the development of self-limited fever, no other side effects were observed. These results suggest that Gendicine can be used to treat patients with cancerous ascites for relief of disease symptoms and improvement of the quality of life.

Patient: Y. Qian, female 49 years old, case # 9529300, Beijing Tumor Hospital. Advanced gastric cancer (Borrmann IV) with less differentiated gastric adenocarcinoma showing huge gastric antral tumor with all around adhesion and extensive metastatic nodes in abdominal and pelvic cavities, and thickened peritoneum and omentum, as well as large amounts of ascitic fluid in abdominal cavity. As the tumor was inoperable, patient received conventional chemotherapy for 3 months; however, it was ineffective and did not stop the tumor progression. Patient was perfused abdominally with Gendicine, 1×10^{12} VP in 1000 ml physiological saline twice a week, in combination with DDP 40 mg or 5-Fu 1000 mg. After 3 weeks of treatment, her ascites disappeared and the severe side effects caused by chemotherapy were relieved. After Gendicine treatment for 12 weeks, CT imaging showed that abnormally thick gastric antrum with all around adhesion were obviously reduced, and so did the thickened peritoneum and omentum. Tumor recurrence was shown negative by CT imaging after 12-month follow-up.

TABLE 49.10
Tumor Size and Patients' KPS Score before and after Treatment

	<i>n</i>	Tumor Size	KPS Score
Before treatment	21	17.21 ± 8.77	43.33 ± 11.97
After treatment	21	11.72 ± 8.66	57.14 ± 20.53

Liu et al. (2006) at Xijing Hospital, Xi'an, Shanxi, treated 32 patients with malignant mesothelioma and alimentary tract carcinoma, including esophageal carcinoma, gastric cancer, pancreatic cancer, colon cancer, diagnosed by pathological evidence or image and serum tumor markers. Following tumor effusions, Gendicine was administered via peritoneal perfusion in 100 mL normal saline. After 72 h, the patients received radiofrequency hyperthermia. The treatment was performed with a frequency of one cycle per week. The volume of the effusions was examined at the beginning and 2 weeks later. There were two cases of CR, three PR, and three patients with no discernable effect (NE) in eight patients with malignant mesothelioma. The clinical response rate was 62%. There were 5 CR (1 case of esophageal carcinoma, 2 gastric cancer, 1 colon cancer), 7 PR (1 esophageal carcinoma, 4 gastric cancer, 2 colon cancer), and 12 NE in the 24 malignant alimentary tract cancer patients. The overall clinical response rate was 50%.

Another study of the use of Gendicine in combination with chemotherapy for treatment of malignant body cavity effusion was reported by Cao et al. (2005), from Hebei Provincial Qinhuangdao Seaport Hospital. Fifty patients with malignant body cavity effusion were randomly divided into two groups. The treatment group were given intracavitary administration of Gendicine 1×10^{12} VP after puncture drainage, which was followed 48 h later by intracavitary administration of 60 mg/m² cisplatin once a week for 3–4 weeks. The control group was given the same intracavitary therapy as the treatment group but without Gendicine. The total response rates of the treatment group and the control

group were 85.7% and 51.7% ($P < 0.05$), respectively. The common side effect was self-limited fever.

Results from the above extensive clinical application of Gendicine show that Gendicine is a wide-spectra anticancer agent with minimal side effects. Gendicine can be used in monotherapy as well as in combination with traditional cancer treatment approaches such as chemotherapy, radiotherapy, and surgery, etc. In addition to achieve synergistic effects with the traditional therapies, Gendicine treatment can also alleviate the common side effects caused by radiotherapy and chemotherapy and achieves a better improvement in the patients' quality of life.

49.4 MANUFACTURE OF GENDICINE

The following is a general description of the large-scale production technologies that are used for the manufacture of Gendicine.

49.4.1 LARGE-SCALE CELL CULTURE TECHNOLOGY

Large-scale culture of the production cells is a critical step in the production of Gendicine. The technology has undergone significant development in the past decade, from the first-generation adherent cell culture using roller bottles, CellCube bioreactor (Corning Life Sciences, Acton, MA), and packed bed Celligen plus bioreactor (New Brunswick Scientific, Edison, NJ), to the second-generation suspension, serum-free culture in large-scale bioreactors. Gendicine is produced using a patented large-scale bioreactor system. The patented producer cell line, SBN-Cel, is a subclone derived from the HEK293 cell line through a repeated cell clone selection processes. The SBN-Cel clone showed stronger attachment to culture surface, faster growth rate (doubling time approximately 18 h) and better viral productivity than the parental HEK293 cells.

49.4.2 CHROMATOGRAPHY PURIFICATION TECHNOLOGY

For large-scale production of Gendicine, a downstream processing and automated chromatography purification process have been developed and optimized. Downstream processing

TABLE 49.11
Clinical Response after Treatment

Diagnosis	<i>n</i>	Clinical Responses				Effective Rate (CR + PR) (%)
		CR	PR	NC	PD	
NPC	6	0	5	1	0	83.33
NSCLC	5	0	1	4	0	20
HCC	4	0	0	2	2	0
Metastasis cancer	6	0	2	3	1	33.33
Total	21	0	8	10	3	38.10

includes tangential flow filtration for harvest clarification and tangential flow ultrafiltration for concentration and diafiltration. The concentrate is further treated with Benzonase to breakdown large cellular DNA. The material is further clarified and chromatographically purified using an automated chromatography system (FPLC). After a single-step column purification, more than 98% purity can be achieved for the Gendicine final product. Approximately 4×10^{15} VP purified final product can be produced from a single batch 14 L bioreactor run. Both master/working cell banks and master/working virus banks (MVB/WVB), which are critical raw materials for the commercial production of Gendicine, have been established and qualified.

49.5 QUALITY CONTROL AND QUALITY ASSURANCE OF GENDICINE

In response to the rapid development in the gene therapy field and to promote gene therapy research and eventual commercialization in China, The SFDA published "Points to Consider for Human Gene Therapy and Product Quality Control" in 2003 (SFDA 2003a,b; SiBiono 2004). This document was published in the *Biopharm International* journal in May 2004. This guideline is one of the most comprehensive documents published by a government agency for gene therapy product quality control. It specifies that extensive quality control testing should be performed during the manufacture of gene therapy products. Product release testing should be performed

on crude harvest, bulk product (drug substance), and the final drug product. However, depending on the nature of the manufacturing process, some testing should be performed on in-process samples if the excipients included in the final product formulation interfere with the testing.

Table 49.12 outlines the SFDA specified 12 quality control tests, and the 21 test methods and specifications performed on in-process and final product samples during the manufacture of Gendicine. The tests can be divided into the following three groups.

49.5.1 GENERAL TESTS REQUIRED FOR BIOPHARMACEUTICALS

This group includes physical characteristics, chemistry characteristics, purity and detection of residual impurities, sterility testing, mycoplasma testing, general safety testing, and bacterial endotoxin testing. These tests are generally applied to all biopharmaceuticals.

49.5.2 BASIC TESTS

This group includes identity and efficacy tests. The purpose of these tests is to demonstrate the presence of the correct therapeutic gene, gene expression, and biological activity of the expressed gene product. Restriction mapping and PCR analysis are used to identify the presence of the correct therapeutic gene. Efficacy testing comprises a

TABLE 49.12
Quality Control Methods and Specifications for Gendicine

No	Assays	Method	Specification
1	Physical characteristics	Appearance	Examine under light
		Recoverable volume	Capacity assay
2	Chemical characteristics	pH	8.0–8.5
3	Identity	RE mapping	Restriction mapping
		p53 gene	PCR analysis
4	Purity	HPLC	≥95.0%
5	Viral titer	VP	A260 assay
		Infectious Unit	TCID50
		IU/VP	
6	Gene Efficacy	Gene expression	Western blot
		Bioactivity	Saos-2 cell bioassay
7	RCA	A549 cell bioassay	≤1RCA/3 × 10 ¹⁰ VP
8	AAV Detection	PCR	Negative
9	Residuals	BSA	Cell agglutination
		HCP	ELISA
		Cell DNA	Southern blot
		Benzonase	ELISA
10	Microbe	Sterility testing	Membrane filtration
		Mycoplasma testing	DNA fluorescent
11	General safety	Guinea pig and suckling mice	Safe
12	Endotoxin	LAL	≤10.0 EU/ dose

measurement of gene expression and biological activities of the expressed gene product. Gene expression is measured by Western blot or enzyme-linked immunosorbent assay (ELISA) of cells infected with the rAd product (e.g., expression of p53 protein in H1299 cells). Bioactivity of the expressed gene product is assayed on a specific cell infected with the rAd product (e.g., induction of cell apoptosis by p53 on SAOS-2 cells).

49.5.3 UNIQUE TESTS

These tests include virus particle titer determination, infectivity, IU/VP ratio, and detection of replication-competent adenovirus (RCA).

49.5.3.1 Virus Particle Titer Determination

This procedure is generally done using the A260 UV absorption method. In the presence of sodium dodecyl sulfate (SDS), one absorption unit at 260 nm equals to 1.1×10^{12} VP/ml.

49.5.3.2 Infectivity

Infectivity is measured using a TCID₅₀ method by serial dilution. Infectivity titer is calculated using the formula: $T = 10^{1+d(S-0.5)}$ (IU/100 μ l), wherein d is dilution log S is the sum of infection rate from the highest dilution.

49.5.3.3 IU/VP Ratio

According to the SFDA guidelines, the specific activity (IU/VP ratio) of clinical grade rAd needs to be at least 3.3%. Gendicine generally has an IU/VP ratio of 4.0% with an infectious titer of $4-5 \times 10^{10}$ IU/ml, exceeding the guideline requirement.

49.5.3.4 Purity Test

Although purity determination is not unique to rAd product, the use of A260/280 as a purity indication for rAd is unique and should be in the range of 1.2 to 1.3. High-performance liquid chromatography (HPLC) is also used for purity determination. According to HPLC analysis, Gendicine generally has a purity of greater than 98%, exceeding the SFDA guideline specification.

49.5.3.5 Detection of RCA

Determination of RCA level is an important safety criterion for rAd product. RCA can arise by homologous recombination between adenovirus vector and the host cell genome during the adenovirus production process. Amplification in A549 cells is generally used to detect the presence of RCA. The RCA level in Gendicine meets the less than 1RCA/ 3×10^{10} VP, as specified in the SFDA guideline document.

In addition to performing all the necessary quality control tests, Gendicine is produced following strict good manufacturing

practices (GMP) regulations, as outlined in ICH Q7A guidelines. SiBiono has instituted an independent quality assurance function to ensure the consistent production of high-quality Gendicine product.

In the seven years since the submission of phase I clinical trial application, in March 1998 to March 2004, when the GMP production certificate was issued, Gendicine underwent five stringent reviews and approval steps. These steps included application for initiation of a phase I clinical trial, application for initiation of phase II/III clinical trials, submission of a new drug license application, submission of a production license application, and submission of a GMP certification application. Strict review by an expert advisory team is conducted for each phase of the clinical trial application. Clinical trials can only begin after the sponsor satisfactorily addresses any questions the reviewers have and the application is approved.

After the approval of the new drug license, the Guangdong Food and Drug Administration inspected SiBiono's facility and submitted three batches of sealed samples to the National Institute for the Control of Pharmaceutical and Biological Products (NICPBP) for lot release testing. The SFDA granted the production license only after three lots of NICPBP successfully passed all the tests. China's Drug Law specifies that new drug has to obtain production license first before the sponsor can apply for GMP certificate for its facility. Prior to market launch, the sponsor has to apply for pricing approval from the State Price Bureau. There are two stages of GMP certificate approval. The first GMP certificate is valid for 1 year. A second GMP certificate application needs to be resubmitted in the second year. After review and approval, the second GMP certificate is valid for 5 years. Gendicine's production facility and the more than 1100 SOPs used for the production of Gendicine all passed the second GMP certification.

49.6 SUMMARY AND PROSPECTS

Gendicine, the first gene therapy product approved by a government agency, has been shown to be safe and effective for treatment of a variety of cancers. Since its market introduction in China in April 2004, more than 6000 cancer patients of diverse ethnic background have received Gendicine treatment. Although effective as a monotherapy, Gendicine showed synergistic therapeutic effects when used in combination with other traditional cancer treatment methods such as surgery, chemo- and radiotherapies. More importantly, Gendicine also alleviated the deleterious side effects commonly associated with both chemo- and radiotherapies.

As the first gene therapy product for a revolutionary new way of cancer treatment, significant basic research and clinical studies are required to understand the complex biological and therapeutic mechanisms of Gendicine's action. Dr. Lu and his colleagues provide a comprehensive review of the biological mechanisms of the roles of the p53 tumor suppressor gene in Chapter 48. Working closely with clinical collaborators, our scientists at SiBiono have begun to elucidate the therapeutic

mechanisms for Gendicine. We believe data from the additional postapproval clinical studies that are currently underway at Sibiono to broadening the approved clinical indications for Gendicine will further our understanding of the therapeutic mechanism and provide insight for the development of the next generation of cancer gene therapy products.

49.7 POINTS TO CONSIDER FOR HUMAN GENE THERAPY AND PRODUCT QUALITY CONTROL*

49.7.1 INTRODUCTION

Gene therapy is a medical intervention based on the modification of the genetic material of living cells. Currently, gene therapy is restricted in application to somatic cells. Based on transferring methods, gene therapy can be classified into two categories: *ex vivo* and *in vivo*. *Ex vivo* gene therapy refers to cells being modified *ex vivo* for subsequent administration to humans, while *in vivo* refers to cells being altered *in vivo* by giving gene therapy directly to the subject. The products of *ex vivo* gene therapy are cells that are modified and are intended to be administered to the patient. *Ex vivo* gene therapy is expected to be performed in well-established medical care establishments with specially trained medical professionals and GMP facilities. The products of *in vivo* gene therapy are recombinant DNA or RNA in the form of naked DNA, DNA complex, or viral vectors that are manipulated by genetic technologies. Both *ex vivo* and *in vivo* gene therapy products are subject to the regulations in this guidance. Because of the complexities of the different modalities of gene therapy, it is not possible to generalize a common guidance that is suitable for all kinds of products. However, the following basic principles should be followed when sponsoring the development of a gene therapy product:

1. Safety and efficacy of the product should be ensured. A comprehensive assessment of the benefit and risk of the product should be conducted.
2. New and innovative ideas should be promoted when sponsoring a gene therapy product development. Considering the uniqueness of gene therapy relative to traditional chemically synthesized and genetically engineered protein medicines, there will be certain flexibilities for the regulation of novel gene therapy products. Gene therapy as a form of medical intervention is still in its early phase of development. SFDA expects the sponsors to not just follow this guidance but also conduct rigorous scientific study to ensure the development of a safe and efficacious gene therapy product.

* This document was worked out and translated into English mainly by Dr. Zhaohui Peng, SiBiono GeneTech Co., Ltd. Shenzhen 518057, China, and officially issued by SFDA on March 20, 2003. Up to date, it is a systemic gene therapy guideline.

49.7.2 APPLICATION CONTENT AND PRODUCT QUALITY CONTROL

The following should be included in the application proposal.

49.7.2.1 Construction of the DNA Expression Cassette and the Gene Delivery System

49.7.2.1.1 Therapeutic Target Gene

A detailed description of the clonal origin of the therapeutic target gene, including a patent search on the gene, should be provided. Method of gene cloning and sequence identity should be provided.

49.7.2.1.2 Vector

Information supplied should include restriction mapping and gene-bank data for the vector. Known regulatory elements such as promoters, enhancers, and PolyA should be identified. If there is change in the vector backbone gene structure (such as deletion, mutation, or insertion), the DNA sequence data should be provided. For a new viral vector, it is necessary to provide information on the material, method of construction, and testing of the new vector.

For nonviral gene delivery systems, plasmid is needed to express the target gene in human cells. In addition to naked DNA, another component is generally used to form complex with the DNA. This guidance does not cover oligoribonucleotide (such as antisense RNA, ribozyme, and siRNA) products.

49.7.2.1.3 DNA Expression Cassette

A detailed description of the cloning procedure, the methods and materials used, and DNA sequence data should be given. Known regulatory elements such as promoters, enhancers, and PolyA should be identified. Restriction mapping of the gene expression cassette and the kinetics of gene expression should be provided.

49.7.2.1.4 Construction of the Gene Delivery System (Including Viral and Nonviral Gene Delivery Systems)

49.7.2.1.4.1 Viral Gene Delivery System Including Adenoviral Vector, Retroviral Vector, and Adeno-Associated Viral (AAV) Vector

A thorough description of the clonal origin of the viral vector should be provided. The methods and materials used for the construction of the viral vector should be included. Testing methods and results should also be provided. General testing should include structural analysis (e.g., restriction mapping and PCR), complete sequencing of the viral genome (≤ 40 kb), gene expression and bioactivity analysis, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), DNA sequencing of the gene expression cassette, Western blot analysis of the expressed protein, transduction efficiency analysis, negative-staining transmission electron microscopy of the purified viral vector, replication-competent virus detection, testing for adventitious agents, and analysis for residual process contaminants.

49.7.2.1.4.2 Nonviral Gene Delivery System

Nonviral gene delivery systems encompass naked DNA, mammalian cell carrier systems, and other carrier systems such as liposome, polypeptide, and gold particles. The nature and characteristics of the nonviral delivery system should be described adequately. To prevent allergic reaction to penicillin in some patient populations, it is recommended that a kanamycin- or neomycin-resistant gene be used as the drug selection gene.

For the physical delivery system, a detailed description of the delivery method, procedure, efficiency of gene delivery and expression, gene stability after delivery, and bioactivity should be included. Evidence of absence of gene arrangement and mutation should be provided. Detailed testing results should be given including plasmid restriction mapping, PCR analysis, DNA sequencing of the gene expression cassette, SDS-PAGE, and Western blot analysis of the expressed protein.

49.7.2.2 Generation and Characterization of Cell Banks and Engineered Bacteria Banks

A three-tier bank system should be established. These typically include a primary seed bank, a master cell bank, and a working cell bank. For engineered bacteria, these typically include a primary bacteria bank, a master bacteria bank, and a working bacteria bank.

49.7.2.2.1 Cell Bank

Primary seed bank. The origin, cell passage history, and cell characterization, as well as cell culture and banking procedures, should be described.

Master cell bank. The master cell bank should be derived from one or more ampoules of the primary seed bank by serial subculture to a specific passage number. The passage number should be identified.

Working cell bank. The working cell bank is derived from one or more ampoules of the master cell bank by serial subculture to a specific passage number. The passage number should be identified.

Characterization of cell banks. The master cell bank or working cell bank should be characterized according to guidelines in "Guidance for application of clinical trials for human gene therapy." Additional testing should include:

1. Testing of susceptibility of virus infection and production
2. Testing the status and stability of the transfected gene and level of gene expression
3. Testing for generation of replication competent viruses

If a helper virus is needed in the testing, the origin, methods of preparation and separation, and virus passage history should be provided.

49.7.2.2.2 Bacteria Bank

A master bacteria bank and a working bacteria bank should be established and tested according to the specifications of the "Chinese Pharmacopoeia."

1. Testing of the master bacteria bank

- (a) Uniformity and the identity of bacteria host strain: Testing should include the origin, genotype, and phenotype of the bacteria strain. The genotype should be tested by random amplified polymorphic DNA (RAPD). The phenotype should be tested for the specific marker or antibiotic resistant gene marker of the engineered plasmids.
- (b) Purity: The bacteria should be shown to be free of other adventitious agents, such as fungi and bacteria.
- (c) Stability: The ratio of transformed bacteria, propagation condition, copy numbers, level of gene expression, and passage number should be qualified.
- (d) Sequencing of gene expression cassette: The inserted gene of interest and associated regulatory elements should be sequenced.

2. Working bacteria bank. Testing of the working bacteria bank should be performed in accordance with the requirements for the master bacteria bank mentioned above with the exception of the sequencing of the gene expression cassette.

49.7.2.3 Manufacture of Gene Therapy Product

49.7.2.3.1 General Requirements

1. Description of manufacturing facility and environment GMP regulations should be followed in the manufacturing of gene therapy products. This rule applies to both the *ex vivo* cell products and recombinant viral products. Recombinant viral products intended for preclinical and clinical studies should be manufactured using a validatable production process.
2. A detailed description of the manufacturing process, raw materials, and the components used should be provided.
3. Manufacturing process controls should be provided. Critical process parameters should be identified, controlled, and recorded.
4. Batch production records and testing records of one lot of product should be provided.
5. One lot of product should be tested by institutes that are designated by SFDA for lot release testing. The testing report should be provided.

49.7.2.3.2 Recombinant Viral Vector as Gene Therapy Product

An MVB and a WVB should be established and tested. The WVB should be derived from the MVB. A detailed description of the origin, construction, cloning, passage, and storage of the virus bank should be provided. Quality control testing procedures outlined in this document should be followed. Production should be initiated from producer cells derived from working cell bank. Nonqualified cells should not be used for production purposes. For a viral vector

product, the producer cell infection should be carried using a virus from the WVB. Infection should not be performed using a nonqualified virus. Production can be performed using large-scale attachment-dependent cell or suspension cell culture. Virus banks can be prepared directly from a cell culture without further purification. Buffer formulation for virus banks should be qualified to protect virus infectivity during storage.

49.7.2.3.3 Nonviral Plasmid DNA Complex as Gene Therapy Product

A detailed description of the following aspects should be provided:

1. Manufacturing process and quality control of the recombinant plasmid DNA
2. Origin, characteristics, and method of preparation of the liposome if used
3. Origin, characteristics, and method of preparation of the polypeptide if used
4. Origin, characteristics, and method of preparation of other components in the product complex
5. Method of preparation and quality control of the final product complex

For gene therapy products in the form of gene gun and other physical gene delivery approaches, detailed description of the following items should be provided:

- (a) Origin and preparation of the therapeutic gene
- (b) Gene expression
- (c) Propagation of the naked DNA
- (d) DNA purification
- (e) Equipment characteristics
- (f) Method of gene delivery

49.7.2.3.4 Genetically Modified Somatic Cells as Products

This category encompasses *ex vivo* gene therapy products. Manufacture of this category of products should follow guidelines in “Guidelines for Study of Somatic Cell Therapy and Quality Control.” Detailed description of the process for cell propagation, media used for cell culture, method of cell collection, method of *ex vivo* cell transduction and selection, and formulation used for washing and storage of the transduced cells, as well as testing performed on the transduced cells should be provided.

49.7.2.4 Quality Control

Sufficient quality control testing should be performed during the manufacture of gene therapy products. Product release testing should be performed on the final drug product. However, depending on the nature of the manufacturing process, some testing should be performed on process samples if the excipients included in the final product formulation interfere with the testing.

49.7.2.4.1 Recombinant Viral Vector as Gene Therapy Product

In reference to the domestic and international viral vector development status, testing of a recombinant adenovirus (rAd) product is used as an example of the quality control testing for viral vector products. The testing can be used as a reference for other viral vector products.

49.7.2.4.1.1 Quality Control for Rad Gene Therapy Product

1. Crude harvest
 - (a) Sterility tests to be performed in accordance with “SFDA Guidance for Biological Products, subpart—Sterility Testing” 2000 edition.
 - (b) Measurement of virus particles
 - (c) Titration of infectious virus titer
 - (d) Mycoplasma testing
2. Bulk product (drug substance)
 - (a) Sterility test
 - (b) Measurement of virus particles
 - (c) Endotoxin testing
3. Final product (drug product)
 - (a) Particulates
 - (b) Physical appearance
 - (c) Recoverable volume
 - (d) pH
 - (e) Identity testing by restriction mapping analysis of the gene expression cassette
 - (f) Purity: A260/280 nm or HPLC
 - (g) Virus particle concentration: Spectrophotometric OD260 method
 - (h) Potency: Testing level of gene expression and bioactivity testing
 - (i) RCA. A549 cell-culture detection method (no more than 1 RCA in 3×10^{10} VP)
 - (j) AAV. Testing of the presence of AAV using PCR
 - (k) Testing of residuals. Residuals, such as host cell DNA, host cell protein, bovine serum albumin for process using fetal bovine serum, and other residuals specific to the production process should be tested and quantified
 - (l) Sterility testing
 - (m) General safety testing
 - (n) Endotoxin testing
 - (o) Infectivity testing (such as infectious titer by TCID50)
 - (p) Stability study: Stability of three batches of final product during real-time storage, freeze, and thaw; and accelerated stability study should be provided

49.7.2.4.2 Quality Control for *ex Vivo* Gene Therapy Using Retrovirus Gene Therapy Product

Manufacture of gene therapy products for *ex vivo* transduction of somatic cells should follow guidelines in “Guidelines for Study of Somatic Cell Therapy and Quality Control.” Testing for replication-competent retroviruses (RCR) should be emphasized. Testing should be performed for the master cell

bank, the working cell bank, end-of-production cells, and final virus products. Five percent of the total supernatant should be tested for RCR. One percent of total pooled end-of-production cells or 10^8 cells, whichever is less, should be cocultured with a permissive cell line (such as *Mus dunni* cells) for a minimum of five passages in order to amplify any potential RCR present. Then, the amplified material is detected in a combination of two appropriate indicator cell assays, such as PG4 S+L-cells, maker rescue, or RT/PCR method. All assays should include positive (such as supernatant from COS4070A cells) and negative controls to assess specificity, sensitivity, and reproducibility of the methods used.

49.7.2.4.2.1 Retroviral Vector Producer Cells as Product

Testing should include:

- (a) Morphology, karyology, surface marker and homogeneity of the cells
- (b) Cell viability and concentration
- (c) Stability, copy number, and level of expression of the inserted gene (particularly, describe the risk of insertional mutagenesis in target cells and method of evaluation)

49.7.2.4.2.2 Quality Control of Thawed Cells

1. These tests should be performed for thawed cells:
 - (a) Percentage of cell recovery and viability after thaw
 - (b) Transduction efficiency
2. These tests should be performed for supernatant from thawed cells:
 - (a) Sterility testing
 - (b) Endotoxin testing
 - (c) General safety testing
 - (d) Transduction efficiency
 - (e) Mycoplasma testing
3. Retroviral vector supernatant as product

The following testing should be performed:

- (a) Virus titer
- (b) Restriction mapping
- (c) Transduction efficiency
- (d) RCR testing (it is critically important to test the level of RCRs in the product considering the nature of chromosomal integration of retrovirus and associated potential genetic toxicity)
- (e) Testing for sterility and endotoxin
- (f) Measurement of residual bovine serum albumin (BSA)
- (g) Mycoplasma testing

Note: For cell products, the expiration is very short. In those cases, the cell product can be released pending results from testing that requires a longer time. If testing results are positive, the cell product should be immediately recalled and investigation should be initiated for the positive results.

49.7.2.4.3. Nonviral DNA Vectors as Gene Therapy Product

The following testing should be performed:

1. Purity: Testing for percentage of supercoiled DNA, residual bacterial RNA and DNA, and residual bacterial host protein

2. DNA restriction mapping
3. Origin and characteristics of liposome, polypeptide and gold particles used (due to the inherent variation in the production of liposome and polypeptide, measures should be implemented to ensure the consistency of the production process)
4. Sterility testing
5. Endotoxin testing
6. Allergy testing
7. General safety testing
8. Bioactivity testing
9. Testing for process residuals

49.7.2.5 Evaluation of Efficacy for Gene Therapy Product

49.7.2.5.1 In Vitro Testing

Data should be provided to show therapeutic effect when the exogenous gene is delivered into the target cells. For *ex vivo* cell therapy, data should be provided to show the gene expression level in the transduced cells.

49.7.2.5.2 In Vivo Testing

Animal study data should be provided to show the gene expression level in the target tissue cells, biodistribution of the product and gene expression, and therapeutic effect. The selection of the animal model should be justified. The route of administration should simulate that of clinical situation. If limited by the animal model, and the clinical route of administration cannot be used, justification should be provided for selection of other routes of administration. If efficacy cannot be produced in animal model studies, surrogate indicators for efficacy should be provided.

49.7.2.6 Safety Evaluation

In addition to the above quality control requirements, the following product safety information should also be provided.

49.7.2.6.1 Overall Safety Evaluation

For *ex vivo* somatic cell therapy products, the following information should also be provided:

1. For growth-factor-dependent cells, cells cannot be used if loss of growth-factor-dependence is observed during cell expansion.
2. For allogeneic somatic cell therapy products, immunological safety data should be provided.
3. For xenogeneic somatic cell therapy products, the survival of the xenogeneic cells and *in vivo* safety data should be provided.
4. Tumorigenicity testing should be performed for all somatic cell therapy products. For cancer vaccine products, procedures taken to attenuate the growth potential of cells derived from the tumor tissue should be provided. The tumorigenicity testing should include testing in nude mice and colony formation in soft agar.
5. Testing for cell homogeneity: For cancer vaccine products, measures should be provided detailing the

separation of nontumor cells from tumor cells. If nontumor cells are selected from tumor cells (e.g., lymphocytes), measures used to eliminate tumor cells should be provided.

6. Testing for replication competent viruses—See related parts of these guidelines.
7. Additives. In addition to the additives used for cell culture and product storage, additives are used in some *ex vivo* or *in vivo* gene therapy products. The safety profile of those additives should be provided from animal studies.

49.7.2.6.2 Genetics Study

For *in vivo* gene therapy products, the biodistribution of the viral and nonviral DNA products and expression of the recombinant DNA in target and nontarget tissue should be provided. For *ex vivo* gene therapy products, the biodistribution and gene expression of the transduced cells should be provided. Risks for stem cell transduction should be carefully evaluated.

49.7.2.6.3 Toxicology Study

Toxicity evaluation is an important part of the safety testing.

1. For *in vivo* gene therapy products, a detailed description of the toxicology study should be given. In addition to the study of potential toxicity of the therapeutic gene product, a safety evaluation of the delivery system should be performed.

The toxicology study should include an acute toxicity study (maximum tolerated dose) and a chronic toxicity study. A relatively wide range of doses should be tested, such that a reasonable dose–response curve for toxicity can be obtained. The dose range should include at least a dose equivalent to that to be used in a clinical trial and higher doses.

The routes of product administration should simulate that to be used in clinical trial study. Justification should be provided if any other route of administration is used. Product doses based on either body weight or total body surface area are preferred to facilitate comparisons across species. In addition to observations for standard toxicities, genetic toxicity specific to gene therapy products should also be included.

2. For autologous cancer vaccine, lymphocyte, or macrophage *ex vivo* gene therapy products, toxicity study in an animal model is not required. However, if specific additives (e.g., gelatin, suture, or special catheters) are included in the *ex vivo* gene therapy product, or the gene therapy product is delivered to critical organs (e.g., heart, brain, or liver), a toxicity study in an animal model is required. If cell growth factors are supplemented in the *ex vivo* cell expansion process, a safety study is required on the growth factors. For subcutaneous and intramuscular

administration, information on any injection site reaction should be provided.

49.7.2.6.4 Immunology Studies

The immunological response, including anaphylaxis, repellency, and autoimmune reaction, should be evaluated for both viral and nonviral gene therapy products after administration. A strategy to deal with potential immunological reactions should be established. For gene therapy products that are used to elicit immunological responses, such as cancer vaccines, cytokines, or genetically modified immune cells, changes to the immunological system and their potential side effects should be described. A strategy for monitoring and resolving the potential side effects should be established. Refer to “Guidelines for Study of Somatic Cell Therapy and Quality Control” for details.

49.7.2.6.5 Tumorigenicity Studies

See related section in this guidance. (Author’s note: For viral gene therapy product derived from recombinant retrovirus and AAV, tumorigenesis caused from insertional mutagenesis should be carefully studied.)

49.7.2.7 Clinical Trial of Gene Therapy Products

Clinical trials of gene therapy products are different from those with other biotechnology products. First, gene therapy products tend to be very complex. For example, *ex vivo* gene therapy products require a medical specialist to administer the product to the targeted tissues. In some cases, surgery is required in order to administer the product. Secondly, gene therapy product development is still in its early phase with possible unknown risks. Intensive patient monitoring should be implemented during clinical trial. The following information should be included when clinical trial plans are submitted.

1. Sponsor GMP compliance certificate
2. Clinical study site and biography of the principal investigator
3. Route of administration, dose, time and period of treatment (if surgery is required for product administration, detailed description of the surgery procedure is required)
4. General clinic status index and laboratory test
5. Signed consent forms of patients and family members
6. Molecular biology analysis of target and nontarget tissues
7. Recording and reporting of side effects
8. Follow-up strategy and plan
9. Medical intervention plan should be provided to deal with unexpected immune reactions

49.7.2.8 Ethics Studies

Special attention should be paid to medical ethics during clinical trials of gene therapy products. Details can be found in SFDA’s GCP (Good Clinical Practice) regulations. The study plan and

potential risks associated with the clinical study should be clearly communicated to the patient and family members. Patients have the right to choose medical treatment options and terminate participation in the gene therapy clinical trial study. The patient's medical history should be kept private. The patient cannot be enrolled in the study until the patient or family member signs the study consent form.

ACKNOWLEDGMENTS

We would like to thank Drs. Hua Lu, Mu-Shui Dai, and Ms. Jayme Gallegos at the Department of Biochemistry and Molecular Biology, School of Medicine, Indiana University, Indianapolis and Dr. Huijun Zou Ring, Director of Pharmacogenetics, DNA Direct Inc., San Francisco, California for active discussion and proofreading.

50.1 INTRODUCTION

The transfer of genetic material into a target cells offers a potentially powerful strategy in the treatment of a wide variety of diseases. While gene marking does not confer therapeutic benefit, much of the biological information gained from these trials has been proving to be valuable for improving the outcome of therapies such as stem cell transplantation [1,2]. Gene marking can be used to track the *in vivo* behavior of almost any tissue [3], and the success of the strategy depends on tracking the marked cell not only for its entire lifespan, but

also for the lifespan of all its progeny. The vectors used must therefore integrate in the host cell DNA and efficiently replicate with the cell. For this reason, the majority of marker studies performed to date have used murine retroviral vectors. Although these agents are able to integrate stably, they have many limitations. In particular, they are only able to integrate into dividing cells and have low transduction efficiency.

The aims of this chapter are threefold: (1) to identify the reasons why gene marking studies have been performed and why this research was important to the ever-broadening field

of gene transfer, (2) to discuss the vectors and marker genes employed and the factors that influence gene transfer efficiency and gene expression, and (3) to review the concerns about the safety issues surrounding gene transfer.

50.2 GENE MARKING OF HEMATOPOIETIC PROGENITOR CELLS

The principle of gene marking is the transfer of a unique DNA sequence (e.g., a nonhuman gene) into a host cell (e.g., T-cell, hematopoietic stem cell [HSC], etc.) allowing the gene or the gene product to be easily detected, thereby serving as a marker for these labeled cells. Detection of the marker gene may be phenotypic or genotypic. For example, the frequently used bacterial neomycin resistance (*neo*) marker gene encodes the enzyme neomycin phosphotransferase, which can inactivate neomycin or its analogs such as G418. When cells are expressing the *neo* gene, they become resistant to G418 in culture medium and can be detected by the ability to grow in G418. The transgene can also be readily detected in these cells using the polymerase chain reaction (PCR) technique [2].

50.2.1 GENE MARKING IN AUTOLOGOUS STEM CELL TRANSPLANTATION

In the first gene marking trials involving HSCs, the question posed was whether relapse following autologous stem cell transplant was due to a contribution from contaminating malignant cells in the stem cell harvest [4]. In order to answer this question, a portion of the HSC product was marked at the time of harvest with a murine retroviral vector encoding the neomycin resistance gene. If the patient subsequently relapsed, it was possible to detect whether the marker gene was present in the malignant cells. Since 1991, studies were initiated using this approach in a variety of malignancies treated by autologous HSC transplantation [4–13]. As shown in Table 50.1, the underlying malignancies treated with marked autologous HSCs include acute myeloid leukemia (AML), chronic myeloid leukemia (CML), acute lymphoblastic leukemia (ALL), neuroblastoma, lymphoma, multiple myeloma, and breast cancer.

The initial studies evaluating this approach took place at St. Jude Children's Research Hospital (SJCRH) in pediatric

TABLE 50.1
Clinical Gene Marking Studies in Autologous HSC Transplantation

Institution	Patient Population (Number)	Target Cell and Transduction Method	Findings	Reference
Single marking studies				
St. Jude Children's Research Hospital	Pediatric AML (12); neuroblastoma (8). Extended study included 25 and 12 patients, respectively	Marrow, 6 h culture with vector	Marking detected in marrow progenitor and peripheral blood (PB) in 15 of 18 patients at 1 month Marking detected in neutrophils, T cells, and B cells Extended follow-up detected marked cells in blood and marrow in 32 of 37 patients at 2 years with persistence for at least 9 years Marked tumor cells detectable in two of two AML and three of three neuroblastoma relapses in initial report. Follow-up detected marked tumor cells in three of four AML and four of five neuroblastoma relapses	[2,14,16, 20,21]
M.D. Anderson	Adult CML (4)	CD34-enriched marrow. 6h culture with vector	Marked normal cells and leukemia cells for up to 280 days	[17]
Indiana University	Adult AML (4); ALL (1)	Marrow, 4h culture with vector	Minimal detection of marked cells. No marked tumor cells in two relapses	[18]
University of Toronto	Adults. Multiple myeloma (15)	Stroma-based long term (21 days) marrow culture	Marked normal cells detected for up to 2 years	[35]
University Hospital, Freiburg, Germany	Adult. CML (3)	CD34-enriched PB. Cultured with Flt-3 ligand, SCF, IL-3, \pm IL-6, \pm G-CSF (5-day culture)	Marked normal cells detected in all patients early on (day 11) but no significant detection after 9 months	[69]
Karolinska Institute	Adult. Multiple myeloma (6)	CD34 selected marrow or PB. Transduced in presence of SCF, IL-3, IL-6, bFGF (24 h culture)	Marked normal marrow cells detected up to 5 years No marked myeloma cells in three cases of disease progression	[23]

TABLE 50.1 (continued)
Clinical Gene Marking Studies in Autologous HSC Transplantation

Institution	Patient Population (Number)	Target Cell and Transduction Method	Findings	Reference
Double marking studies				
St. Jude Children's Research Hospital	Pediatric. AML (12)	Marrow purged with 4HC versus IL-2, 6 h culture with vector	Marked cells from 4HC arm persisted for >3 years. Marked cells from IL-2 treated arm detected transiently only No marked tumor cells in 3 relapses	[20,21,25]
National Institutes of Health	Adult. Multiple myeloma (6); breast cancer (5)	CD34 selected PB versus marrow, 72 h culture with SCF, IL-3, ± IL-6	Marked cells persisted for >18 months with contribution from both PB and marrow No marked tumor cells in three breast cancer relapses	[19]
National Institutes of Health	Adult. Multiple myeloma (3); breast cancer (2)	CD34 selected PB versus marrow, 6 h culture with vector. No growth factors	Marked cells detected in four of five patients early posttransplant (two from PB source only, one marrow only, one both) No marking detectable at 1 year	[22]
National Institutes of Health	Adult. Multiple myeloma (2); breast cancer (2)	CD34 selected PB versus marrow, 72 h culture on autologous stroma layer	Marked cells detected early posttransplant in one of four patients from marrow only. No marking detectable at 1 year No marked tumor cells in one breast cancer relapse	[22]
M.D. Anderson	Adult. Follicular lymphoma (3)	CD34 selected PB versus marrow, 4 to 6 h culture	Marked cells detected from both PB and marrow up to 9 months No marked tumor cells in one relapse	[24]

AML, acute myeloid leukemia; bFGF, basic fibroblast Growth Factor; G-CSF, granulocyte colony stimulating factor; 4HC, 4-hydroperoxycyclophosphamide; IL-2, interleukin-2; IL-3, interleukin-3; IL-6, interleukin-6; PB, peripheral blood; SCF, stem cell factor.

patients receiving autologous bone marrow transplantation (BMT) as part of therapy for AML or neuroblastoma [4,6,13]. In both studies, one-third of the marrow was marked in a 6 h transduction protocol in the absence of growth factors. Four of 12 AML patients who received marked marrow relapsed. In three of the four patients, detection of both the transferred marker and a tumor-specific marker in the same cells at the time of relapse provided unequivocal evidence that the residual malignant cells in the marrow were a source of leukemic recurrence [14]. For example, in one patient the malignant blasts had the unique phenotypic features of CD34 and CD56 coexpression and a complex t(1:8:21) translocation, resulting in an AML1/ETO fusion transcript that could be identified by PCR. Malignant cells sorted by this phenotype contained both the AML1/ETO fusion transcript and the transferred neomycin gene [14]. In the neuroblastoma study [6], five of the nine patients relapsed, and gene marked neuroblastoma cells, coexpressing the neuroblastoma-specific antigen GD2 together with the transferred marker gene, were detected in four cases [15,16]. In one of these patients, marked neuroblastoma cells were detected in an extramedullary relapse in the liver [16]. Similarly, marked malignant cells coexpressing the t(9:22) and *neo* transcripts were found in two patients with CML at relapse [17]. These data show that in these three malignancies, marrow harvested in apparent clinical remission may contain residual tumorigenic cells that

can contribute to a subsequent relapse. In contrast, marked cells have not been found in adult patients relapsing after autografts for ALL [18]. However, for logistic reasons, only around 10% of the marrow was marked in this study and gene transfer to normal cells was very low. In a study at the NIH, autologous transplantation for breast cancer used CD34 selected HSC from blood and marrow. In the two patients who have relapsed the marker gene was not found [19]. This may reflect a lower efficiency of the marking of breast cancer cells or the CD34⁺ selection procedure used may have reduced contamination with malignant cells. Alternatively, relapse in breast cancer may occur predominantly from residual disease in the patient.

As only modest levels of gene transfer into malignant progenitor cells is obtained, a definitive conclusion about the contribution of marrow-based disease to recurrence can only be drawn if a relapse is marked. Therefore, although the presence of gene-marked cells within relapse samples is proof that reinfused cells contribute to relapse, their absence is less informative. Studies where all relapses were negative for gene-marked cells include three children with relapsed AML after transplantation with purged marrow [20,21], two adults with relapsed AML after BMT [18], and four relapsed breast cancer [19,22], three progressive myeloma [23], and one relapsed follicular lymphoma [24] after CD34 selected stem cell transplantation. It is possible that these findings reflect

true differences in tumor biology or stem cell product; however, other factors, in particular tumor marking efficiency and chance effect inherent to small studies, cannot be ruled out. For example, unmarked relapses might mean that marrow does not significantly contribute to recurrence or may mean that relapse is generated by only a few marrow-derived malignant cells that have escaped being marked because of the inefficiency of the transduction process.

50.3 USE OF MULTIPLE VECTORS

50.3.1 DOUBLE GENE MARKING TO MONITOR PURGING

The overall implication of the above studies was that residual malignant cells can contribute to relapse and the outcome of HSC rescue may be improved by strategies targeted at residual malignant cells [21]. One means of achieving this is purging of the transplanted marrow and gene-marking techniques are useful in the evaluation of the purging technologies. In second-generation studies, two genetically distinct marker genes were used to compare either marrow purging versus no purging, or two different purging techniques [12,25,26]. Two closely related vectors, G1Na and LNL6, were used. These vectors differ in their 3' noncoding sequences so primers can be designed allowing the vectors to be discriminated by virtue of the differing fragment sizes they produce after PCR amplification. In the AML study [25], 15 patients were enrolled between September 1993 and November 1996. At least 10^8 marrow cells/kg were frozen without manipulation as a safety backup. The remaining marrow mononuclear cells were divided in half and randomized to marking with G1Na or LNL6. The aliquots were then randomly assigned to the two purging techniques being evaluated. Initially the pharmacologic "gold standard" hydroperoxycyclophosphamide (4HC) was compared with an immunologic purge by culture with IL-2 [27]. Later in the study, CD15 antibodies (instead of IL-2) were used in conjunction with 4HC [28]. At the time of transplant, both aliquots were reinfused. If the patients relapsed, the premise was that detection of either marker would reveal which of the compared purging techniques had failed.

Over the 3-year period, 15 patients received gene marked marrow. In five patients, aliquots of marrow were purged with 4HC and IL-2 and in three patients the marrow was purged with 4HC and CD15. PCR studies on PB granulocytes and mononuclear cells consistently showed a stronger signal from the 4HC-purged fraction than that from the IL-2-purged fraction, regardless of which vector was used for marking each aliquot. These observations suggested that the 4HC-purged fraction was making a greater contribution to hematopoietic reconstitution than the IL-2-purged fraction thus resulting in the substitution of CD15 antibodies for IL-2. Seven patients received marrow purged with 4HC alone. This was due to either insufficient number of cells harvested or unavailability of one clinical grade retroviral vector. In all, three of the fifteen patients relapsed. Two patients relapsed early at 2 and 3 months and were noninformative, as marked malignant cells were not

detected. A third patient relapsed at 20 months and his blasts were also negative [20]. The *neo* gene was detected in normal hematopoietic and immune system cells at a lower level than in the studies using unpurged marrow.

50.4 GENE TRANSFER TO NORMAL CELLS

These marking studies also provided information on the transfer of marker genes to normal hematopoietic cells and showed that marrow autografts contribute to long-term hematopoietic reconstitution after transplant [2,21] (Table 50.1). Long-term transfer up to 9 years has been seen in the mature progeny of marrow precursor cells, including PB T and B cells and neutrophils [20]. It was also detected in lymphoblastoid cell lines and cytotoxic T cell (CTL) lines derived from these patients. However, the level of gene transfer varied and was highest in marrow clonogenic hematopoietic progenitors, where an average of 6% of myeloid colonies were G418-resistant at 3 months. The levels of transfer into marrow progenitors are higher than predicted from animal models and may be attributed to the fact that marrow was harvested during regeneration after intensive chemotherapy, when a higher than normal proportion of stem cells are in cycle [21]. In the mature PB cells, the level of gene transfer was, however, some fivefold lower than in the marrow progenitors with levels of 0%–1% seen [29].

Useful information was gained from these initial studies leading to the development of more complex gene marking protocols (Table 50.1). These include the following. (i) Double gene marking to allow simultaneous study of two distinctly treated cell populations, for example, of unmanipulated HSCs versus stem cells treated with growth-stimulatory agents. (ii) The use of more purified populations of early progenitor cells to allow the "true" pluripotent stem cell to be identified phenotypically and increase the efficiency of gene transfer by more precise tailoring of transduction conditions.

50.4.1 DOUBLE GENE MARKING TO COMPARE LONG-TERM RECONSTITUTION FROM DIFFERENT POPULATIONS OF HEMATOPOIETIC PROGENITOR CELLS

No *in vitro* assay can yet assess the capacity of a cell population to produce short- and long-term repopulation of humans. The use of double gene marking with distinguishable vectors in a single patient potentially allows (i) comparison of these properties between different sources of putative stem cells, such as PB and marrow, (ii) determination of the function of stem cell subpopulations, for example CD34⁺ CD38⁺ versus CD34⁺ CD38⁻ progenitor cells, (iii) the consequences of *ex vivo* manipulation, such as culture of putative stem cells on stromal support or with cytokines. By using the two distinguishable retroviral markers, it is possible to compare quantitatively *in vivo* and within each patient the short- and long-term reconstituting capacity of different populations of HSC.

One aim of clinical stem cell transplantation is to minimize the period of marrow aplasia posttransplant by increasing the number of progenitor cells infused. This approach is only of value if progenitor cell manipulation does not induce loss of self-renewal capacity when the treated cells are reinfused. One strategy is to expand the progenitor cells at least 50-fold *ex vivo* using stimulatory cytokines [19,30] or stromal [20,31] components. There are, however, concerns that stimulatory cytokines will not only induce primitive cells to expand but will also cause them to differentiate and lose their capacity for self-renewal. In other words, the cytokine stimulation *ex vivo* may produce a faster initial engraftment but at the cost of later graft failure. Gene marking can be used to not only address concerns about the effects of growth-stimulating agents on pluripotent progenitor cells and long-term engraftment, but also determine if *ex vivo* stimulation increases gene transfer efficiency.

The NIH study by Dunbar et al. [19] compared the reconstitution of PB and bone marrow in patients receiving autologous HSC rescue for myeloma or breast cancer. They differentially marked mobilized PB and marrow CD34⁺ cells using two distinguishable *neo* containing retroviral vectors and infused both populations of stem cells into the same patient. An average of 21% of colony forming units (CFUs) were transduced using a 3-day culture in the presence of SCF, IL-3, and IL-6. The level of gene transfer into committed progenitor cells posttransduction was as high as 50% using this approach. However the engraftment of the marked cells was not accelerated compared to the earlier SJCRH studies [2,14,25,32] in which growth factors were not used. In addition, although vector sequences were found in myeloid and lymphoid cells at 0.01%–0.001% for up to 18 months, these levels were lower than the earlier SJCRH studies [33,34]. These findings may reflect the different patient population both by virtue of age (adult versus pediatric) and disease (breast cancer/myeloma versus leukemia/neuroblastoma). Alternatively, this may indicate that that culture with growth factors commits transduced cells to differentiation, so that high-level, long-term engraftment is not obtained.

Although the study by Dunbar et al. showed low levels of gene transfer detected *in vivo*, the marker gene derived from PB and marrow HSC demonstrated that each can contribute to long-term recovery [19]. It is of interest that the marked-PB stem cells (PBSCs) contributed to hematopoiesis earlier and for a longer period compared to the gene marked-marrow cells. It is possible that this phenomenon may be related to physiological differences in these two populations of HSCs. This includes the ability of each HSC to contribute to hematopoiesis, the cell cycle status of the HSC or the susceptibility of the HSC to retroviral transduction [31].

Another promising method by which progenitor cells may be expanded and their transducibility increased is the initiation of long-term cultures or the addition of stromal support components to culture. One group [11,35], established marrow in long-term cultures where an autologous stroma developed over the course of 3-week culture. The cultures were transduced weekly. Initially a mean of 16% of gene marked pro-

genitors were seen in the early posttransplant period. This level dropped to 3% by 2 years posttransplant and only 0.01% of the circulating blood cells were marked.

Although the use of double gene markers was hampered by the complexity of the studies, the approach was a powerful way of investigating the biology of different stem cell populations and of determining the consequences of stem cell manipulation.

50.4.2 CD34⁺ SELECTED HSC TRANSPLANTATION

In the context of gene marking, the justification for CD34⁺ selection is that it reduces the required volume of vector supernatant. It may also serve as a means of marrow purging in patients in whom the malignant cells are CD34⁻ or co-express CD34⁺ and one or more lineage (lin) commitment antigens. The marking approach can be used to discover the relative ability of distinct populations of CD34⁺ cells to produce long-lived, multilineage reconstitution following reinfusion. The strategy can also be used to determine if lin-positive and -negative CD34 subsets make a different contribution to short and long-term reconstitution. The potential disadvantage of selecting CD34⁺ cells or their subsets is that immune reconstitution may be delayed because mature lymphocytes are not transferred with the graft. This delay may then increase the risks of subsequent neoplastic change if undetected replication-competent retrovirus has contaminated the vector as demonstrated in an animal study [36].

The advantages of CD34 selection may therefore be counterbalanced, at least in part, by a decrease in the margin of safety for marker studies. Nonetheless, many of the later marker studies (as shown in Table 50.1) used CD34⁺ cells as the vector target [12,19,33].

50.5 ROLE OF MARKER STUDIES TO VALIDATE EFFORTS TO INCREASE THE LEVEL OF GENE TRANSFER TO THE HSC

50.5.1 ROLE OF CELL CYCLE

Attempts to induce HSCs to cycle generally use various cytokines/growth factor combinations. However, it has been demonstrated that culture of human CD34⁺ CD38⁻ cells in serum free media with IL-3, IL-6 SCF, Flt-3 ligand, and thrombopoietin or megakaryocyte-derived growth factor (MDGF) for 9 days can increase both the number of HSCs cycling and the length of time they can be maintained *in vitro* [37–39]. HSCs may also be induced to cycle *in vivo* as a normal physiologic response to hematopoietic cytoablation or cytokine mobilization. In the SJCRH studies in pediatric patients [2,14,25,32], a 6h incubation with retroviral supernatant was employed for transduction. The success of the transduction efficiency and long-term persistence of marker gene expression in these studies compared to similar studies in adults [19,35] may, however, be attributed to the fact that HSCs from children have an endogenously higher proliferation index. There is also evidence that treatment of animals with a combination of granulocyte-stimulating factor (G-CSF) and SCF mobilizes marrow

progenitor cells that are more primitive and more readily transduced than after treatment with G-CSF alone [40].

50.5.2 ROLE OF STROMAL SUPPORT ELEMENTS

Some groups add stromal supports such as a recombinant fragment of fibronectin to bring the retroviral vector and target cell into close apposition thereby increasing the efficiency of progenitor cell marking [41,42]. Several studies have tried to address the extent of long-term engraftment of retrovirally transduced PB progenitor cells using recombinant fibronectin [43–45]. One study [45] assessed the effects of recombinant fibronectin on marrow repopulating cells and on the efficiency of gene transfer using the multidrug resistance (MDR1) gene or *neo* gene to ascertain the fate of the treated cells. In this study, half of the enriched CD34⁺ cells were transduced with MDR1 and the other half with *neo*. There was low level gene marking of granulocytes (0.01%–1%) by PCR analysis up to 6 months posttransplant. In all six patients, there was a higher level of engraftment of MDR1-containing cells relative to *neo*, suggesting that MDR1 overexpression was beneficial to the engraftment potential of hematopoietic cells.

One study [42] reports the highest level of long-term engraftment of retrovirally transduced PBSCs. The 11 enrolled patients were all adults (17–51 years) undergoing tandem autologous PBSC transplants for germ cell tumors. In this study, MDR1 was used as a marker gene and in the hope that it may render the HSC resistant to oral etoposide [46], thereby allowing for further dose-intensive therapy without the delay of prolonged cytopenia posttransplant. The PBSCs were mobilized using G-CSF. The initial harvest was unmanipulated and used for the initial transplant. The second collection was CD34⁺ selected, stimulated *ex vivo* with cytokines (SCF, IL-6, MGDF, G-CSF), and cultured with MDR-1 retroviral vector on plates coated with recombinant fibronectin (CH-296) then cryopreserved on day 5. The median gene transfer efficiency of all colonies immediately after transduction was 14% (4%–52%). At 12 months postinfusion of the MDR1-PBSCs, four of the seven evaluable patients had detectable levels (5%–15%) of transgene-containing colonies in their bone marrow samples. This study also showed that exposure of CD34⁺ cells to CH-296 did not adversely affect either engraftment kinetics or long-term hematopoietic function.

These studies therefore indicate the feasibility of using MDR gene transfer as a means of enriching marrow for MDR-transduced cells. It remains unclear whether or not the approach will be valuable for protecting and selecting other cell types following chemotherapy.

50.6 GENE MARKING STUDIES OF T CELLS

50.6.1 GENE MARKING OF TUMOR-INFILTRATING T LYMPHOCYTES

The first gene marking protocol was conducted to determine the fate of lymphoid cells that infiltrate solid tumors [47]. These tumor-infiltrating lymphocytes (TILs) were obtained

from tumor biopsies, expanded *ex vivo*, and then re-infused. It was therefore important to determine if these infused TILs were tumor-specific and ascertain their distribution and persistence at tumor sites after infusion. Initially, studies to assess the ability of TILs to traffic to and remain at tumor sites postinfusion used TILs, which were radioactively labeled with ¹¹¹In [48,49]. However, this approach requires a high labeling to enhance the detection level and duration, resulting in potentially toxic radiation exposure to cells from the gamma radiation emitted by the isotope. In addition, the half-life of ¹¹¹In is only 2.8 days and it is therefore not suitable for monitoring TILs over extended periods of time [50].

It was apparent that a need existed for an alternative labeling technique. The genetic marking of the TIL *ex vivo* using a *neo* encoding retroviral vector helped answer several questions about TILs in cancer therapy. After *neo*-marked TILs were infused in to the patient and tumor sites biopsied, it was shown that large numbers of gene-marked TILs could be safely returned to patients, and that the marker could be transiently detected in the PB by PCR analysis using *neo*-specific primers [51,52]. Analysis of PB and tumor deposits for presence of the marker gene suggested that TIL could persist for up to 2 months [51]. Studies in one patient showed presence of the marker gene in biopsy tissue from a tumor deposit [53]. In a French study marked TIL were detected for up to 260 days and TIL were also detected in 4/8 tumor biopsies after therapy [54]. A subsequent double-marking study compared the survival and tracking of PB lymphocytes (PBL) and TIL by marking with distinguishable retroviral vectors [55]. Both marked PBL and TIL could be detected in PB for 4 months and no selective homing of TILs to tumor sites compared to unmanipulated PBL was seen [55]. None of these studies therefore provided support for the theory that TILs are capable of selective homing.

50.6.2 GENE MARKING TO TRACK ADOPTIVELY TRANSFERRED CTLs AFTER ALLOGENEIC BMT

Several studies have shown the feasibility and apparent clinical efficacy of adoptive transfer of CTLs directed at viral or tumor antigens [54–63]. The transfer of a marker gene has allowed monitoring of adoptive transfer approaches to determine the survival of infused T cells. In addition, the T cells can be tracked to learn if they can home to sites of disease and if they mediate adverse effects such as graft versus host disease (GVHD). The clinical results of gene marking approaches using T cells are summarized in Table 50.2.

Matched unrelated-donor or mismatched family-donor BMT results in a high risk of GVHD due to the greater genetic disparity between the donor and the recipient. An effective means of reducing this risk is to T cell deplete the donor marrow *ex vivo*. The disadvantage of this approach is that recipients of the T-cell-depleted bone marrow have delayed immune recovery and an increased incidence of viral infections. One such infection is Epstein–Barr virus lymphoproliferative disease (EBV-LPD), which is due to a proliferation of

TABLE 50.2
Clinical Gene Marking Studies on T Cells

Institution	Disease (Number of Patients)	Target Cell Type	Findings	Reference
National Cancer Institute	Melanoma (5)	TILs	Marked cells detected in blood and tumor sites for up to 2 months	[47]
Centre Leon Berard, Lyon, France	Melanoma or renal cell carcinoma (5)	TILs	Marked cells detected in blood for up to 260 days Marked cells detected in four of eight tumor deposits	[54]
University of California Los Angeles	Melanoma (6) or renal cell carcinoma (3)	Double marking study using TILs versus PBL	Marked cells from both components detectable in blood, tumor deposits, and normal peripheral tissues (muscle, fat, skin) for up to 99 days. No evidence for preferential trafficking of TILs to tumor deposits	[55]
St. Jude Children's Research Hospital	Prophylaxis or treatment of EBV-associated posttransplant lymphoproliferative disorder in T-cell depleted allogeneic BMT (39)	EBV-specific CTLs	Marked cells detected in unmanipulated PB for up to 18 weeks using semiquantitative PCR, and up to 6.7 years using real-time PCR. Remained detectable following <i>ex vivo</i> antigenic stimulation for up to 10 years Initial expansion <i>in vivo</i> and long term antigen responsiveness <i>in vivo</i> and <i>ex vivo</i> Accumulation of marked cells in tumor sites	[57,59,60]
Center for Cell and Gene Therapy, Houston	EBV-positive Hodgkin's Lymphoma (7)	EBV-specific CTLs	Marked cells detected in PB for 3–12 months Accumulation of marked cells in tumor sites	[61,65]
Fred Hutchinson Cancer Research Center	HIV-positive patients (9)	HIV gag-specific CD8 + CTL clones modified with HyTK (6 patients) or neo(3 patients)	T cell mediated eradication of cells modified with HyTK Neo-marked cells detected in blood for 3–4 weeks Accumulation of neo-marked cells adjacent to HIV-infected cells in lymph nodes	[56,62]

CTL, cytotoxic T lymphocytes; EBV, Epstein–Barr virus; HIV, human immunodeficiency virus; HyTK, hygromycin phosphotransferase and herpes simplex virus thymidine kinase; PCR, polymerase chain reaction.

EBV-infected B cells that are highly immunogenic and are not eliminated in the immunocompromised host. This complication occurs in 5%–30% of patients receiving T-depleted marrows from mismatch family or unrelated donors. Donor-derived EBV-specific T cells were generated by culturing donor T cells with donor-derived EBV-infected lymphoblastoid cell lines [57,59,60,64]. To determine whether these cells persisted and whether they caused adverse effects they were marked with the *neo* gene before administration. Twenty-six patients received *neo*-marked CTLs. Infusion of virus-specific CTLs produced a virus-specific immune response as documented by a fall in EBV DNA levels [57]. The gene-marking component of this study allowed the demonstration of the persistence of the *neo* gene (using sensitive real-time

quantitative PCR) in the PB in more than 75% of patients, for up to 6.7 years, with the median being 227 days [60]. Three patients who were treated for clinically evident EBV-LPD attained prolonged remission after CTL infusion and *in situ* hybridization as well as semiquantitative PCR showed that the gene marked CTL had selectively accumulated at disease sites [59].

50.6.3 GENE MARKING OF EBV-SPECIFIC CTLs FOR RELAPSED EBV-POSITIVE HODGKIN DISEASE

Marking of autologous EBV-specific polyclonal CTLs has also been used in a clinical study for patients with relapsed EBV genome positive Hodgkin disease [61]. Seven patients

with multiply relapsed Hodgkin disease have received gene-marked EBV-specific CTL in a phase I dose-escalation study. Gene-marked CTLs were found in PB up to 12 months following infusion. One patient had erosion of tumor through the L upper lobe bronchus and died 2 months after CTL infusion. In situ PCR revealed gene-marked CTLs within part of the mediastinal tumor but not at the site of L upper lobe bronchus erosion. In another patient, EBV-specific CTLs were localized to a malignant pleural effusion 3 weeks after CTL infusion as assayed by gene marking. The conclusions from this study were that marked CTLs expanded *in vivo* and were found to persist for up to 12 months as tracked by RT-PCR analysis [65].

50.6.4 GENE MARKING OF T CELLS IN HIV THERAPY

To study the survival of normal T cells in patients with HIV, PBLs from unaffected syngeneic twins were transduced with a *neo* vector and transferred to their HIV-infected sibling [63]. Marked CD4⁺ T cells persisted in the circulation for 4–18 weeks after transfer in all patients and at 6 months, marked cells were found in lymphoid tissues [63]. In subsequent studies, autologous HIV gag-specific CD8⁺ CTL clones genetically marked with the LN retrovirus were infused [62]. The infused CTLs were seen to accumulate adjacent to HIV-infected lymph nodes and transiently reduced the levels of circulating productively infected CD4⁺ T cells. This decline was transient, likely due to a lack of CD4⁺ help. However the study did provide some rationale for pursuing this approach in conjunction with strategies to circumvent the requirement for CD4 cells.

50.7 GENE MARKING OF MESENCHYMAL CELLS

Over the last few years, there has been increasing interest in the use of mesenchymal cells to treat patients with genetic disorders affecting mesenchymal tissues, including bone, cartilage, and muscle. To evaluate this therapeutic option, Horwitz et al. infused gene-marked, donor marrow-derived mesenchymal cells to treat six children who had undergone standard BMT for severe osteogenesis imperfecta [66]. The marking component of this study showed that the mesenchymal cells could engraft in bone, skin, and marrow stroma [66]. Of interest the marker gene could not be detected in one patient likely due to an immune response directed at the *neo* gene [66].

50.8 SAFETY CONCERNS

Safety is clearly an important consideration in gene marking studies. Since 1991, more than 170 patients have been treated with gene-marked HSCs or T cells, and none have had discernible deleterious effects. In particular, there has been no evidence of selective or autonomous expansion of marked cells on follow-up extending beyond 10 years [20,59,67]. In contrast to this impeccable safety record, four children with

X-linked severe combined immunodeficiency (SCID-X1) treated with autologous CD34⁺ selected stem cells transduced with common γ -chain subsequently developed T cell lymphoproliferation as a result of insertional mutagenesis to the LMO2 proto-oncogene [68]. The superior safety profile of marking studies can likely be explained by the genetic modification of a smaller number of cells, each with fewer integrants, and by the absence of a transgene with growth promoting activities. The target cell type is also likely to be important. To date, insertional mutagenesis has not been reported in T cell gene transfer. Nonetheless, the fact that a previously hypothetical risk of retroviral vectors had now become reality changed many people's perception of the safety of gene marking. Since gene marking had no direct therapeutic benefit to the patients receiving the modified cells, any risk of oncogenesis was now considered unacceptable; however, the probability of such an event is low. We have to accept that for the foreseeable future, gene therapy of all types will be held to a much higher level of accountability and safety than any other therapeutic modality. It is troubling to realize that few of our most successful treatment options for life threatening conditions—from organ transplantation to cancer chemotherapy—would have been adopted had they too been held to “gene therapy standards of safety.”

Paradoxically, it was further investigation into the retroviral associated leukemias in the affected patients that reanimated the field. These studies focused on analyzing the sites of viral integration in the host genome, and greatly improved on the methodologies available for this purpose. Although their primary intent was to establish how the leukemias had originated, the availability of more robust techniques for integrant site analyses provided additional sophistication to marking studies and greatly increased the information they could provide.

50.9 INTEGRANT ANALYSES

50.9.1 INTEGRATION SITE ANALYSIS TO ANALYZE CLONAL FATE

Measures of the presence and overall level of marker gene positivity in a cell population are highly informative, but determining the sites in the genome at which the provirus integrates provides a further level of sophistication to the analyses. Every retroviral integration event results in a host integrant junction that is unique to the transduced cell and its progeny. Integration sites as clonality markers enable one to not only enumerate clones but also to track the fate of individual clones *in vivo* over time. It is therefore possible to find out, for example, the minimum number of transduced cells that have contributed to hematopoietic reconstitution [69] or tumor relapse [16], the kinetics of individual clonal contribution [69], whether clonal dominance evolves *in vivo* [70,71], and even the true pluripotency of transduced cells [71,72].

The earliest available techniques for integration analysis were insensitive and had poor resolution. Amplification of the host integrant junction where the sequence at one end is

unknown requires an adaptation of PCR amplification techniques. An early example of clonal analysis in humans was the study of gene marked neuroblastoma relapse using inverted PCR [7]. In this example, the host integrant junction was amplified by PCR prior to Southern blotting. PCR amplification was made possible by inverting the sequence [73]. In each of two neuroblastoma samples studied, two integration sites were detected. Assuming that approximately 1% of reinfused tumor cells were gene marked [32], and that there was one integrant per transduced cell, it could be estimated that a minimum of 200 tumor cells had contributed to relapse [16].

Techniques for host integrant junction analysis have become much more sensitive and are now capable of analyzing complex polyclonal populations. Broadly speaking, these techniques are based on ligation-mediated PCR (LM-PCR) in which a known sequence is ligated to the unknown flanking end to allow PCR amplification. Linear amplification-mediated PCR (LAM-PCR) has been most widely used [71,74–76]. This involves repeated cycles of linear PCR using a biotinylated primer, enrichment of resulting fragments on streptavidin magnetic beads followed by second strand synthesis with random hexamer priming. The resulting double-stranded DNA is digested and ligated to a complementary ligation cassette, thereby giving rise to DNA fragments with known sequences on both ends: The vector sequence in one and the ligation cassette sequence in the other. Nested exponential PCR is then performed and the resulting bands can be isolated and sequenced [71,75,76]. This method has a sensitivity of 1/100 to 1/1000 [76] and could detect more than 50 integration sites at a time [75].

LAM-PCR has provided important insight into the true pluripotency of gene-modified progenitor cells. In the SCID-X1 trial, clonality analysis has detected common integration sites shared by T cells, B cells, neutrophils, and monocytes, thereby demonstrating the transduction of pluripotent common progenitor cells [77]. Clonal analysis of patients from the adenosine deaminase (ADA)–SCID trial found that in one patient, the majority of T cells, as well as some myeloid cells, shared a common integration site. This clonal dominance remained stable without any evidence of progression to leukemia in over 8 years of observation [78]. LAM-PCR has also been used to characterize the kinetics of PB repopulation following autologous PBSC transplantation in adults with CML [74]. Depending on the level of gene-marking, between three and 59 different insertion sites could be identified in each patient *in vivo*, with different clones appearing at different time points [74].

50.9.2 MAPPING INTEGRATION SITES

With the completion of the human genome-sequencing project, the precise sites of retroviral integration can be readily mapped. This allows the identification of any integration “hotspots” and integration sites that have the potential for causing insertional mutagenesis [79]. In the CML study, a total of 69 unique sites were identified in three patients using LAM-PCR [74]. Fifty-one could be mapped using BLAST search tool, of which around 80% were found to be within or

near genes. Mapping of integration sites in T cell therapy has been largely been performed on patients who received HSV-TK-modified donor T cells [80,81]. In one study, 300 integration sites from the infusion product or patient PB T cells were detected, sequenced, and mapped [80]. Of these, 52% were within transcribed region of genes and 35% were within 30kb of genes. An analysis of 40 clones with integration within or near genes found that 20% of integration could affect expression of nearby genes. Reassuringly, there were no discernable functional differences between transduced and nontransduced T cells and no evidence of clonal selection at up to 9 years.

50.9.3 EACH PATIENT CAN BECOME HIS OR HER OWN CONTROL BY INCORPORATING MARKER SEQUENCES INTO THERAPEUTIC TRANSGENES

The added information obtained from integrant analyses was insufficient to overcome the concerns investigators had developed about pure marking studies. Fortunately, it quickly became apparent that it was possible to incorporate marker oligonucleotide sequences in therapeutic transgenes that could then be tracked *in vivo*. In this way, a single patient could receive two or more genetically distinguishable populations of cells all expressing the same therapeutic transgene. Hence, it would still be possible, in a single patient, to compare the consequences of expressing the transgenes in different or differently treated cell populations. As alluded to earlier, the enormous heterogeneity of human responses makes such internally controlled experiments extremely powerful even with only small numbers of patients. One example is the study of gene modified T cells for the treatment of cancer.

50.10 IMPROVING MARKER STUDIES

50.10.1 MARKER GENE

Most of the clinical studies reported to date have used *neo* as the reporter gene. This marker has the advantage that its safety has been widely studied in many different animal models and it can be detected both phenotypically and genotypically. In gene marking, the concern is that the activity of neomycin phosphotransferase (the product of the *neo* gene) is also likely to phosphorylate cellular proteins and may thereby modify the growth or differentiation of cells expressing the gene. *In vitro*, this effect has been observed in the HL60 cell line [82]. There is evidence that a similar phenomenon occurs *in vivo*. There is the almost uniform observation that the proportion of cells positive for the *neo* marker gene in circulation is 0.5–1 log below the number of cells that are positive as determined by *in vitro* colony assays in the presence of the neomycin analog G418 [15]. It may be that *neo* expression retards progenitor growth and differentiation *in vivo* thus rapidly diminishing the numbers of *neo* progeny detectable. It is also possible that the expression of the transgene (i.e., *neo*) by the transduced cell results in an immune response that eliminates the transduced population. For some gene products, such as

the hygromycin-thymidine kinase (Hy-TK) fusion protein, the potency of this immune response is such that the response is a rapid elimination of large numbers of transduced cells in less than 48 h [56]. It is as yet unclear if so potent an immune response regularly occurs after *neo* transduction, since neo-positive cells can be detected for up to 9 years after infusion and neo-marked T cells can be readily expanded *in vivo* by appropriate antigenic stimulation [59,60]. If the discrepancy between levels of marking in CFU and mature cells is a consequence of the immunogenicity of the marker signal, then the interpretation of certain marker studies may be rendered more difficult.

Because of the limitations of the *neo* gene as a marker, several alternatives have been proposed. Amongst the most widely used in studies are green fluorescent protein (GFP) and cell surface markers such as the truncated (low-affinity) receptor for nerve growth factor (dLNGFR) [83–85]. Unfortunately, many of these have the same limitations as *neo* and there is concern that some of these proteins (e.g., GFP) may prove to be significantly immunogenic *in vivo* [86]. Moreover, aberrant expression of cell-surface molecules may lead to unwanted cell trafficking or harmful intercellular contacts, even if the cell-surface molecule has been modified to preclude intracellular signaling. One such concern is highlighted in a murine model using the same truncated nerve growth factor receptor (dLNGFR) marker gene that had been used in clinical studies [85]. This gene was introduced by a replication-incompetent murine retroviral vector into bone marrow cells, which were then transplanted into irradiated mice. Marrow was then harvested after 28 weeks, pooled, and transplanted into secondary irradiated mice. These recipients subsequently developed hematopoietic disorders, carrying the same leukemic clone with a single vector copy integrated into the transcription factor gene *Evi1* [87], and it was suggested that the capacity of dLNGFR to produce aberrant signal transduction contributed to the oncogenic events.

Because of the above concerns that marker gene may be immunogenic, may affect cell growth and may contribute to oncogenicity, the most ideal marker may in fact be a nonexpressed sequence [66].

50.10.2 USE OF ALTERNATIVE VECTORS

For gene marking studies, in which stable transduction is required and in which all daughter cells should contain equal amounts of the marker gene, integrating vectors are required. To date, this has meant using Moloney murine leukemia virus (MoMuLV) [21,26,88]. The main limitation of the Moloney-based vectors is that they can only effectively transduce actively dividing cells, a major limitation when human HSCs are the targets because too few of these cells are in cycle at any one time.

Because of these limitations, human and feline lentiviral vectors have attracted increasing attention as gene delivery systems [89,90]. Lentiviral vectors have been reported to

readily transduce hemopoietic progenitor cells [91]. Because they form a more stable preintegration complex than MoMuLV, they are also able to infect quiescent subsets of primitive hemopoietic stem cells, such as the CD34⁺ CD38⁻ or the CD38⁻ lin negative population, where they persist and integrate once these cells enter cycle [92]. HIV can also efficiently infect terminally differentiated cells such as neurons [93] and in both types of cell, high levels of gene expression have been reported.

50.11 FUTURE DEVELOPMENTS

Noninvasive tracking of gene-marked cells using imaging techniques is being actively developed. Until recently, imaging has been limited to bioluminescence technology suitable only for small animals. However, human imaging is now possible through the use of radionuclide imaging (positron emission tomography [PET] or single photon emission tomography [SPECT]) or magnetic resonance imaging (MRI) [94]. Several approaches have been taken but in general, they involve the selective accumulation of labeled-substance by gene-modified cells. One example is the phosphorylation of uracil or guanosine derivatives (¹²⁴I- or ¹³¹I-FIAU or [17] F-FHBG, respectively) by HSV-TK, thereby preventing their efflux from cells. Another is the active transport of iodide by human sodium iodide symporter (hNIS). In addition to cell tracking, both systems have potential for therapeutic application: HSV-TK transduced cells can be eliminated by ganciclovir and radioactive iodide can be used to ablate hNIS-expressing cells. At present, human imaging is restricted to gene-marked tumor cells [94,95]. However, FIAU imaging of EBV-specific T cells has been shown to be feasible in mouse models [96] and will likely translate into human application.

Increasing interest in cell therapies using stem cells derived from, or targeted to, nonhematopoietic tissues, will doubtless widen the range of cells to which the above marker techniques can be applied. The use of hematopoietic or cardiac stem cells to treat heart failure, for example [97,98], is one important area in which cell tracking and fate determination would greatly simplify assessment of the contribution of the infused stem cell product to the cardiac tissues, and would allow comparison of multiple strategies in a single patient. The use of mesenchymal cells to treat tissue injury or prevent GVHD is another example in which the approach would help resolve many of the current controversies [99,100].

50.12 CONCLUSION

Gene marking is a useful scientific tool in the study of HSC transplantation and adoptive cellular therapy. It has also guided us as to appropriate techniques for *ex vivo* manipulation to augment gene transfer. The large number of patients and the long follow-up available for many of them form a useful source of reference for therapeutic gene transfer.

The full potential of gene marking studies is yet to be realized. While it is hoped that this valuable approach will not be curtailed by inappropriately perceived risks, it seems likely that the future of gene marking lies in incorporating multiple distinguishable marker sequences within transgenes that offer some therapeutic potential, thereby evolving from purely marking studies to a combination of marker/therapy.

51.1 OVERSIGHT OF GENE THERAPY IN THE UNITED STATES

51.1.1 FDA REGULATORY AUTHORITY

For over the past 100 years, the American public has been concerned about the purity and quality of their food and medicines going as far back as 1848 when the state of California passed a pure food and drink law. By the end of the nineteenth century scientific discoveries were taking place that were being applied to the prevention and treatment of dangerous diseases. Live vaccines were being used for smallpox and rabies, killed-vaccines for cholera, typhoid and plague, and antitoxins for diphtheria and tetanus. During this time, laws regulating biologics were being enacted in Europe and Russia, whereas in the United States even though there was a concern regarding the safety of biologics there was an eagerness to use these products without the implementation of regulatory safeguards. In 1901, 13 children in St. Louis died of tetanus after

receiving diphtheria antitoxin from a horse. This tragedy led in 1902 to Congress making appropriations to establish food standards and in the same year, the Biologics Control Act was passed to license and regulate interstate sale of serum, vaccines, and other biologics used to prevent or treat disease in humans. The 1902 Act established federal inspection of licensed facilities, prohibition of false labeling, and the concept of a dating period during which a biological product would be medically used. In 1906, the Congress passed the Food and Drug Act and prohibited interstate commerce of misbranded and adulterated foods, drinks, and drugs. The basis of the 1906 law rested on the regulation of product labeling and not on premarket approval. In 1938, the Federal Food Drug and Cosmetic (FD&C) Act was enacted, making the 1906 Food and Drug Act obsolete. The FD&C Act extended controls to cosmetics and therapeutic devices and also required predistribution clearance of new drugs based on safety. In addition, this act authorized standards of identity and quality for foods and drugs as well as authorizing factory inspections.

In 1944, the Public Health Service Act (PHSA) was established and consolidated the major rule making authority for biological products under Sections 351 and 352. The PHSA requires that the product and the establishment where the product is manufactured meet standards to ensure continued safety, purity, and potency of the biologic.

Today the primary mission of the Food and Drug Administration (FDA) is to protect the public health by assuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation's food supply, cosmetics, and products that emit radiation. The FDA is also responsible for advancing the public health by helping speed innovations that make medicines and foods more effective, safer, and more affordable and helping the public get the accurate, science-based information they need to use medicines and foods to improve their health. This is accomplished by upholding established regulatory principles, such as quality control (QC), sound scientific rationale, and risk-benefit assessment. During the regulatory process, it is important that these principles be applied in a way that will encourage early product development while ensuring patient protection. This is particularly challenging for the field of gene therapy, where some of the risks are still unknown while potential benefits to patients may be great. To apply these principles, the Center for Biologics Evaluation and Research (CBER) takes a comprehensive approach to the regulation of biological products. This approach involves scientific review of submissions, a strong research program to support the regulatory process, surveillance, and policy development based on sound science to ensure that the manufacture of biological products and the conduct of clinical trials are performed in accordance with the regulations and statutes set forth to safeguard subjects enrolled in clinical trials.

CBER is one of six centers comprising the FDA and is responsible for the regulation of biological products. The authority to regulate biologics is promulgated by both the FD&C Act and the PHSA. These acts outline binding procedures for the agency and the sponsor. The FD&C Act provides the legal interpretation that a "biologic product" is also a "drug," and Section 351 of the PHSA makes provisions for the regulation of biological products through licensure of the product and the establishment in which the product is manufactured. Under the PHSA a biologic is defined as "a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, analogous product, or arsphenamine or derivative of arsphenamine (or any other trivalent organic arsenic compound), applicable to the prevention, treatment or cure of a disease or condition of human beings."

Regulations pertaining to conduct of clinical investigations using biological products are outlined in title 21 of the Code of Federal Regulations (CFR). Regulations are interpretations of the laws and are binding like laws. The regulations covered under 21 CFR 312 specify requirements necessary for submission of Investigational New Drug (IND) applications, while standards for licensure of a biologic product are described under 21 CFR 601 and 610. FDA's regulatory

authority in the somatic cell and gene therapy area was established in the Federal Register notice of October 14, 1993 entitled "Application of Current Statutory Authorities to Human Somatic Cell Therapy Products and Gene Therapy Products." This document establishes that somatic cell and gene therapy products are biological products and as such are subject to the licensing provisions of the PHSA.

Besides the statutes and regulations by which the FDA governs its day-to-day interactions with industry and academia, the agency also issues guidance documents, which are not binding but rather describe CBER's policy and regulatory approach to specific product areas. Examples of documents that present recommendations and give relevant guidance to somatic cell and gene therapy products are provided in Section 51.5.

51.1.2 STATUS OF GENE THERAPY IN THE UNITED STATES

As provided in "Guidance for Industry: Gene Therapy Clinical Trials—Observing Subjects for Delayed Adverse Events," a gene therapy product is defined as "all products that mediate their effects by transcription and/or translation of transferred genetic material and/or by integrating into the host genome and that are administered as nucleic acids, viruses, or genetically engineered microorganisms. The products may be used to modify cells *in vivo* or transferred to cells *ex vivo* prior to administration to the recipient." Examples, which fall under this definition, include peripheral blood stem cells modified with a viral vector, intramuscular injection of a plasmid DNA vector, and direct injection of a viral vector. Since submission of the first human gene therapy IND in 1989, 552 human gene therapy INDs have been submitted to CBER for review (through June 2007). The review of gene therapy INDs is coordinated through the Office of Cellular, Tissue, and Gene Therapies (OCTGT) within CBER.

Currently there are 314 active gene therapy INDs at CBER (Figure 51.1). While more than half of the INDs submitted in

FIGURE 51.1 Schematic of currently active INDs showing the types and number of vectors being used in U.S. gene therapy clinical trials.

the early 1990s involved *ex vivo* modification of cells using gene therapy vectors, since 1995 the number of INDs involving direct administration of gene therapy vectors has been increasing. Currently, almost 60% of all INDs use direct vector administration. Overall, almost 95% of INDs submitted have involved expression or replacement of a gene with therapeutic intent and comprise indications as broad as cancer, human immunodeficiency virus (HIV), cystic fibrosis, hemophilia, peripheral and arterial vascular disease, arthritis, Parkinson's disease as well as many rare diseases (i.e., x-linked SCID, Fanconi's anemia). In approximately 30% of the INDs, nonviral plasmid vectors were used for gene delivery. A variety of viral vector systems are currently used in clinical studies, such as retroviral, adenoviral, adeno-associated virus (AAV), vaccinia, and herpes viral vectors. As a general rule, most of these vector systems consist of replication defective virus containing a therapeutic transgene. Although not considered a gene therapy vector system in the strictest sense, the investigational use of oncolytic viruses for certain cancer indications has been increasing over the past few years. This class of viruses usually does not contain a therapeutic gene but rather is a replication competent virus (RCV), which functions by producing lysis of tumor cells when administered directly into the tumor. Although oncolytic viruses are not considered to be gene therapy vectors, their oversight and regulation follows a similar pathway as traditional gene therapy products. Bacterial vectors are also being studied as a vector system for gene delivery. Most of these bacterial vectors are attenuated to reduce virulence or are inactivated by heat or other means.

For the area of gene therapy, CBER's regulatory approach has included an element of public process. The goal of this public interaction has been to increase the community's understanding of the CBER review process and requirements, to allow deliberation of ethical and social issues that surround the area of gene therapy, to receive input into CBER gene therapy policy development, and to provide accurate information to the public about the progress of gene therapy clinical trials. CBER's approach has included convening its Cellular, Tissue and Gene Therapies, Advisory Committee (CTGTAC), formerly known as the Biologic Response Modifiers Advisory Committee (BRMAC) to discuss relevant issues regarding the safe use of gene therapy products and conduct of clinical trials. In addition, FDA routinely takes part in forums with industry, trade groups, academia, and the public in order to foster public understanding in the area of gene therapy, which is essential for continued progress of the field. CBER considers this interaction with the scientific community important when developing policy and guidances on gene therapy. Another large part of this process has been facilitated by the National Institutes of Health (NIH), Office of Biotechnology Activities (OBA), through quarterly meetings of the Recombinant DNA Advisory Committee (RAC).

51.1.3 OVERSIGHT OF FDA/RAC

Unlike other areas under clinical investigation which are regulated by the FDA, gene therapy clinical investigations are

subject to the oversight of two federal agencies within the Department of Health and Human Services, the FDA and the NIH, OBA. FDA and NIH have complimentary roles with respect to oversight of human gene therapy clinical trials. FDA's primary role is to ensure that manufacturers of gene therapy products produce quality products that have been demonstrated to be safe for administration into subjects. NIH's primary role is to evaluate the quality of the science involved in gene therapy research, fund scientists who perform gene therapy clinical studies, and review and evaluate the composition of Institutional Biosafety Committees (IBC). Oversight of human gene therapy clinical trials at the NIH involves a public process of review and discussion, conducted by the RAC that ensures public awareness of clinical trial registration and follow-up. The RAC meets quarterly for public discussion of proposals which are deemed novel. In contrast, FDA review of gene therapy INDs is confidential and conducted by agency reviewers on an ongoing basis.

Both the NIH and FDA deliberate preclinical and clinical issues; however, the RAC's responsibilities extend beyond safety and efficacy to the consideration of the ethical, legal, and social implications of such research. The FDA also provides careful and thorough review of product manufacturing related to product safety, purity, potency, and identity. Currently, information regarding human gene therapy clinical trials must be submitted to both the FDA and the NIH.

51.1.3.1 History of RAC

The RAC was established in 1975 as a result of public concern over the potential risks of the new field of recombinant DNA (rDNA) research. Scientists worldwide had voluntarily halted their research and met in Asilomar, California, to debate the future of the use of rDNA technology. The RAC evolved from these debates and met for the first time just after the Asilomar meeting. The RAC mission was to advise the NIH Director and to review in public each experiment involving recombinant DNA research. Subsequently NIH established the OBA to provide administrative support to the RAC. Over the first few meetings, the RAC set minimum standards for biological and physical containment of rDNA molecules. This was accomplished through public debate and with input from scientists and lay representatives, including ethicists and economists. In 1976, as a result of these discussions, the "NIH Guidelines for Research Involving Recombinant DNA Molecules" (NIH Guidelines) were published in the Federal Register. The NIH Guidelines provided for submission and review of rDNA experiments by the RAC and also provided for the element of public debate of rDNA research. The NIH Guidelines are not regulations, but establish their authority through the NIH funding process. Investigators receiving NIH funding for Research Involving Recombinant DNA Molecules, or who are affiliated with an institution that has NIH funding for recombinant DNA research, must comply with the NIH Guidelines. In addition, they ask for voluntary compliance by non-NIH funded investigators. This process

has provided a precedent for the public discussion and consideration of gene therapy clinical trials conducted today.

In 1982, in response to the report of the President's Commission, entitled, "Splicing Life: Social and Ethical Issues of Genetic Engineering with Human Beings," the Human Gene Therapy Subcommittee (HGTS) to the RAC was established to review the application of rDNA technology to human gene therapies. The first human gene therapy protocol was approved after public discussion by this committee and separately by the FDA in 1990. Over time, as the public concern over rDNA experiments subsided and the interest in gene therapy increased, the HGTS merged with the full RAC and the combined group discussed and approved each gene therapy protocol prior to its initiation. In 1994, an accelerated review process was adopted for certain categories of clinical trials that had been routinely reviewed by the RAC and determined not to represent significant risk to human health and the environment. Under this mechanism, such protocols were subject only to written review by several RAC members, and OBA approval, outside of the quarterly meetings.

The RAC is currently composed of 21 members from the disciplines of science, medicine, law, ethics, and members of patient and other lay communities. Members of the RAC meet quarterly for the public review and discussion of novel gene therapy protocols. However, they no longer approve or disapprove protocols. Currently, their function is purely to provide a platform for public discussion of novel issues involved in gene therapy clinical trials. In addition, the RAC sponsors the Gene Therapy Policy Conferences (GTPC),

which provides a mechanism for in-depth discussion of relevant gene therapy issues. For this forum, a panel of experts is convened with the goal of reaching consensus and developing guidance in a particular area. GTPC discussions have focused on topics such as genetic enhancement, inadvertent germline transmission, use of lentiviral vectors, prenatal gene therapy, and immunogenicity of AAV vectors. In 2002, OBA formed an RAC Informed Consent Working Group composed of members of the RAC, outside experts, and representatives of the FDA and the Office for Human Research Protections (OHRP) to assist the in the development of the "NIH Guidance on Informed Consent for Gene Transfer Research." This is a Web-based (<http://www4.od.nih.gov/oba/rac/ic/index.html>) guidance document that is intended to serve as a resource and learning tool for individuals involved in gene transfer studies and others with an interest in this field.

51.1.3.2 Dual Submissions

As illustrated in Figure 51.2, there is a parallel path of submissions required prior to initiation of a gene therapy clinical trial. Sponsors of a gene therapy clinical trial must submit an IND application to CBER, FDA for review under a 30-day review cycle and may not proceed until the IND is found to be acceptable. In addition, the FDA requires that a sponsor receives the approval of the Institutional Review Boards (IRBs) and IBCs affiliated with the institutions at which the trial will be conducted. Concurrently or prior to submission of an IND to the FDA, investigators conducting the clinical

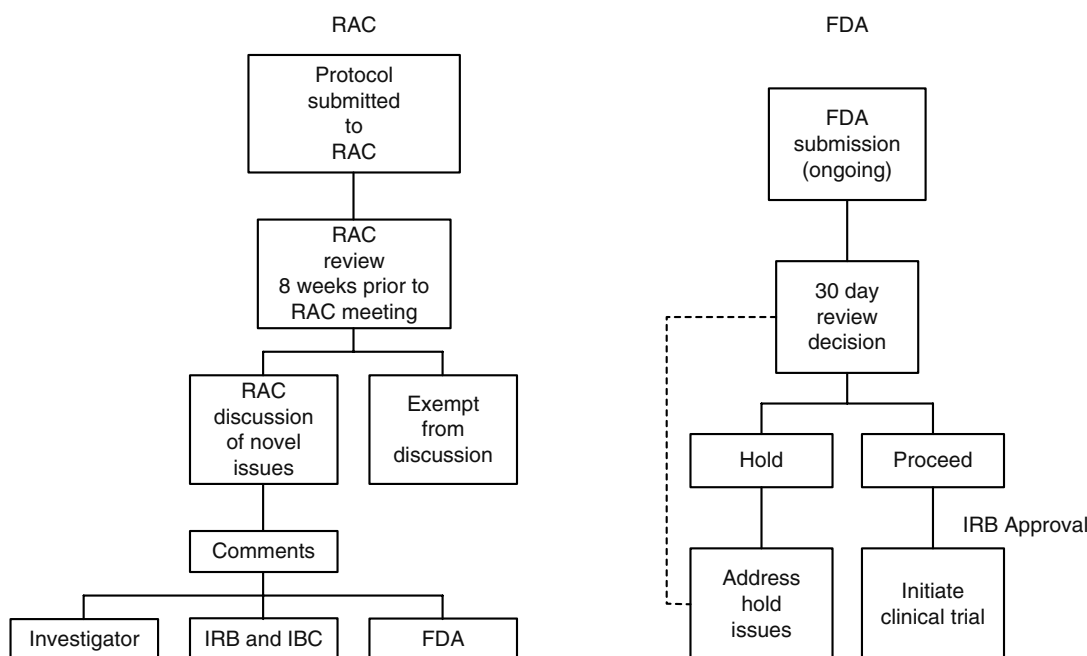

FIGURE 51.2 Overview of parallel processes for submission of documentation related to initiation of human gene therapy clinical trials to the RAC and the FDA.

trial should also submit their protocol and information specified in Appendix M of the NIH Guidelines to NIH, OBA for review by the RAC. Appendix M is a section included in the NIH Guideline that describes points to consider in the design and submission of human gene therapy trials, including the standards and procedures to which investigators need to adhere. Based on the changes made in May 2002 to the NIH Guidelines for Research Involving Recombinant DNA Molecules, all investigators/sponsors who receive or who are sponsored by an entity that receives NIH support for recombinant DNA research must submit their clinical protocol to the RAC for review. Failure to follow the NIH Guidelines can result in withdrawal of NIH funding to the investigator and any supporting institutions. Although an investigator may submit the protocol to the FDA and IRB prior to submittal to the RAC, review by the RAC is required before final IBC approval, so the committee can be informed of the RAC recommendations before making its final determination. The OBA submission must be received no less than 8 weeks prior to the next scheduled RAC meeting. RAC members will review the submitted Appendix M and will notify the sponsor within 15 days of receiving the submission the outcome of the initial review and whether the protocol has been selected for public RAC review. A gene therapy clinical trial will be judged as exempt from, or in need of, full RAC/public discussion based on the following factors: Novelty of the vector or gene delivery system, special disease concerns, unique applications of the gene therapy research, or important social or ethical issues raised by the proposed research. Recommendations and comments resulting from discussion at the RAC meetings are forwarded to the investigator, the IRB, IBC, and the FDA.

Due to timing and regulatory requirements, there are situations where the FDA decision to allow a clinical trial to proceed must be made before public discussion can occur. In this situation, the investigator/sponsor is reminded by the FDA of the need to comply with NIH guidelines regarding DNA recombinant research and that enrollment of subjects into the clinical trial may not begin until review and, if selected, public discussion of the protocol by the RAC has taken place. In order to avoid this potential conflict, sponsors are encouraged to submit to NIH and if selected go through public discussion prior to submitting their IND to FDA. In general, public discussion of gene therapy clinical trials has been highly beneficial since it allows for consideration of societal and ethical issues surrounding the field of gene therapy and ensures the continued public acceptance and progression of the field.

51.2 IND PROCESS

As mandated under Section 505 of the FD&C Act and Section 351 of the PHSA, it is illegal to sell or distribute into interstate commerce any biologic unless it is licensed or under an IND Exemption (21 CFR 312.2). Submission of an IND to provide for this exemption allows clinical investigation of the product to proceed in order to determine safety, dosage, and effectiveness. This investigational process is usually divided into three phases, with each phase providing the next step in support of product licensure.

51.2.1 DEFINITION OF IND PHASES

As illustrated in Figure 51.3, product development begins with the pre-IND stage and progresses through the investigational or IND stage (phases I–III) where data are obtained to support product licensure. This is followed by the postlicensing stage (phase IV), during which postmarketing studies are often performed. An IND may be submitted for one or more phases of an investigation, although in general the phases of a clinical study are conducted sequentially. The FDA's primary objective when reviewing all phases of an IND is to assure the safety and rights of the patient, and later in phases II and III, to help assure that the validity and quality of the scientific data used to evaluate the product are adequate to assess product safety and efficacy.

A phase I trial includes the initial introduction of an IND into humans. The primary focus of a phase I study is to monitor product safety in a specific patient population although it should be noted that assessment of product safety remains a primary issue throughout product development. Phase I studies should be designed to determine the metabolic and pharmacologic actions of the drug in humans, the side effects associated with increasing doses and, if possible, to gain early evidence of product effectiveness. During the phase I study, the investigator should focus on obtaining sufficient information about the drug's pharmacokinetics and pharmacological effects that would permit for the design of well-controlled, scientifically valid, phase II studies. In a phase I study, the product may also be assessed for structure–activity relationships as well as the mechanism of action in humans. The total number of subjects included in a phase I gene therapy study varies but is typically between 10 and 40.

Phase II of an IND should include controlled clinical studies conducted to evaluate the effectiveness of the product for a particular indication in patients with the disease or condition under study. These studies should be designed to determine

FIGURE 51.3 Phases of product development and approval.

common short-term side effects and risks associated with the biologic product. Phase II studies are typically well-controlled, closely monitored, and conducted in a relatively small number of patients, usually involving no more than several hundred patients.

Phase III studies are expanded controlled and uncontrolled trials that are performed after preliminary data for the effectiveness of the product have been obtained. These studies are intended to gather the additional information about product effectiveness and safety that is needed to evaluate the overall benefit–risk relationship of the product and to provide an adequate basis for physician labeling. Phase III studies usually include from several hundred to several thousand patients depending on the clinical indication and patient population.

Clinical evaluation of a biological product rarely ends with issuance of a biologics license. Phase IV or the postmarketing stage refers to the ongoing period of development after the product is licensed. Examples of postmarketing studies include clinical studies to extend claims or usage for the addition of a new patient population or indication, studies to demonstrate product comparability after manufacturing changes, and studies to validate surrogate clinical endpoints that are required in cases of expedited review and accelerated approval.

51.2.2 PRE-IND PHASE

An IND application and the application process itself can be a challenge for novice sponsors. Therefore, before IND submission, CBER encourages an early interaction, in the form of a pre-IND meeting, to discuss preclinical animal testing, product development, and clinical trial plans. While the central focus of the pre-IND meeting is to define what is needed to support the IND submission, another important goal is to create a dialogue between CBER and the sponsor/investigator, which can be maintained throughout the process of product development. The pre-IND meeting is arranged at the request of the sponsor; however, before CBER can grant a pre-IND meeting, the sponsor will need to prepare a meeting package, which needs to be submitted at least 30 days prior to the meeting. Although the investigational plan does not have to be in its final form, the sponsor should be prepared to briefly describe all aspects of the proposed clinical study in the meeting package. This should encompass a description of the biological product, product manufacturing, and testing schemes, established preclinical data, preclinical studies performed and any plans for additional preclinical studies, the proposed clinical protocol and the general proof-of-concept behind the proposal. Most importantly, the pre-IND meeting should be used as a mechanism for focusing on unresolved issues relating to preclinical studies, clinical studies or product development. It is recommended that questions and objectives be submitted with the pre-IND package addressing any concerns or potential problems with the investigational plan that would require guidance or discussion with the agency before submission of the IND. Past experience has proven that early

identification and resolution of these issues will ultimately enhance and accelerate the product development process.

51.2.3 IND PHASE

Before submitting an IND, the sponsor must have generated enough preclinical data to ensure the safety of the proposed clinical trial. Preclinical data can be generated using either *in vivo* animal studies or *in vitro* studies, or both, to assess the product's activity, efficacy, pharmacology, pharmacokinetics, and toxicity. The preclinical data should be adequate to support the proposed clinical trial with recommendation of initial safe dose and dose escalation scheme in humans. The schedule or duration of treatment and route of administration should mimic those planned for the clinical trial. There should be sufficient safety data available to determine endpoints for monitoring in the clinic.

The general requirements for safety evaluation for gene therapy products are similar to other biologics such as the pharmacologic profiles; “proof-of-concept” studies; dose–response relationship, and toxicology profile. In addition, issues specific for gene therapy that can be addressed with preclinical studies include biodistribution or trafficking of vectors, level and persistence of gene expression, and germline alteration. From the Chemistry, Manufacturing, and Controls (CMC) point of view, the sponsor should also have a well-developed and controlled product manufacturing scheme and have collected data regarding product characterization and consistency to support the manufacturing process. This data should also be used to support proposed specifications for product QC and release.

Once these issues have been addressed, the next step is the preparation of the IND submission. For assistance in preparation of an adequate and complete IND, the sponsor should contact the Office of Communication, Training and Manufacturers Assistance (OCTMA) to request an IND submission package. The package contains forms to be submitted, copies of the IND regulations, informed consent, and IRB regulations, information pertaining to good laboratory practices/good manufacturing practices (GLP/GMP), and the essentials required for conducting adequate and well-controlled clinical trials. An IND submission package can also be obtained at the FDA Web site: www.fda.gov/cber/ind/ind.htm

51.2.3.1 IND Submission

The content and format of an IND submission is specified in 21 CFR under part 312.23. This part lists, in order, the items that a sponsor (person who takes responsibility for, and conducts a clinical investigation) should submit in the IND (Figure 51.4). The IND should be submitted to CBER in triplicate and upon receipt the sponsor of the IND will be issued an acknowledgement letter containing the date of receipt, the assigned IND number and a reminder of their responsibility for submission to NIH, OBA according to Appendix M of the NIH Guidelines. The IND receipt date begins the official

Cover sheet—Form FDA 1572
Table of contents
Introductory statement and general investigational plan
Investigator's brochure
Required if product is supplied to clinical investigators other than sponsor
Chemistry, manufacture, and control information
Description of composition, manufacture, and purification of the investigational drug
Substance and drug product
Description of placebo
Labeling
Environmental analysis requirements
Pharmacology and toxicology information
IRB Approved consent form
Previous human experience with the investigational drug
Additional information

FIGURE 51.4 Content and format of the IND submission as specified in 21CFR 312.23.

review clock and the IND review will take place over the next 30 calendar days. INDs automatically become effective 30 days after receipt unless FDA notifies the sponsor that the IND is subject to clinical hold.

In CBER, where human gene therapy INDs are reviewed, the IND review team is composed of a product reviewer, a pharmacology/toxicology reviewer, a clinical reviewer, and a regulatory project manager who handles administrative aspects of the IND review. The product reviewer is responsible for coordinating the review team and ensuring consistency within a product area. Consult reviewers are used on an ad hoc basis, depending on the product and its application, and could come from other offices in CBER or other centers within the agency, depending on the required expertise.

At any point in the review process, a reviewer may call the sponsor to request additional information or to discuss deficiencies in the IND. After each reviewer has completed their review, the team meets to discuss the file and make a final decision on the status of the application and whether the clinical trial may proceed or will be placed on clinical hold. The IND may also be discussed at office level meetings for further input. The review decision is communicated to the sponsor by phone within the 30-day period. The reviewing office also issues a letter giving the details of hold issues (if any), review comments or requests for further information. If the file is placed on clinical hold the letter is issued 30 days from the decision date.

The criteria for placing INDs on clinical hold are addressed in 21 CFR 312. Phase I INDs may be placed on clinical hold, as covered under 21 CFR 312.42(b), if: human subjects are exposed to unreasonable and significant risk of

illness or injury; the IND does not contain sufficient information to allow adequate assessment of the risk; the information in the investigator's brochure is misleading, erroneous, or materially incomplete; or the clinical investigators are not qualified to conduct the study. In addition, for investigational studies of drugs intended to treat a life-threatening disease or condition that affects both men and women, phase I INDs may be placed on clinical hold if men or women of reproductive potential are excluded from the clinical trial because of reproductive risk, or the potential of reproductive risk, due to the reproductive or developmental toxicity associated with the drug. Phase II and phase III INDs may be put on clinical hold if any of the conditions cited above apply or if the protocol design is deficient to meet the objectives of the proposal.

In order to proceed with the clinical study the sponsor must correct the deficiencies identified during the review and submit the additional information or data in an amendment to the IND. Once the amendment containing the complete response to clinical hold has been submitted and reviewed (within 30 days of receipt date) by the FDA, the sponsor will be notified as to whether the hold issues have been adequately addressed and if the clinical trial may proceed. The review decision is communicated to the sponsor by phone within the 30-day period and a letter is issued.

51.2.3.1.1 Annual Reports

An annual report describing the progress of the investigation should be submitted to the IND within 60 days of the anniversary date that the IND went into effect. 21 CFR part 312.33 should be consulted for specific details, but in general the annual report should provide information on the status of each

study in progress or completed during the previous year. To this effect the annual report should include an update on the following: the title of studies, the number of subjects enrolled and their status, serious adverse experiences observed, summary of available study results if the study is completed, information relevant to understanding of the drug's action, results of additional preclinical studies performed during the year, manufacturing changes, and an investigational plan for the coming year. The annual report should also provide results of product characterization and lot release testing for all lots of product produced during the year under report. For human gene therapy trials, reports should be submitted annually that include additional information relevant to gene therapy vectors such as assessment of evidence of gene expression, biological activity, immune response, evidence of gonadal distribution, results from long-term patient follow-up, and status of requests for autopsy. The update on information requested in the March 6, 2000 gene therapy letter (posted on the CBER Web site: www.fda.gov/cber/ind/ind.htm) may be provided in the annual report or be provided in a separate amendment.

51.2.3.2 Master File Submission

Another mechanism available for submission of information to the FDA is the Master File (MF). The procedures for submitting an MF are outlined in part 314.420 of 21 CFR. In contrast to the IND, which contains manufacturing, preclinical, and clinical information, the MF could contain product manufacturing or facilities information only. Submission of an MF allows the MF holder to incorporate the information by reference when the MF holder submits an IND. The MF holder may also authorize other sponsors to rely on the information to support an IND submission without disclosing the information to the IND sponsors. There are four types of MF submissions, of which Type II is the one most commonly used for biological product development. Information submitted in a Type II MF can include: information on drug substance or drug product specifically regarding product manufacturing and purification schemes, standard operating procedures (SOPs), lot release protocols, test methods and release acceptance criteria, descriptions of tissue culture media components, and other proprietary information needed to support an IND application. A Type V MF, the second most commonly used, can include detailed information about facilities, processes, or articles used in the manufacturing, processing, packaging, and storing of gene therapy products. The IND sponsor should obtain a letter from the MF holder granting written permission for a cross-reference, and a copy of the cross-reference letter should be submitted to the IND and should identify by name, reference number, volume, and page number the exact information that each IND sponsor is authorized to incorporate. A copy of this cross reference letter should also be submitted to the MF. For example, in the case where retroviral vector supernatant is provided to an IND holder by a manufacturer and the method of manufacture is proprietary, the manufacturer

could submit an MF documenting retroviral vector production and testing in support of the IND for review by CBER staff. As product lots are produced, lot release data should be submitted to the product MF as well as to the cross referenced IND for CBER review.

MFs are neither approved nor disapproved and are often reviewed only in the context of an IND application. CBER will comment on the contents of the MF and ask for clarifying information in order to more adequately review an IND, which cross-references the MF. Importantly, the MF has to contain complete information to support the decision to allow the associated IND to proceed. If there are safety concerns raised because of insufficient information provided in the MF, which is cross-referenced by an IND, then the IND may be put on clinical hold until all identified concerns are addressed by the MF sponsor.

51.3 REVIEW CONSIDERATIONS: EARLY PHASES

51.3.1 PHASED-IN APPROACH

Product characterization and QC of gene therapy products include issue and concerns common to most biological products, such as demonstration of safety, development of methods for assessment of potency, determination of identity and purity, as well as product stability. In addition, development of specifications for each of these parameters is an important part of product development and characterization. Specifications are the quality standards (i.e., tests, analytical procedures, and acceptance criteria) that confirm the quality of products and other materials used in the production of a product. Acceptance criteria are the numerical limits, ranges, or other criteria for the tests described. FDA believes that certain release specifications, such as those related to product safety, should be in place prior to initiating phase I clinical studies. As product development proceeds, additional specifications for product quality and manufacturing consistency should be developed and implemented. FDA recommends that proposed analytical procedures and release acceptance criteria for the final product be based on scientific data and manufacturing experience obtained during development of the product. During phase I, analytical procedures are usually based on the CFR methods or alternative methods, if appropriate. If an alternative to the CFR method is used, it is recommended that sponsors initiate validation of the alternative method by phase III. For phase I trials, release acceptance criteria are generally based on data obtained from lots used in preclinical studies. During phase II trials, these release acceptance criteria should be refined and tightened based on data generated during the phase I study.

Another aspect common among biologics is control and regulation of not only the product, but also each step of the manufacturing process. Adherence to this approach, which is encompassed under current good manufacturing practices (cGMPs) provides for quality and safety throughout the process and will lead to consistency of product lots.

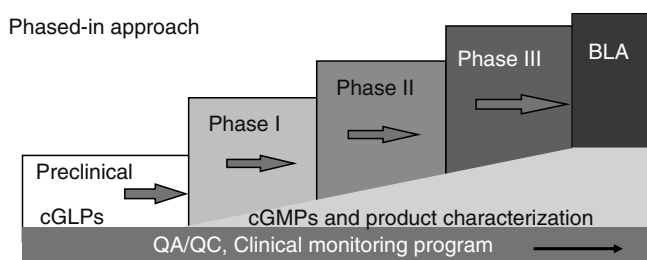

FIGURE 51.5 Phased-in approach.

In the area of gene therapy, a flexible approach to regulatory requirements has been attempted in order to find a balance between ensuring patient safety and fostering development of the field. In order to facilitate this process a phased-in approach to product characterization and compliance with cGMP has been adopted. This approach involves a progressive scale of requirements for product characterization and compliance with cGMPs, which increase as the study moves from phase I toward phase III (Figure 51.5). The first step in this approach, which occurs during phase I of the clinical trial but is required throughout all of product development, is the demonstration of product safety. As the clinical trial precedes so should the characterization of the product, such that by phase III, the product is fully characterized with regards to safety, purity, identity, and potency. In addition, by phase III, the product should be produced under full compliance with cGMP regulations although complete validation of all methods and processes are not required until licensure. Requirements for licensure of a biological product, product standards, and cGMPs are specified in Parts 610, 210, and 211 of Section 21 of the CFR. The phased-in approach applies to each aspect of gene therapy product manufacture, including vector development, establishment and characterization of cell banks, product manufacture, and characterization, establishment of release acceptance criteria for the final product, and control of reagents and components used during manufacture (ancillary products). It is equally important that a QC program, which is separate from manufacturing, be in place at the earliest phase of product manufacture. The QC unit should be responsible for ensuring the quality of the product and for product release for clinical use. The role of the QC unit is described in Part 211 of Section 21 of the CFR. Control of each of these aspects is important to assure product consistency and safety and is the focus of the CMC review.

51.3.2 CMC REVIEW

Each step of product development, characterization, manufacture, and control should be described in the IND under the Chemistry Manufacturing and Controls section. Sufficient information is required in this section to assure the proper identification, quality, and safety of the investigational drug. For phase I trials, data must be submitted to establish product safety. In addition, information regarding product characterization should include a description of the product's physical,

chemical, or biological characteristics, the method of manufacture, analytical methods used during manufacture and testing, and initial product specifications. The emphasis of the review of an IND submission is on data; therefore, in all cases data, as opposed to conceptual information, should be provided in support of the IND. Valid scientific principles should be applied throughout product development with regard to product safety, characterization, and QC of the manufacturing process. To ensure product quality, there should also be proper testing in place for all the components and materials used during product manufacture. During the review process, a case-by-case approach is applied in order to ensure that requirements and recommendations are satisfied in a manner appropriate to a particular product and manufacturing method. An example of some of the information that is considered during the review includes production and purification of the gene therapy vector, preparation of *ex vivo* gene-modified cells, and final formulation of the product. This information will allow the FDA reviewer to assess the identity, quality, purity, and potency of the product.

An early step in the development of a gene therapy product is construction of the initial gene therapy vector. The information supplied to the IND regarding the vector construct should include a description of the history and detailed derivation of the gene therapy vector, a description of vector components and their sources, including vector constructs used during generation of the final vector and a vector diagram. The vector diagram should include relevant restriction sites, gene insert, and regulatory elements, such as a promoter, enhancer, and polyadenylation signal. Currently the FDA requires that all gene therapy vectors less than 40 kb be fully sequenced prior to initiation of a phase I clinical trial. A fully annotated DNA sequence and sequence analysis report should be submitted, identifying all open reading frames (expected and unexpected) and genes encoded in the vector. The report should provide an evaluation of the significance of all discrepancies between the expected sequence found in a relevant current database and the investigational vector, and evaluation and significance of any unexpected sequence elements, including open reading frames. For vectors over 40 kb, any testing performed by restriction endonuclease analysis and sequence analysis of the gene insert, flanking regions (at least 500 base pairs either side) and any regions of the vector, which have been modified, should be submitted.

The next component important for the manufacture of a gene therapy product is a cell or cell bank system. Cells can be a component used during production of the vector product or *ex vivo* genetically modified and administered as final product. These cells can be either autologous or allogeneic. Information that should be submitted in the CMC section regarding the cells includes the cell source, collection method, whether a mobilization protocol is used, and donor screening and testing (if applicable). Requirements for screening and testing donors of human cells and tissues are described in 21 CFR Part 1271. If autologous cells are used, then it should be determined whether the donor tests positive for specific pathogens such as HIV or cytomegalovirus (CMV). It is

important that any culture methods used to propagate the cells do not cause an increase in the level of pathogen. If allogeneic cells are used these cells should be screened and tested for adventitious agents such as HIV-1, HIV-2, hepatitis B virus (HBV, surface and core antigen), hepatitis C (HCV), human T-lymphotropic virus types 1 and 2 (HTLV-1, HTLV-2), CJD (screening only), and CMV. Further information concerning donor screening and testing can be found in "Guidance for Industry: Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/Ps) 2007."

If a cell bank system is utilized to assure consistency of production then the next step in product development is usually the establishment of a master cell bank (MCB). MCB characterization includes testing to establish the properties and stability of the cells and is performed on a single-time basis. For the IND submission, information on the history of the cell line, as well as culture and storage conditions of the MCB should be included. Testing should be performed to establish identity, which includes cellular phenotype and genotype, cellular isoenzyme expression, and stability. If the cell line has been engineered to express exogenous genes, then tests should be performed to establish the presence and stability of the transgene. Safety testing should be performed to demonstrate the MCB is sterile and free of mycoplasma, endotoxin, and adventitious agents (through *in vitro* and *in vivo* assays). Depending on the origin, MCBs should be tested for species-specific pathogens. For example, if the MCB is of human origin then testing for human pathogens such as CMV, HIV-1 and 2, HTLV-1 and 2, EBV, B19, AAV, HBV, and HCV should be performed. Analytical methods used for testing should be summarized and initial release acceptance criteria for qualification of the MCB established. The MCB is usually the first tier of a two-tier cell bank system; the second is the working cell bank (WCB), which is derived from one or more vials of the MCB. The amount of information needed for characterization of the WCB is generally less extensive and includes testing for sterility, mycoplasma, and adventitious agents by *in vitro* assay and identity. Additional information on cell banking procedures and cell bank characterization can be found in the "Points to Consider in the Characterization of Cell Lines to Produce Biologicals 1993."

Depending on the gene therapy vector, the next step in gene therapy product development may be the establishment of a master viral bank (MVB). MVBs are generated by infecting or transducing the specific vector into cells grown from one or more vials of banked cells. As with MCBs, a second-tier or MWVB can also be generated. Requirements for MCB/WCB testing and characterization would also apply to testing of the MVB/MWVB, with the addition of tests for the presence of RCV related to the vector.

All procedures used during production and purification of the gene therapy vector product should be included in the CMC section of the IND submission. Safety testing and characterization of gene therapy vectors should be performed on bulk production lots, before and after purification steps and final product after formulation and fill, as appropriate for the

particular assay. Safety testing should include tests for sterility, mycoplasma, endotoxin, and RCV, as well as tests for adventitious virus by *in vitro* assay. Testing for general safety is required for licensure of all gene therapy vector products unless the product is exempt under 21 CFR 610.11(g). Product identity for a gene therapy vector product may be established through the physical or chemical characteristics of the product using *in vitro*, *in vivo*, or when appropriate, molecular methods. If the final product is an *ex vivo* gene modified cell product, then the final cell product also needs to be tested for identity. Although it is recommended to initiate identity testing early in product development it is not absolutely required at phase I. Purity of a gene therapy vector is typically established through determination of levels of residual materials such as cellular DNA, RNA, and protein, and ancillary products. With regard to product potency, for early phase trials the level of gene expression is acceptable as a measure of potency. However, before initiation of a phase III clinical trial, a potency assay will need to be developed and in place that measures the relative biological activity of the product. As with testing of the MCB and MVB, analytical methods used should be summarized in the IND and initial release acceptance criteria for qualification of the gene therapy vector product established. This summary is often presented in the form of a Certificate of Analysis.

To date approximately 40% of gene therapy clinical trials have involved the genetic modification of autologous or allogeneic cells *ex vivo*. This has been accomplished using viral and nonviral vectors. Information regarding the process of *ex vivo* modification of cells should be documented in the IND submission as follows: a description of the source of cells, results of donor screening (if applicable), method of cell collection and processing, culture conditions, and the procedure for *ex vivo* modification of cells. Safety testing and characterization of the *ex vivo* gene modified cells should include assessment of sterility, mycoplasma, endotoxin, identity, potency, and freedom from RCV. Analysis of phenotypic markers as well as confirmation of the integrity of the genetic insert may be used to confirm cell identity. Care should also be taken to assure patient specificity for autologous products using proper labeling and tracking systems. Additional parameters to be assessed include transduction efficiency, longevity of gene expression, and cell viability. If the cells are irradiated or frozen and thawed prior to use, then the effect of these parameters on cell viability will need to be assessed. In addition, the vector used for *ex vivo* modification should be tested as described above before use in the *ex vivo* modification of the cell product. Analytical methods used should be summarized in the IND and initial release acceptance criteria for qualification of the *ex vivo* modified cells established.

For gene therapy vector products and *ex vivo* gene modified cell products, a stability program that assesses product safety, activity, and integrity should be established during early phases of investigation. The objectives of stability testing during early phases are to establish that the product is stable for the duration of the clinical trial and to collect information needed to develop a final formulation and

dating period. The submission to the IND should include a brief description of the proposed stability study, the test methods to be used to monitor stability, and preliminary data if available.

The phased-in approach provides flexibility to product manufacture, characterization and testing during early phases of product development. However, testing and assay qualification should be performed in early phases to support data collection, development of release acceptance criteria, and compliance with cGMP in preparation for phase III studies.

Early in product development there should be adequate controls in place for monitoring the manufacturing process. It is recommended that prior to the production of clinical product; there should be the establishment and implementation of written procedures that are well-defined. These should include the responsibilities and procedures applicable to the QC unit, such as responsibility for reagent quality, review, and approval of production procedures, testing procedures, and release acceptance criteria, and responsibility for releasing or rejecting clinical lots based on review of production records. There should be a summary of the QC plan in place to prevent, detect, and correct deficiencies that may compromise product integrity or function or that may lead to the possible transmission of adventitious agents.

51.3.3 REAGENTS AND MATERIALS

The manufacturing process for gene therapy products entails the use of reagents and source materials of different quality, variability, and risk for the introduction of adventitious agents. To ensure that patients receive a safe, consistent, and potent product, it is important to have a qualification program in place for reagents and source materials used in manufacturing. Reagents and materials are those components that are essential for cellular growth, differentiation, selection, purification, or other critical manufacturing steps, but that are not intended to be part of the final product. Examples include fetal bovine serum, trypsin, growth factors, cytokines, monoclonal antibodies, cell separation devices, medium and medium components. These reagents can affect the safety, potency, and purity of the final product, especially with regard to the introduction of adventitious agents.

Ideally, licensed or clinical grade reagents should be used for preparation of gene therapy products; however, these are often not readily available. Recommendations for the use of reagents that are not clinical grade during early phases of product development involve establishing a qualification program and release acceptance criteria for each reagent. The qualification program should include adequate characterization, including safety testing, functional analysis, and a demonstration of purity. The purity of a given reagent need not be 100%, but the purity profile between different lots of the reagent should remain consistent. The extent of reagent testing required will depend on the point at which the reagent is used in the manufacturing process and the biological system used for production of the reagent. For example, in the case of

a growth factor or cytokine, if a murine monoclonal antibody is used during production or purification then the reagent will have to be tested for adventitious agents and murine retrovirus. If there are known toxicities associated with the reagent, testing for residual levels of the reagent in the final product preparation should be performed. It should be noted that the use of reagents produced under full cGMP is recommended for phase III trials. If human albumin is used, there should be a procedure in place to ensure that no recalled lots were used during manufacture or preparation of the product. If using human AB serum, it is important to ensure serum is obtained from an approved blood bank and meets all blood donor criteria. For all other reagents that are human-derived information should be provided to ascertain whether it is a licensed product, clinical, or research grade, and provide a Certificate of Analysis or information regarding testing of the donor or reagent. If porcine products are used then a Certificate of Analysis or other documentation that the products are free of porcine parvovirus should be included in the IND. If a reagent is derived from bovine material, it should be sourced from countries free of BSE. The following information should be included in the IND submission: the identity of the bovine material, the source of the material, information on the location where the herd was born, raised, and slaughtered, and any other information relevant to the likelihood that the animal may have ingested animal feed prohibited under 21 CFR 589.2000. Bovine material may be introduced at different points in production of a reagent, and the information described above should be provided for all bovine materials used. For more information, see "Proposed Rule: Use of Materials Derived from Cattle in Medical Products Intended for Use in Humans and Drugs Intended for Use in Ruminants," Federal Register 72(8) 1581–1619, January 12, 2007. In addition, a Certificate of Analysis should be provided in the IND to document that bovine materials are free of bovine viruses listed in 9 CFR 113.53.

51.3.4 GENE THERAPY-SPECIFIC SAFETY ISSUES

As the development of gene therapy vectors for therapeutic gene delivery broadens and moves forward, the possibility of approved therapeutic products becomes more of a reality. However, the use of these therapeutic products in clinical trials and regulatory approval requires a good safety profile. The use of gene therapy vectors raises certain safety issues that are specific to each vector type. Concerns specific to the safe use of gene therapy vectors include the generation of RCV, vector-associated toxicity (as opposed to toxicity related to the specific transgene), viral shedding, and the risk of inadvertent modification of a recipient's germline. Because of their potential effect on the patient, the public health and future generations, these issues need to be addressed during development of a gene therapy product and should be documented in the IND. Since RCV can arise from recombination events during manufacture, tests designed to detect RCV should be performed at multiple stages of manufacture and for each final lot.

Testing for replication competent retrovirus (RCR) in the production of gammaretroviral and lentiviral vectors needs to be performed at multiple points in production including MVB, WVB, vector supernatants, end of production cells, and *ex vivo* modified cells. A permissive cell line such as *Mus dunni* should be used to test cells producing vector containing the amphotropic murine leukemia virus envelope. If an ecotropic packaging cell line is utilized, then an ecotropic gammaretroviral assay, for the detection of low-level viral contamination, will need to be performed.

Retroviral vector supernatant also must be tested by amplification on a permissive cell line such as *Mus dunni*, followed by detection in an appropriate indicator cell assay (PG-4 S + L-). Based on research reports, it has been demonstrated that detection of RCR/RCL in *ex vivo* modified cells requires cells to be cultured for at least 4 days posttransduction. Therefore, *ex vivo* gene modified cells that are cultured for 4 or more days would require RCR testing as a product release assay. If *ex vivo* gene modified cells are cultured for less than 4 days, then archiving of cells is recommended in place of active RCR testing. Further information regarding RCR testing is contained in the CBER guidance "Guidance for Industry: Supplemental Guidance on Testing for Replication Competent Retrovirus in Retroviral Vector Based Gene Therapy Products and During Follow-up of Patients in Clinical Trials Using Retroviral Vectors, 11/28/2006." In studies using adenoviral vectors, MVBs and WVBs, as well as the final vector product, must be tested for replication competent adenovirus (RCA). The FDA recommends that the level of RCA in the final product be less than 1 in 3×10^{10} viral particles. Adenoviral vectors pose a specific safety risk since toxicity has been observed when these vectors are administered at high doses. Research data suggest that a portion of the observed toxicity is due to the vector particle itself and is not related to the actual infection of the cells by the vector. As a result, CBER requires that adenoviral vector doses be based on the actual particle count as opposed to the infectious titer, which is commonly the unit for quantifying viruses. In addition, the agency asks that all sponsors of INDs using adenoviral vectors report the ratio of viral particle to infectious unit for each clinical lot of vector. The current recommended limit for this ratio is set at ≤ 30 .

After the death in 1999 of a subject enrolled in an adenoviral gene therapy clinical trial the NIH, OBA established the adenoviral Safety and Toxicity Working Group (AdSAT), whose mission was to conduct an in-depth review and evaluation of safety and toxicity data generated from adenovirus gene therapy clinical trials. One outcome of this working group was a recommendation that a qualitative and quantitative adenovirus standard be developed. In response to this recommendation, the FDA, Williamsburg BioProcessing Foundation, and members from industry and academia formed a working group to develop and characterize an adenoviral reference material (ARM). It is FDA's recommendation that the ARM be used by manufacturers of adenoviral vectors to standardize viral particle and titer measurements. In addition, use of the ARM will provide a means of analyzing

the safety and efficacy of adenoviral vectors produced by different manufactures and allow for comparison between different clinical trials.

Safety testing goes beyond testing of the product, and should include monitoring programs for all subjects administered gene therapy vectors. When replication-competent viral vectors are used in a clinical trial, it is important to demonstrate that there is no shedding of virus to health care professionals or family members. One way to ensure that replication-competent virus are not shed to third-party individuals is to monitor patients for viral shedding by analyzing samples such as urine or throat swabs. Monitoring should be continued until the presence of infectious virus is no longer detectable in patients' samples.

For *in vivo* administered gene therapy vectors, data must be submitted demonstrating the extent to which a vector is able to disseminate out of the injection site and distribute to the gonads. This data will provide the information required to assess the risk of inadvertent gene transfer to germ cells, which may result in genetic changes in subsequent progeny. In general, these data should be obtained during the course of product development and provided to the agency for review. However, in cases where a novel vector, route of administration, or vector delivery system is proposed, preclinical studies may be required before initiation of the phase I study. Biodistribution data may be obtained either from studies in animals, analysis of clinical samples or from a combination of preclinical and clinical sample analyses. Clinical data demonstrating vector biodistribution should be derived from peripheral blood cells and semen samples taken during the treatment and follow-up periods for the clinical trial and from gonadal tissues obtained when possible at autopsy from consenting patients. The agency should be updated of the status of these studies at least at the time of each annual report in order to guide further product development and track any potential adverse events. A statement explaining the risk for genetic alteration of sperm or eggs and possible outcome for a fetus and future child, which could occur as a result of study participation, should be included in the informed consent document. This statement should clearly explain the status of biodistribution studies to assess gonadal distribution for each particular clinical trial and the fact that the likelihood of an adverse outcome is currently unknown. In addition, the consent form should advise study participants to practice birth control for a suitable period of time.

A primary safety concern when using gammaretroviral or lentiviral vectors to transduce human hematopoietic stem cells/progenitor cells is the risk of oncogenesis. This risk can occur by: (1) unintended generation of replication competent retrovirus/lentivirus (RCR/RCL) leading to neoplasia due to RCR/RCL infection of the target or nontarget cells *in vivo* or (2) vector integration into chromosomal DNA leading to neoplasia due to insertional mutagenesis. These risks should be addressed in non-clinical and clinical studies. This theoretical risk has recently become an actual risk by the report of four children, enrolled in a French trial for treatment of X-SCID, who developed leukemia after administration of a gammaretroviral vector.

The FDA has developed a long-term follow-up program that will aid in the monitoring of all subjects receiving gene therapy products for unanticipated adverse events that manifest long after administration of the gene therapy product and after the observation period for acute toxicity has ended. FDA issued a guidance for industry “Gene Therapy Clinical Trials—Observing Participants for Delayed Adverse Events” 2007, which provides recommendations regarding the design of studies to include the collection of data on delayed adverse events in participants who have been exposed to investigational gene therapy products. The guidance provides recommendations on the following: (1) methods to assess the risk of gene therapy-related delayed adverse events following exposure to gene therapy products; (2) guidance for determining the likelihood that long-term follow-up observations on study participants will provide scientifically meaningful information; and (3) specific advice regarding the duration and design of long-term follow-up observations.

Factors likely to increase the risk of delayed adverse events following exposure to gene therapy products include persistence of the viral vector, integration of genetic material into the host genome, prolonged expression of the transgene, and altered expression of the host's genes. Persistence of the viral vector, sometimes associated with latency, could permit continued expression of the gene or delayed effects of the viral infection. Integration of genetic material from a viral vector into the host cell genomic DNA raises the risk of malignant transformation. Prolonged expression of the transgene may also be associated with long-term risks resulting from unregulated cell growth and malignant transformation, auto-immune-like reaction to self antigens, and unpredictable adverse events. Altered expression of the host genes could also result in unpredictable and undesirable biologic events. One way to determine persistence of a gene therapy vector is to conduct a biodistribution study in an appropriate animal model over multiple time points. FDA would consider vector persistence to be any vector that can be detected throughout all of the time points tested in the study without any downward trend over several of the measured time points.

51.4 REVIEW CONSIDERATIONS: LATER PHASES

The previous sections have given an overview of the review process, and CBER's expectations for product development as the clinical investigation proceeds through early phases. To better understand CBER's requirements for product licensure and establishment standards, a sponsor should be familiar with practices that are governed by law and specified in Parts 600, 601, 606, 610, 210, and 211 of Section 21 of the CFR. Part 600, 601, 606, and 610 provide information pertaining to product release requirements and general provisions for licensure and in some cases will provide information on specific assay methodology and Parts 210 and 211 explain the cGMPs.

Although the regulations by their nature prescribe requirements, there is a level of flexibility built into the regulations

that allow for modification of required test methods or manufacturing processes. The provision for test method modification is found under 21 CFR 610.9, entitled “Equivalent Methods and Processes.” This provision is especially useful for gene therapy products, where conditions of the manufacturing process and many times the product itself make it difficult to perform standard assays. To apply this provision, a sponsor should provide supporting evidence for why a specific method is not ideal for the gene therapy application and present data, with appropriate controls, to demonstrate that the modified method will provide assurances of the safety, purity, potency, and effectiveness of the product equal to or greater than the assurance provided by the method or process specified in the general standards or additional standards (21CFR 610.9). Data to support the modification can be accumulated during the early IND phases and then validated in support of its use as an established method prior to licensure.

For a product to meet the requirements for licensure it must be fully characterized prior to submission of the license application with regard to safety, purity, potency, and identity. Each of these aspects will be discussed in the context of requirements for initiation of a phase III trial and product licensure.

Demonstration of product safety requires the implementation of specific tests, which measure sterility, mycoplasma, endotoxin, and general safety of the product. Product safety also includes demonstration that the product is free from adventitious virus, which to support the phase III study and product licensure includes *in vitro* and *in vivo* adventitious virus testing of the MCB, MVB, and final product, and when appropriate testing for RCV. Testing for general safety is not as rigidly adhered to during phases I and II studies but by phase III, the required standards and methods specified in 21 CFR 610.11 should be in place. An exception from testing for general safety is made for cellular therapy products [21CFR 610.11(g)(1)] and a sponsor may request for exception from testing for general safety for certain types of gene therapy products, such as plasmid DNA products, adenovirus vector products or *ex vivo* genetically modified cells [21CFR 610.11(g)(2)] if the purity of these products can be demonstrated through extensive testing and characterization.

Tests for potency of a gene therapy product should consist of either *in vitro* or *in vivo* tests, or both, which have been specifically designed for each product [21 CFR 610.10]. Tests for potency should indicate the specific ability or capacity of the product to effect a given result. Acceptability of potency assays will be determined on a case-by-case basis. However, based on current regulatory statutes, they must meet certain criteria such as: indicate biological activity(s) specific to the product; results must be available for lot release; provide quantitative readout; meet predefined acceptance and/or rejection criteria; include appropriate reference material and/or controls; be validated for licensure; measure activity of all active components; and be stability indicating. A suitable potency assay should be one that is quantitative in nature and measures an appropriate biological activity. If development of a quantitative biological assay is not possible, then a quantitative

physical assay, which correlates with and is used in conjunction with a qualitative biological assay, can be used.

Product identity can be demonstrated through the use of an assay or assays that are specific for each product in a manner that will adequately identify it as the designated product and distinguish it from any other product being processed in the same facility. At phase I, a test for identity is not required but it should be in place by the start of phase II, so that data can be collected, specifications determined, and the assay validated by licensure.

Product purity is defined as freedom from extraneous material except that unavoidable in the manufacturing process. Testing for purity of a gene therapy product could involve assays for residual protein, DNA, RNA, solvents used during production and purification, or ancillary products used during manufacture such as cytokines, antibodies, or serum. As with all of the previously mentioned testing, a quantitative assay for purity should be in place by the start of phase III, with development of the assay being initiated much earlier in the investigational trial.

To complete product characterization in support of phase III and product licensure, a stability testing program that includes, but is not limited to, assays that measure product integrity, potency, sterility and, in the case of an *ex vivo* gene modified product, viability is needed. A stability protocol for study of the bulk and final drug products, as well as all MCBs and MVBs, should be defined so that stability data generated during phase III will be appropriate to support licensure. In general, the stability program should be initiated at phase I so that by phase II, the objective of obtaining real-time data to support stability of the investigational formulation can be met. For phase III, data collected should be used to support the proposed expiration-dating period of the final drug product, as well as the container and closure system. The determination of which tests should be included in the stability program will be product-specific. In addition, stability testing of any product intermediates should be in place to support the validation of the duration and conditions of storage of the bulk product.

51.4.1 CURRENT GOOD MANUFACTURING PRACTICES

cGMP is defined as a set of current, scientifically sound methods, practices or principles that are implemented and documented during product development and production to ensure consistent manufacture of safe, pure, and potent products (§501(a)(2)(B)). Some major elements of cGMP include detailed record keeping, development of written procedures or SOPs, institution of QC program and analytical assays, and equipment and process validation. cGMP also requires a program be in place for the certification and training of personnel and for environmental monitoring. The agency believes that applying QC principles to the production of investigational products (i.e., interpreting and implementing cGMPs consistent with good scientific methodology) will facilitate the initiation of investigational trials in humans and protect trial subjects. cGMPs play an important role in control and regulation of not only the product but all steps of the manufacturing

process. Adherence to cGMPs provides for quality and safety throughout the process and will lead to reproducible and consistent performance of product lots. It should be noted that cGMPs apply to the manufacturing process as well as to the facilities. As product development proceeds toward phase III so should the validation of the conditions under which the product is manufactured, controlled, and characterized. Full adherence to cGMP regulations is expected to develop as the clinical trial advances. For example, process validation, methods validation, in-process testing, and establishment of specifications should be incorporated as part of a phased-in approach to fulfilling regulatory requirements.

51.4.2 PRODUCT COMPARABILITY

Changes in the manufacturing process, equipment, or facilities often occur during product development and can result in change in the biological product itself. A manufacturer must fully describe any change to a biological product in the IND or license application, regardless of whether the change occurs prior to or after product approval. The manufacturing change should be assessed and the resulting product compared to the existing product to assure that the change does not alter the safety, purity, potency, or integrity of the final product. Determinations of product comparability may be based on a combination of *in vitro* or *in vivo* studies ranging from chemical, physical, and biological assays, assessment of pharmacokinetics or pharmacodynamics and toxicity in animals to clinical testing. The type of study required would depend on the extent of the change and the phase of clinical development in which the change occurs. Product comparability should be demonstrated through side-by-side analyses of the product lots manufactured under the established procedures and qualification lots of the product manufactured by the new procedure. If a sponsor can demonstrate comparability with nonclinical data, additional clinical safety or efficacy trials with the new product generally will not be needed. FDA will determine if comparability data are sufficient to demonstrate that additional clinical studies are unnecessary. Example of changes that would require a comparability study includes any change in the manufacturing scheme or site, changes to the MCB, modification of the vector product, a change in fermentation, isolation or purification, change in storage container, or product formulation. The final section of this chapter contains references that provide additional guidance on the demonstration of product comparability.

Gene therapy is continuing to evolve with the promise of new products on the horizon for treatment of diseases such as cancer, hemophilia, and many rare diseases. CBER is aware of this promise as well as the public's concern about the safety of human gene therapy studies. CBER is working with NIH, academia, and industry to help ensure that gene therapy products are safe while promoting the further development of this promising area of clinical studies. In particular CBER continues to work with the American Society of Gene Therapy (ASGT), individual sponsors, and the scientific community when we develop new policy and guidance.

FIGURE 4.1 Generalized Ad structure depicting major structural components of a wild-type Ad capsid. Hexon is depicted as a hexagon with 12 homotrimers per capsid face (only 12 of 240 trimers are shown). The penton base, comprised of five subunits at each vertex, and trimeric fiber and pIX structures are shown. Ad serotype-2 and -5 capsids contain a 36-kilobase double-stranded DNA genome (not shown).

FIGURE 4.3 Genetically modified fibers for Ad targeting. (See text for specific examples of each genetic targeting approach and targeting moiety used.) (A) Trimeric wild-type Ad fiber; tail, shaft, and knob regions are shown. (B) Ad5 fiber knob with a constrained targeting peptide in the flexible H-I loop. (C) Ad5 fiber knob containing a C-terminal targeting ligand. (D) Pseudotyped chimeric fiber bearing an alternate human or animal serotype knob domain. (E) "De-knobbed" fiber containing a heterologous trimerization sequence and a C-terminal targeting moiety.

FIGURE 5.2 Cre/loxP system for generating HD vectors. The HDAd contains only ~500bp of cis-acting Ad sequences required for DNA replication (ITRs) and packaging (ψ), the remainder of the genome consists of the desired transgene (yellow) and non-Ad "stuffer" sequences (green). The HDAd genome is constructed as a bacterial plasmid (pHDAd) and is liberated by restriction enzyme digestion (e.g., *PmeI*). To rescue the HDAd, the liberated genome is transfected into 293 cells expressing Cre and infected with a helper virus bearing a packaging signal (ψ) flanked by loxP sites. The helper viral genome also contains a stuffer sequence in E3 to prevent the formation of RCA in 293-derived cells. Cre-mediated excision of ψ renders the helper virus genome unpackageable, but still able to replicate and provide all of the necessary *trans*-acting factors for propagation of the HDAd. The titer of the HD vector is increased by serial coinfections of 293 Cre cells with the HDAd and the helper virus.

FIGURE 5.5 High dose systemic injection of HDAd into nonhuman primates. Baboon injected with (A, C, and E) 5.6×10^{12} vp/kg or (B, D, and F) 1.1×10^{13} vp/kg of HDAd-LacZ. X-gal stained (A and B) liver and (C and D) spleen and (E and F) serum IL-6 from injected baboons. Circles, 5.6×10^{12} vp/kg; triangles, 1.1×10^{13} vp/kg. Note different scales in E and F. (Adapted from Brunetti-Pierri, N., Palmer, D.J., Beaudet, A.L., Carey, K.D., Finegold, M., and Ng, P., *Hum. Gene Ther.*, 15, 35, 2004.)

FIGURE 5.8 Epithelia transduction of the (A) proximal and distal airway, (B) trachea, and (C) bronchiole of mice 3 days post-intranasal administration of 2×10^{10} vp of HDAd-K18LacZ. Blue areas represent HDAd transduced cells. (From Toietta, G., Koehler, D.R., Finegold, M.J., Lee, B., Hu, J., and Beaudet, A.L., *Mol. Ther.*, 7, 649, 2003. With permission.)

FIGURE 5.9 Histology of representative mouse lung 3 days post-intranasal administration of a total of 4×10^{10} vp of an (A) FGAd or (B) HDAd. (From Toietta, G., Koehler, D.R., Finegold, M.J., Lee, B., Hu, J., and Beaudet, A.L., *Mol. Ther.*, 7, 649, 2003. With permission.)

FIGURE 5.10 Lung histopathology following Bcc challenge. Representative H&E stained sections from wild-type littermates (A and B) and CFTR knockout mice (C and D) receiving saline (A and C) or HDAd-K18hCFTR (B and D) prior to bacterial challenge. (From Koehler, D.R., Sajjan, U., Chow, Y.H., Martin, B., Kent, G., Tanswell, A.K., McKerlie, C., Forstner, J.F., and Hu, J., *Proc. Natl. Acad. Sci. U S A*, 100, 15364, 2003. With permission.)

FIGURE 5.11 Pulmonary transduction in 2.8 kg rabbits following AeroProbe-mediated intratracheal aerosolization of 1.25 mL 0.1% LPC containing 5×10^{11} vp of HDAd-K18LacZ. X-gal stained (A) trachea, (B) right upper lobe, (C) left lower lobe, (D) right lower lobe, and (E) bronchus and bronchioles. Blue areas represent HDAd transduced cells. (From Koehler, D.R., Frndova, H., Leung, K., Louca, E., Palmer, D., Ng, P., McKerlie, C., Cox, P., Coates, A.L., and Hu, J., *J. Gene Med.*, 7, 1409, 2005. With permission.)

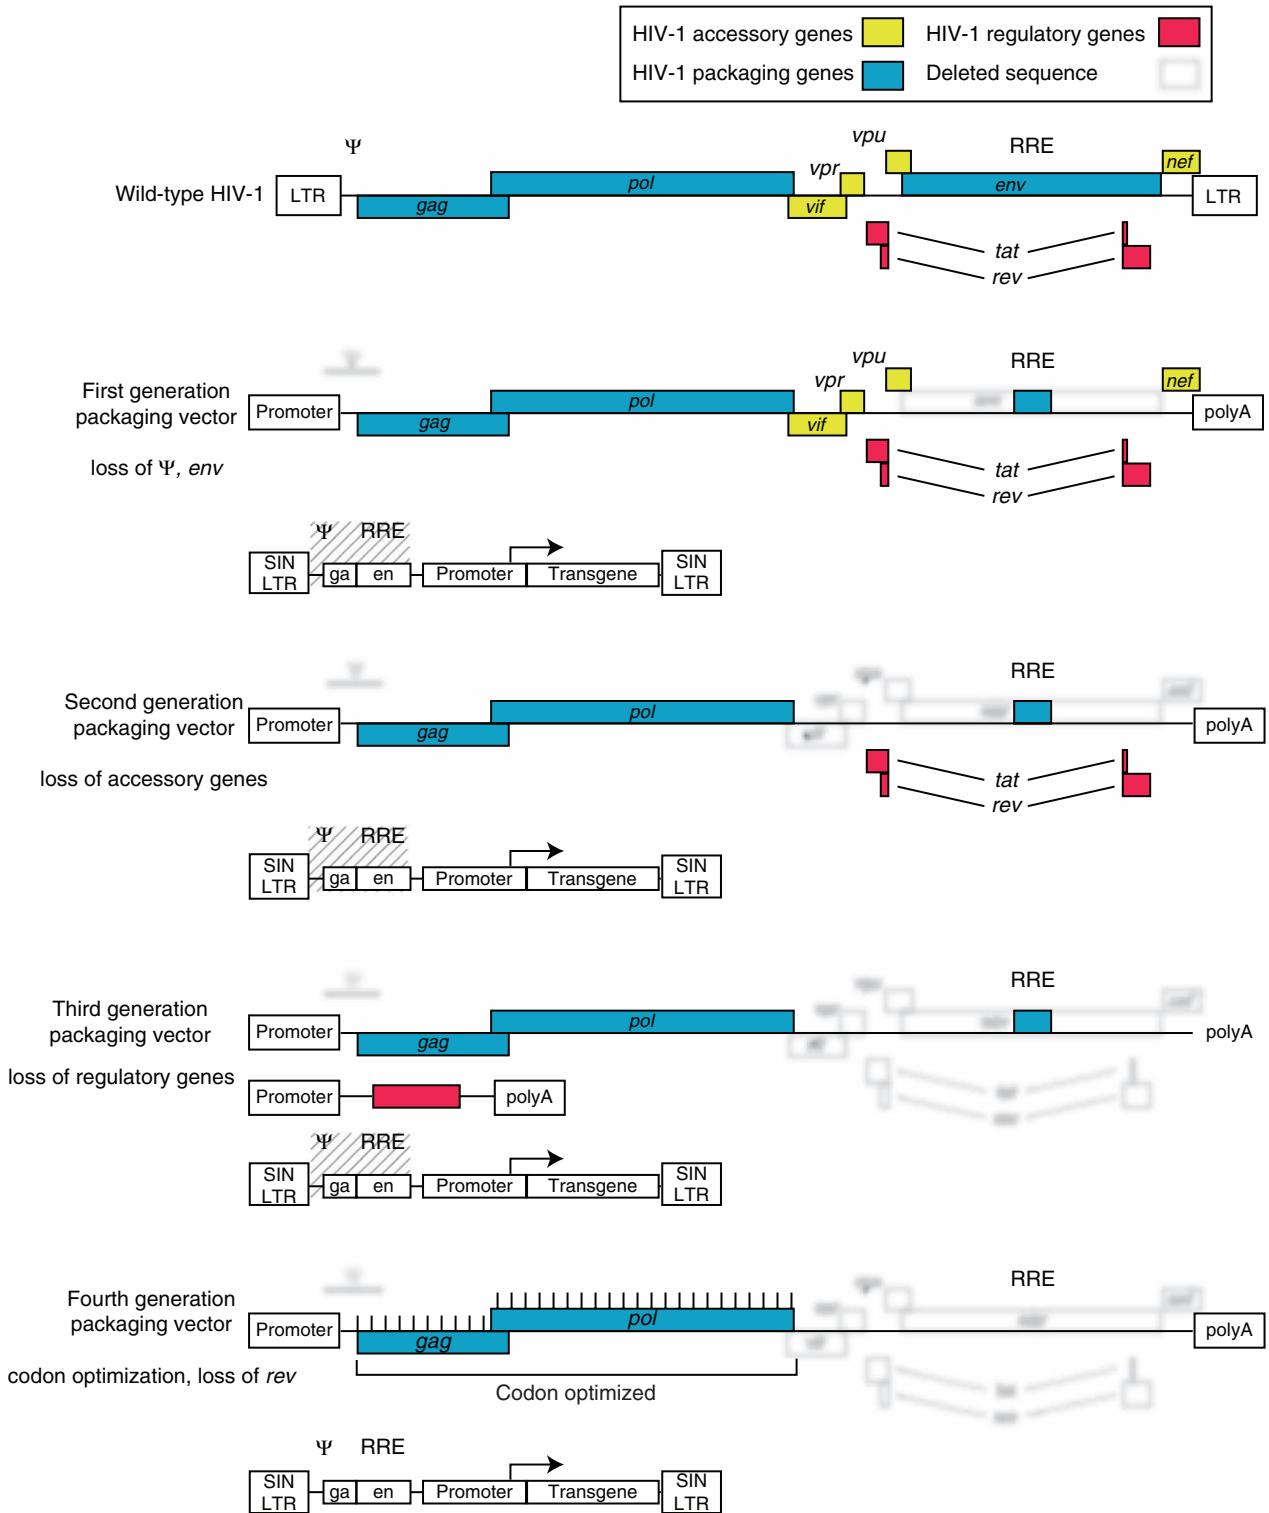

FIGURE 9.7 Wild-type HIV-1 and the various generations of lentiviral packaging vectors for comparison. A minimal transfer vector is shown alongside each packaging vector and areas of sequence homology between the two are indicated by shading.

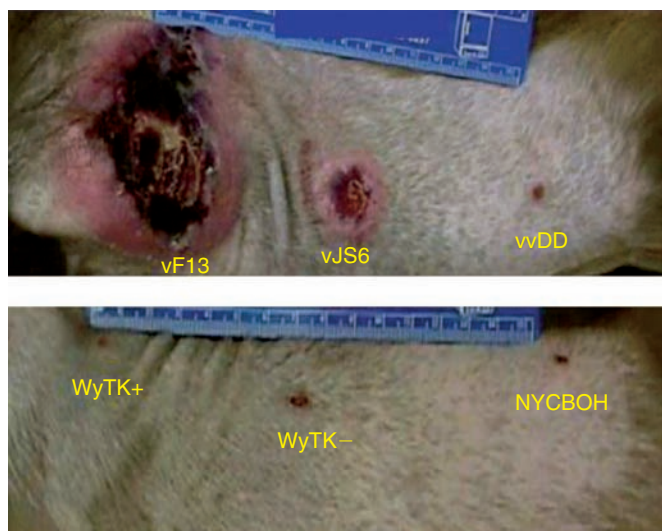

FIGURE 10.4 Cutaneous lesions 8 days after intradermal injection of 106 pfu of the various vaccinia viruses: vF13 (wild-type WR strain), vJS6 (TK⁻ WR strain), vvDD (TK⁻/VGF⁻ WR strain), WyTK⁺ (wild-type Wyeth strain), WyTK⁻ (TK⁻ Wyeth strain), NYCBOH (wild-type New York City Board of Health strain). (From Naik, A.M., et al., *Hum. Gene Ther.*, 17, 31, 2006. With permission.)

(A) PEI/mRNA

(B) HIS6 RPC/mRNA

FIGURE 13.5 Histidine-rich RPCs mediate efficient delivery of mRNA. Fluorescent images of PC-3 cells expressing green fluorescent protein (GFP) following transfection with 0.5 μ g cap-GFP-A64 mRNA condensed with (i) 25 kDa PEI or (ii) reducible polycation (RPC). Phase-contrast images of transfected PC-3 cells are shown in the corresponding right-hand column. (From Read, M. L. et al., *Nucleic Acids Res.*, 33, e86, 2005. With permission.)

FIGURE 16.1 Graphic representation of the delivery of macromolecules by direct injection followed by electroporation to the skeletal muscle for vaccination purposes. First, (A) the DNA vaccine is administered into skeletal muscle; (B) application of an electric field (electroporation); (C) contact of the expressed antigens with dendritic cells (DC) and subsequent activation; (D) activated DCs presenting antigens to B cells (B) and antigen fragments to T cells (T); (E) activated T-cells presenting antigens to B cells, activation of principal components (PC) for the generation of an immune response to the expressed antigen.

Magnetic fields tackle tumors

Image at lower left shows tumor tissue imbued with magnetic nanoparticles

FIGURE 17.1 Magnetic drug targeting. An anticancer drug (e.g., mitoxantrone) bound to magnetic particles is injected into a blood vessel (here tumor-feeding blood vessel) of the patient and is concentrated in the target tissue (e.g., tumor) by an external magnetic field. (From Siemens AG, Pictures of the Future 01/2007, page 64, www.siemens.com/pof. With permission.)

FIGURE 17.6 Enhancements achieved with nonviral magnetofection. (A) Comparison of magnetofections (with magnetic field 10 min incubation) with their corresponding standard transfections (4 h incubation) in NIH 3T3 and CHO-K1 cells. In the table, enhancements of magnetofection over transfections without (w/o) magnet are specified. AVET, adenovirus enhanced transfection. (B) Comparison of Lipofectamine magnetofection and Lipofectamine standard transfection in CHO-K1 cells with regard to their DNA dose-response profile. (From Scherer, F., Anton, M., Schillinger, U., Henke, J., Bergemann, C., Krüger, A., Gänsbacher, B., and Plank, C., *Gene Ther.*, 9, 102, 2002. With permission.)

FIGURE 17.7 Some examples for the applicability of magnetofection. (A) Magnetofection of primary HUVEC-C cells with fluorescence-labeled phosphorothioate oligonucleotides (ODN). Right panel: In the presence of a magnetic field, up to 90% of the cells had oligonucleotide bound or internalized within 15 min of incubation with complexes of ODN with magnetic nanoparticles. Left panel: In the absence of a magnet, only very little binding/uptake was observed within this short period. (From Krotz, F., Wit, C., Sohn, H.Y., Zahler, S., Gloe, T., Pohl, U., and Plank, C., *Mol. Ther.*, 7, 700, 2003. With permission.) (B) Magnetofection of HeLa cells stably expressing GFP with siRNA to knock down GFP expression. From left to right: untreated cells (control), 1 nM siRNA directed against GFP, 4 nM siRNA, 10 nM siRNA, respectively, associated with magnetic nanoparticles and incubated on the cells in the presence of a magnetic field. This experiment was carried out in a 96-well plate. During transfection, the cell culture plate was positioned on a magnetic plate, which is shown in Figure 17.5A. The magnetic nanoparticles used here are a commercially available magnetofection reagents. (From the homepage of Oz Biosciences (www.ozbiosciences.com)). (C) Magnetofection of HeLa (left panel) and A549 (human non-small cell lung carcinoma) (right panel) cells with a pseudo-type HI virus carrying a GFP reporter gene. (From the homepage of OZ Biosciences (www.ozbiosciences.com)).

(B)

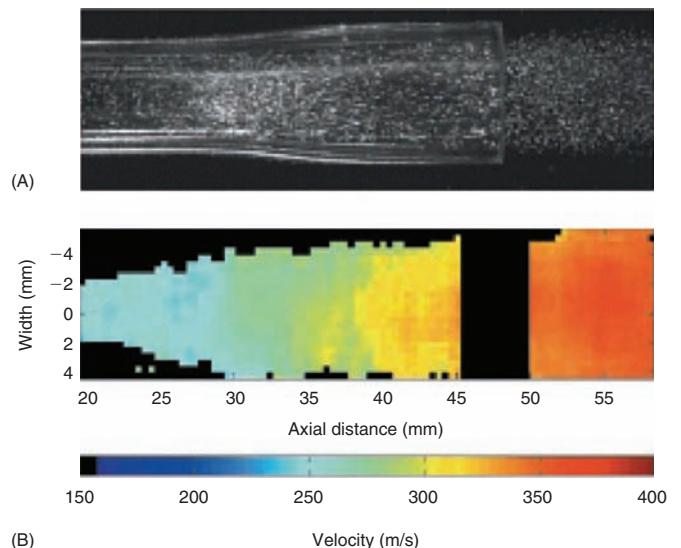

(C)

FIGURE 17.12 (B) X-gal staining performed 48 h after magnetic particle/DNA complexes were applied to the ilea of rats in the absence (left panels) and under the influence of a magnetic field for 20 min (right panels). Blue staining reveals efficient gene delivery only in the presence of magnet (right panels). Upper panels: intestinal tubes after X-gal stain. Insets: cross-sections of tubes. Lower panels: Paraffin sections counterstained with eosin, 400 \times magnification. X-gal staining is found in the lamina propria. L, lumen; LP, lamina propria. (From Scherer, F., Anton, M., Schillinger, U., Henke, J., Bergemann, C., Krüger, A., Gänsbacher, B., and Plank, C., *Gene Ther.*, 9, 102, 2002. With permission.) (C) Injection of fluorescence-labeled ODN/magnetic particle associates into the femoral artery caused site-specific accumulation in the vessels of the ipsilateral mouse cremaster at which a magnet was placed (upper panel, left: large arterioles, middle: small arterioles, right: autofluorescence before injection of magnetic complexes) but not into the contralateral cremaster, which was not in contact with a magnetic field (lower panel). (From Krotz, F., Wit, C., Sohn, H.Y., Zahler, S., Gloe, T., Pohl, U., and Plank, C., *Mol. Ther.*, 7, 700, 2003. With permission.)

(A)

FIGURE 18.2 Mechanical properties (mean \pm standard deviation) as a function of displacement obtained with microprobes indented into murine ears. (A) Storage modulus with 5 and 2 μ m microprobes. (B) Stress with a 2 μ m microprobe. (Adapted from Kendall, M.A.F., Chong, Y., and Cock, A., *Biomaterials*, 28, 4968, 2007. With permission.)

(A)

(B)

FIGURE 18.5 (A) Raw image and (B) derived PIV velocity map of the instantaneous particle flowfield of a CST prototype, taken 225 μ s after diaphragm rupture. The payload was 2.2 mg of 39 μ m diameter polystyrene spheres. (Adapted from Kendall, M.A.F., *Shock Waves J.*, 12, 22, 2002. With permission.)

FIGURE 18.8 Raw gold and larger particle penetration into excised human skin as a function of the particle radius, density, and impact velocity. (Adapted from Kendall, M.A.F., Mitchell, T.J., and Wrighton-Smith, P., *J. Biomech.*, 37, 1733, 2004. With permission.)

FIGURE 18.11 Murine tissue stained for live–dead cell discrimination with a cocktail of acridine orange/ethidium bromide and imaged with near-infrared two-photon excitation. Cells emitting red fluorescence are dead whereas cells emitting green fluorescence are alive. In slide A, the dark spots are perforations in the SC caused by microparticle bombardment. Slide B is the corresponding viable epidermis 11.3 μm below the SC. Slides A and B represent an image set of “high particle density” shown in Figure 18.10. Slide C is the viable epidermis of the control (9.7 μm below the SC) where particle delivery to the tissue was not made. Slide D is representative of the viable epidermis of tissue with intermediate particle densities (10.5 μm below the SC). Images were collected with LaserSharp software (Carl Zeiss, Hertfordshire, U.K.). (From Raju, P.A., Truong, N.K., and Kendall, M.A.F., *Vaccine*, 24, 4644, 2006. With permission.)

FIGURE 19.7 Optimized strategy for delivery and gene expression in the target cell. Optimization of many steps is required to achieve targeted delivery, shielding from nonspecific uptake in nontarget organs and tissues, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

FIGURE 21.4 Osmotic stress method. (From Parsegian, V.A., Rand, R.P., Fuller, N.L., and Rau, D.C., *Methods Enzymol.*, 1986, 127, 400.) DNA liquid crystals are equilibrated against solutions of a neutral polymer (such as PEG or PVP, depicted as disordered coils). These solutions are of known osmotic pressure, pH, temperature, and ionic composition. (From Rau, D.C., Lee, B.K., and Parsegian, V.A., *Proc. Natl. Acad. Sci. USA*, 1984, 81, 2621.) Equilibration of DNA under the osmotic stress of external polymer solution is effectively the same as exerting mechanical pressure on the DNA subphase with a piston that passes water and small solutes but not DNA. After equilibration under this known stress, DNA separation is measured either by x-ray scattering, if the DNA subphase is sufficiently ordered, or by densitometry. (From Strey, H.H., Parsegian, V.A., and Podgornik, R., *Phys. Rev. Lett.*, 1997, 78, 895.) DNA density and osmotic stress thus determined immediately provide an equation of state (osmotic pressure as a function of the density of the DNA subphase) to be codified in analytic form over an entire phase diagram.

FIGURE 21.5 Interactions between biological macromolecules show striking universality at close surface-to-surface separations (or equivalently at very large densities). Hydroxypropyl cellulose, schizophyllan, different DNA salts, xanthan, and DDP bilayers at small intermolecular separations (given in terms of the separation between effective molecular surfaces of the interacting molecules) all show a strong repulsive interactions decaying with about the same characteristic decay length. The log-linear plot is thus more or less a straight line. (Composite data, courtesy D.C. Rau.)

FIGURE 21.11 Thermally excited conformational fluctuations in a multilamellar membrane array (small molecules are waters and long chain molecules are phospholipids) or in a tightly packed polyelectrolyte chain array (the figure represents a hexagonally packed DNA array) leading to collisions between membranes or polyelectrolyte chains. These collisions contribute an additional repulsive contribution to the total osmotic pressure in the array, a repulsion that depends on the average spacing between the fluctuating objects. (Graphics courtesy of B.B. Brooks and M. Hodoscek, NIH)

Lipid	Bending rigidity (10^{-19} J)	Area compression (mN/m)
DMPC	1.15	145
SOPC	0.9	200
EggPC	0.4–2	
Plasma membrane	0.2–2	700
Red blood cell	0.13–0.3	450

FIGURE 21.20 The lipid bilayer. A lipid molecule has a hydrophilic and a hydrophobic part (here shown is the phosphatidylserine molecule that has a charged headgroup). At high enough densities, lipid molecules assemble into a lipid bilayer. Together with membrane proteins as its most important component, the lipid bilayer is the underlying structural component of biological membranes. The degree of order of the lipids in a bilayer depends drastically on temperature and goes through a sequence of phases (see main text): Crystalline, gel, and fluid, as depicted in the middle drawing. The box at the bottom gives sample values of bilayer bending rigidity and area compressibility for some biologically relevant lipids and one well-studied cell membrane. (Graphics courtesy of B.B. Brooks, and M. Hodoscek, NIH).

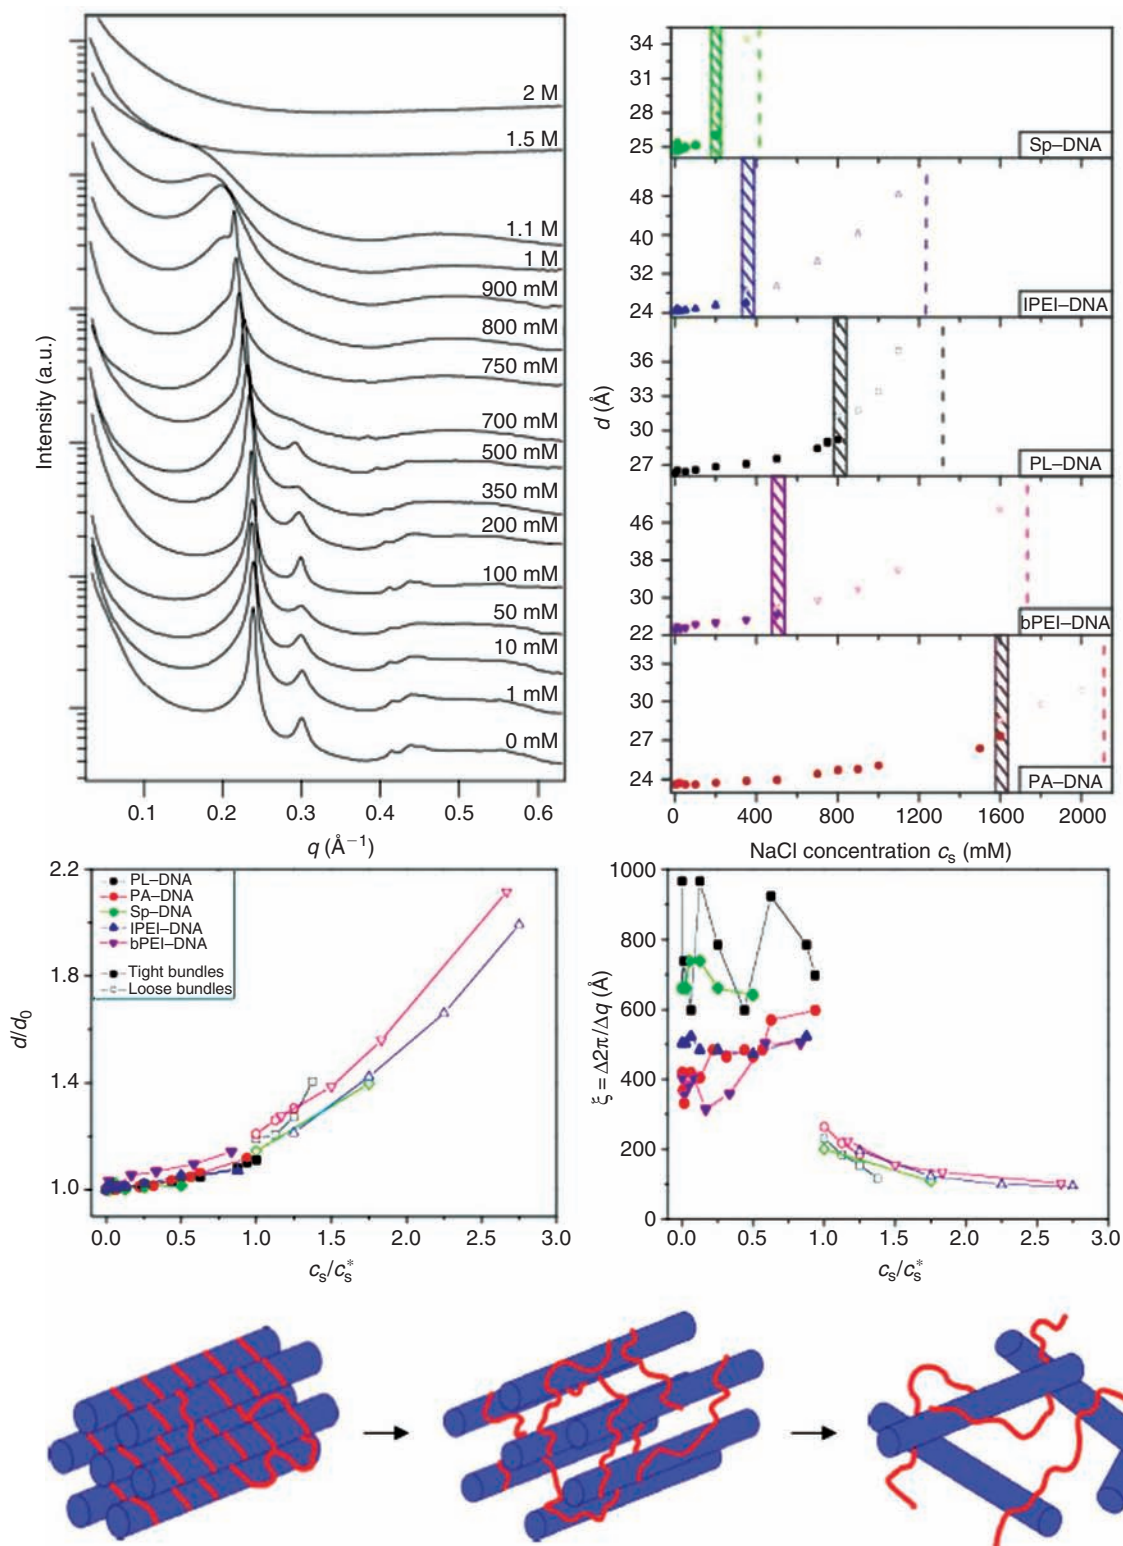

FIGURE 21.30 Phase behavior of polyplexes with increasing monovalent salt concentration. Universal phase behavior is observed for all systems with an initial swelling of a tightly packed hexagonal array of DNA rods. As a critical salt concentration, c_s^* , dependent on polycation, the onset of a coexistence regime is observed between tight and loose bundles. In-plane correlation lengths, ξ , representative of long-range order within the arrays show a sharp decrease upon crossing c_s^* . When scaled with respect to c_s^* , both swelling ratio (d/d_0) and ξ collapse onto universal behavior. With increasing salt, the loose bundles lose both positional and orientational order with an increase in a network structure at the expense of the loose bundle regime. At sufficiently high salt concentration, or dilute polymer concentration, all Coulombic interactions are screened and the samples disassociate completely into the dilute phase.

FIGURE 22.4 Improved survival of fixed ischemic injury following CD47 morpholino treatment of dorsal skin flaps and ischemic hind limbs in C57BL/6 mice. Wild-type C57BL/6 age- and sex-matched mice underwent 1 × 2 cm random myocutaneous flaps. Flaps were treated at the time of surgery with saline, a mismatched morpholino control or a target CD47 morpholino, and tissue survival determined (A). Wild-type C57BL/6 age- and sex-matched mice underwent ligation of the femoral artery at the inguinal ligament. Limbs were treated at the time of surgery by direct intramuscular injection of vehicle (saline), a mismatched control morpholino sequence, or a CD47 morpholino.

FIGURE 22.5 Improved survival of full thickness skin grafts following CD47 morpholino treatment in C57BL/6 mice. Wild-type C57BL/6 age- and sex-matched mice underwent 1 × 1 cm full thickness skin grafts. At the time of surgery, grafts and wound beds were treated by direct injection with saline (vehicle), a missense control morpholino, or a CD47 morpholino (10 μM), recognizing the murine sequence of the protein. Tissue survival was assessed on postoperative day 7.

FIGURE 22.6 CPP does not enhance the efficacy of a CD47 morpholino for ischemic injury. Wild-type C57BL/6 age- and sex-matched mice underwent 1 × 2 cm random myocutaneous flaps. Flaps were treated at the time of surgery with a targeted CD47 morpholino plus the manufacturer's recommended cell uptake agent (Endoporterr®) in saline or a CD47 morpholino in saline alone and tissue survival determined.

FIGURE 23.2 Antisense mechanisms of action. Cartoon depicting three different mechanisms by which an antisense oligonucleotide can inhibit expression of a targeted gene product by hybridization to the mRNA or pre-mRNA, which codes for the gene product.

FIGURE 24.2 Developing RNAi therapeutics. Steps involved in developing an RNAi therapeutic. This three-step process begins with *in silico* design and *in vitro* screening of target siRNA, is followed by incorporating stabilizing chemical modifications on lead siRNA as required, and ends with selection and *in vivo* evaluation of delivery technologies appropriate for the target cell type/organ and the disease setting. A schematic illustration of some of the important features of siRNA structure (two base pair overhangs, seed region, and mRNA cleavage site) is shown. An example of an optimized siRNA molecule, which incorporates chemical modifications to increase nuclease stability and to minimize off-targeting, is shown below. The phosphorothioate and 2' base modifications shown are illustrative of exo-nuclease and endo-nuclease stabilizing chemistries, respectively; other chemistries also exist that confer similar properties on an siRNA duplex. (From Bumcrot, D. et al. *Nat. Chem. Biol.*, 2006, 2, 711; de Fougères, A.R. et al., *Nat. Rev. Drug Discovery*, 6, 443, 2007.)

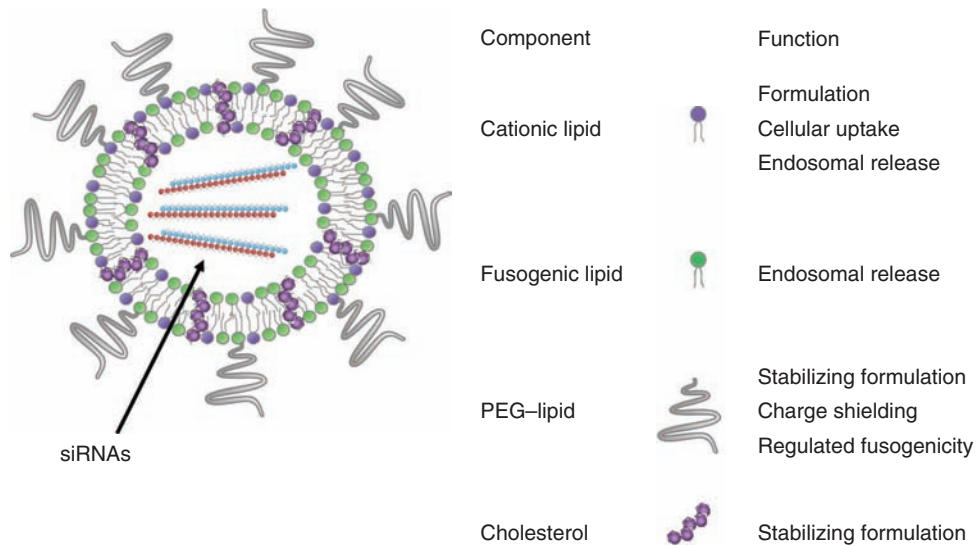

FIGURE 24.4 Structure and function of a cationic liposome. Composition of a SNALP is shown. Other cationic liposome formulations also exist, which may or may not contain a fusogenic or PEG-lipid. Ratios of different components also can vary between formulations.

FIGURE 27.2 Hematoxylin/eosin staining of sections of 17.5-day-old mouse embryo skin (left) and of tissue formed from ESCs grown on a matrix secreted by a skin cell line (right). (From Coraux, C., Hilmi, C., Rouleau, M., Spadafora, A., Hinnrasky, J., Ortonne, J.P., et al. *Curr. Biol.*, 13, 849, 2003. With permission.)

FIGURE 27.3 Phase contrast and fluorescence composite image of murine ESCs grown for 21 days in the presence of osteogenic supplements (β -glycerophosphate, ascorbate, and dexamethasone). Bone nodules are indicated by areas that stain positively for alizarin red S, which fluoresces when bound to calcified ECM.

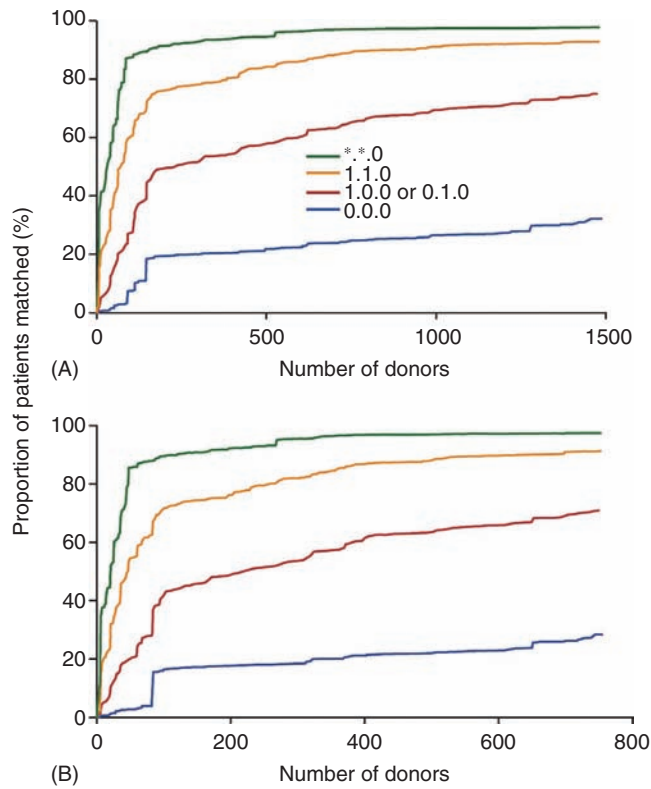

FIGURE 27.4 Graphs of estimates of how many ESC donors are required to provide different degrees of HLA matching in potential recipients. (0.0.0) indicates a zero HLA-A, HLA-B, and HLA-DR mismatch; (1.0.0 or 0.1.0) indicates a zero HLA-DR mismatch with no more than a single HLA-A or HLA-B mismatch; (1.1.0) indicates a zero HLA-DR mismatch with no more than a single HLA-A and a single HLA-B mismatch; and (*.*.0) indicates a zero HLA-DR mismatch. (A) was obtained using data from 1500 consecutive cadaveric organ donors and (B) 760 consecutive blood-group-O cadaveric organ donors. (From Zhan, X., David, G., Ye, Z., Hammond, H., Shablott, M., Gearhart, J., et al., *Lancet*, 364, 163, 2004. With permission.)

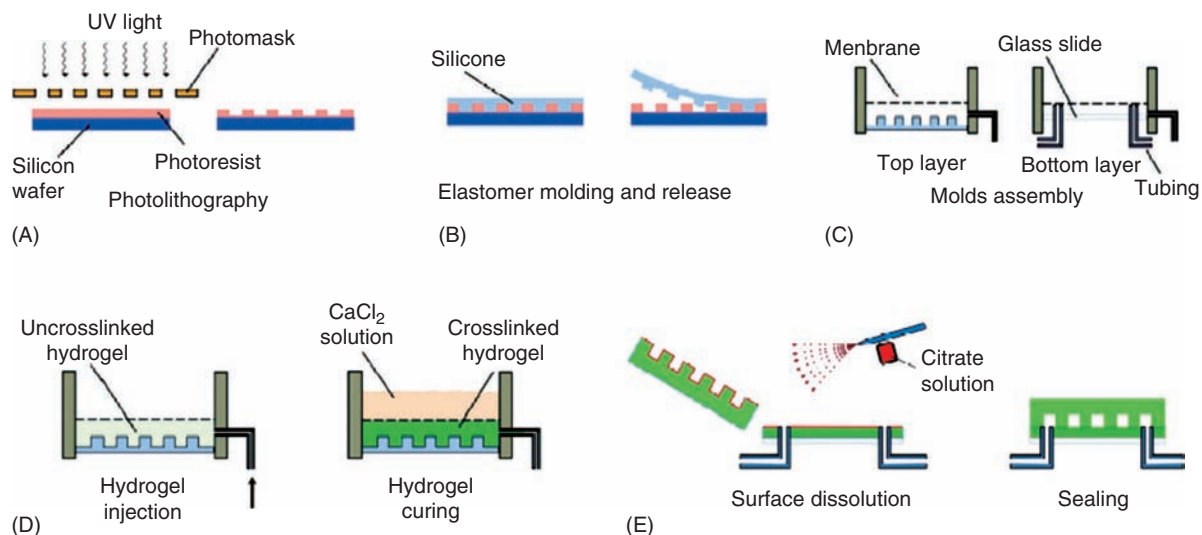

FIGURE 27.5 Process by which patterned hydrogel scaffolds can be constructed. Silicon photoresists are first patterned by exposure to UV light (A). A curable gel, such as silicone can then be molded over the photoresist (B) and used as a mold to create structure in a biocompatible hydrogel such as alginate that may contain cells (C and D). Channels in the hydrogel can then be perfused with a liquid such as growth medium (E). (From Cabodi, M., Choi, N.W., Gleghorn, J.P., Lee, C.S.D., Bonassar, L.J., and Stroock, A.D., *J. Am. Chem. Soc.*, 127, 13788, 2005. With permission.)

FIGURE 27.7 Amphiphilic molecules can be designed with a hydrophilic peptide “head” (5) and a hydrophobic tail (1) (A). These peptides self-assemble to form thread-like nanofibres (B and C). (From Hartgerink, J.D., Beniash, E., and Stupp, S.I., *Science*, 294, 1684, 2001. With permission.)

FIGURE 30.1 Basic principles of optical CCD imaging (fluorescence/bioluminescence). There are fundamentally two different types of optically based imaging systems: fluorescence imaging, which uses emitters such as GFP, wavelength-shifted GFP mutants, RFP, smart probes and near-infrared fluorescent (NIRF) probes, and bioluminescence imaging, which utilize systems such as firefly luciferase/D-Luciferin or Renilla luciferase/coelenterazine. Emission of light from fluorescent markers requires external light excitation while bioluminescent systems generate light de novo when the appropriate substrates/cofactors are made available. In both cases, light emitted from either system can be detected with a thermoelectrically cooled CCD camera since they emit light in the visible light range (400–700 nm) to NIR range (~800 nm). Cooled to -120°C to -150°C , these cameras can detect weakly luminescent sources within a light-tight chamber. Being exquisitely sensitive to light, these desktop camera systems allow for quantitative analysis of the data. Image shown above the “fluorescence imaging” schematic is a representative image obtained from a glioma model, which expresses RFP (image used with permission from Anticancer, Inc.). The method of imaging bioluminescent sources living subjects with a CCD camera is relatively straightforward: The animal is anesthetized, subsequently injected with the substrate, and immediately placed in the light-tight chamber. A light photographic image of the animal is obtained which is followed by a bioluminescence image captured by the cooled CCD camera positioned above the subject within the confines of the dark chamber. The two images are subsequently superimposed on one another by a computer, and relative location of luciferase activity is inferred from the composite image. An adjacent color scale confers relative concentration of luciferase activity. Sample image above the “Bioluminescence imaging” schematic is a typical image obtained with this technology. In this specific example, image was obtained after intravenous injection of coelenterazine into a mouse containing intraperitoneal Renilla luciferase-expressing tumor cells. Significant bioluminescence is detected from the region of the xenograft. (From Bhaumik, S. and Gambhir, S.S., *Proc. Natl. Acad. Sci. USA*, 99, 377, 2002. With permission.)

FIGURE 30.5 Optical (fluorescence) imaging of transgene expression. The adenoviral (vAd) vector AdCMV5GFPΔE1/ΔE3 [vAd-GFP] (Quantum, Montreal, Canada) constitutively expresses an EGFP, which is driven by a cytomegalovirus (CMV) promoter. The vector was delivered to the brain after an upper midline scalp incision and creation of a parietal skull window. Twenty microliters containing 8×10^{10} plaque-forming units (pfu)/ml vAd-GFP per mouse was injected into the brain. Twenty four hours later, fluorescence imaging of the entire animal (lower magnification) was carried out in a light box illuminated by blue light fiber optics, which provided the external excitation wavelength and imaged by using the cooled color CCD camera. Emitted fluorescence was collected through a long-pass filter GG475 on a three-chip thermoelectrically cooled, color CCD camera. Images of $1,024 \times 724$ pixels are captured directly on a personal computer or continuously through video output on a high-resolution video recorder. Images are subsequently processed for contrast and brightness and analyzed with imaging software. Higher magnification images (not shown here) can be accomplished by using a fluorescence stereomicroscope equipped with a 50 W mercury lamp. In this scenario, selective excitation of GFP is produced through a D425/60 bandpass filter and 470 DCXR dichroic mirror. Emitted fluorescence are captured and processed as described above. Images (A) and (B) demonstrate GFP transgene expression following adenoviral delivery to the brain. Image (C) demonstrates Ad-CMV-GFP delivery to the liver via portal vein cannulation. (Courtesy of Anticancer, Inc. and from Yang, M., Baranov, E., Moossa, A.R., Penman, S., and Hoffman, R.M., *Proc. Natl. Acad. Sci. USA*, 97, 12278, 2000. With permission.)

FIGURE 30.6 Optical (bioluminescence) imaging of cardiac reporter gene expression. Replication-defective adenovirus carrying firefly luciferase (*Fluc*) driven by a constitutive cytomegalovirus (CMV) promoter (Ad-CMV-*Fluc*, 1×10^9 pfu) was injected directly into the myocardium (anterolateral wall) of a rat. Images obtained 2, 5, 8, and 14 days later from a cooled CCD camera demonstrate significant cardiac emissions from FL activity ($P < 0.05$ vs. control). By day 8, luciferase activity is seen in the liver, which is probably from spillover of adenoviral vector into the systemic circulation and subsequent hepatic transfection of the virus via coxsackie-adenovirus receptors on hepatocytes. On day 14, the heart of the same rat was explanted after whole-body imaging was performed and sliced into three sections (bottom right). Firefly luciferase activity is localized at anterolateral wall of left ventricle along the site of virus injection. Control rats, which received an intracardiac injection of Ad-CMV-*HSV1-sr39tk* (1×10^9 pfu), demonstrate no significant firefly luciferase activity 2 days after the injection (upper left). Please note the bioluminescent scales are different for control rat, study rat days 2 to 5, and study rat days 8 to 14 to account for the wide range of cardiac firefly luciferase activity observed. Scales are a quantitative indicator of light photons detected (relative light units [RLU]/minute [min]). RA indicates right atrium; RV, right ventricle; and LV, left ventricle. (Reproduced from Wu, J.C., Inubushi, M., Sundaresan, G., Schelbert, H.R., and Gambhir, S.S., *Circulation*, 105, 1631, 2002. With permission.)

FIGURE 30.7 Optical (bioluminescence) imaging of targeted transgene expression using a tissue-specific promoter. One way to target gene therapy is through the use of tissue-specific promoters. However, most tissue-specific promoters yield low levels of transcription. In this example, certain key regulatory elements of the promoter and enhancer of prostate-specific antigen (PSA) have been multimerized to yield a construct, PSE-BC, which is 20-fold more active than the native PSA promoter/enhancer. Following incorporation into an adenovirus vector (AdPSE-BC-luc) and subsequent intratumoral injection into a human prostate cancer xenograft model (LAPC series), firefly luciferase expression can be seen in the main tumor xenograft (left flank) as well as other extratumoral sites, such as the back and chest, in this male SCID mice 21 days after vector delivery. Detailed histologic analysis of the xenograft and extratumoral sites demonstrates that firefly luciferase expression is restricted to the prostate tumor and prostate metastases, respectively. The metastases, in this case, are located in the spine and lung. By comparison, CCD imaging and histologic analysis of xenografts injected with AdCMV-luc show markedly diminished expression of firefly luciferase in the xenograft and increased nonspecific expression in the liver at 21 days postinjection (figure not shown). Results from this study indicate that tissue-specific transgene expression is possible and that CCD imaging can be used to track firefly luciferase-marked tumor cells. Scale indicates the number of photons detected (RLU/min). (Reproduced from Adams, J.Y., Johnson, M., Sato, M. et al., *Nat. Med.*, 8, 891, 2002. With permission.)

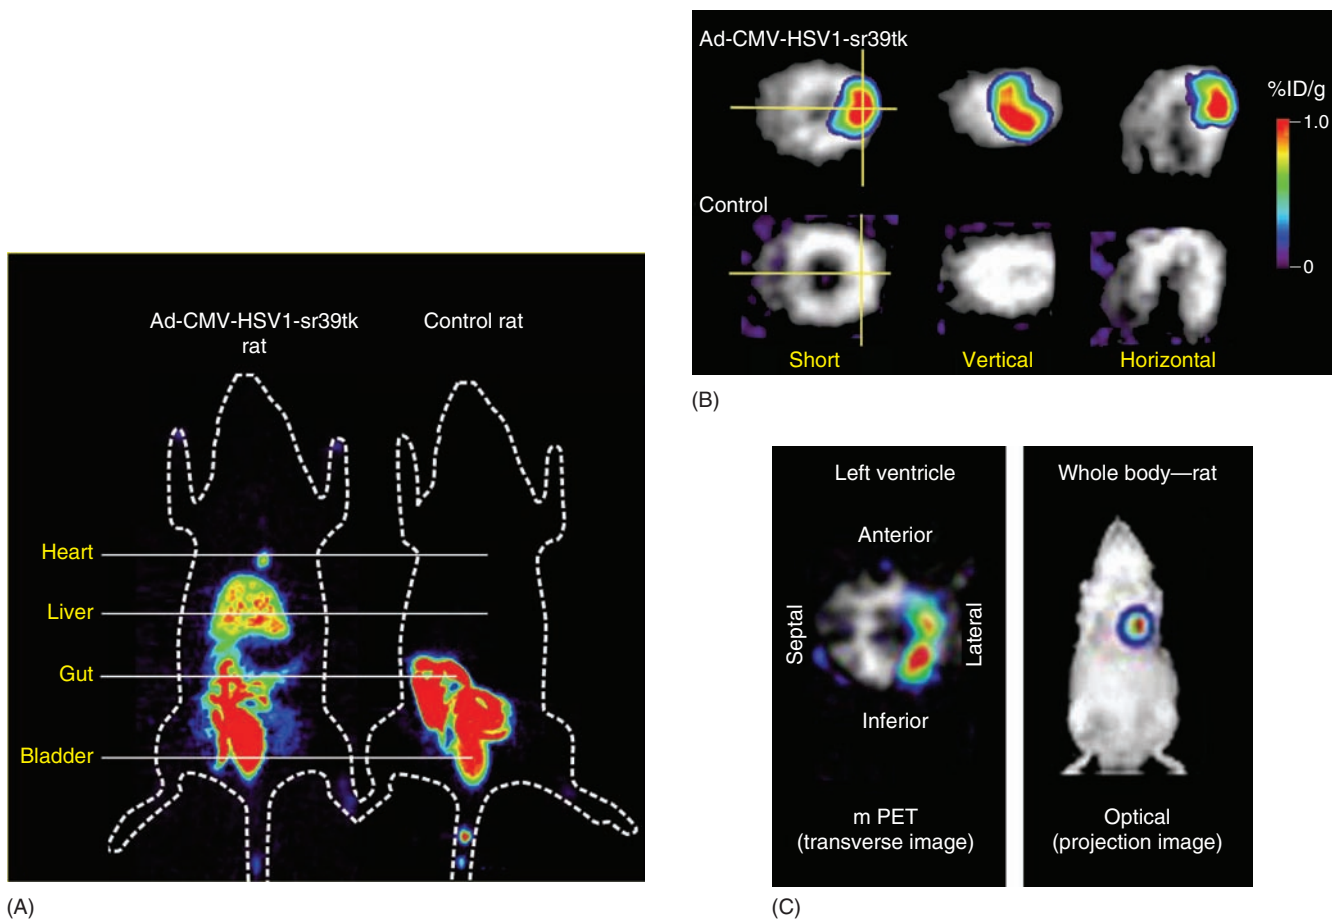

FIGURE 30.8 MicroPET and optical (bioluminescence) imaging of cardiac reporter gene delivery. (A) Imaging cardiac gene expression using adenoviral-mediated mutant thymidine kinase (HSV1-sr39tk) as PET reporter gene and [^{18}F]FHBG as PET reporter probe. Trapping of tracer occurs only in cells expressing the reporter gene. At day 4, whole-body microPET image of a rat shows focal cardiac [^{18}F]FHBG activity at the site of intramyocardial Ad-CMV-HSV1-sr39tk injection. Liver [^{18}F]FHBG activity is also seen because of systemic adenoviral leakage with transduction of hepatocytes. Control rat injected with Ad-CMV-*Fluc* shows no [^{18}F]FHBG activity in either the cardiac or hepatic regions. Radiolabeled probe is always “visible” with radionuclide imaging regardless of whether it has localized to its target or not. As a result, radionuclide-based images will exhibit a certain degree of nonspecific tracer localization since “unbound” reporter probe is metabolized through either the enterohepatic or urinary system or both. In this example, nonspecific reporter probe activity gut and bladder activities are seen for both study and control rats because of route of [^{18}F]FHBG clearance. (B) Tomographic views of cardiac microPET images. The [^{13}N]NH $_3$ (gray scale) images of perfusion are superimposed on [^{18}F]FHBG images (color scale), demonstrating HSV1-sr39tk reporter gene expression. [^{18}F]FHBG activity is seen in the anterolateral wall for experimental rat compared with background signal in control rat. Perpendicular lines represent the axis for vertical and horizontal cuts. Color scale is expressed as % ID/g. (C) Comparison of typical images obtained with PET (left) and optical imaging (right). The optical method is more sensitive (at limited depths), easier to perform, and demonstrates minimal background noise. With PET, we can see that the transgene was delivered to the anterolateral aspect of the left ventricle. Such spatial resolution is not afforded by *in vivo* optical imaging at this time. (Reproduced from Wu, J.C., Inubushi, M., Sundaresan, G., Schelbert, H.R., and Gambhir, S.S., *Circulation*, 105, 1631, 2002; Wu, J.C., Inubushi, M., Sundaresan, G., Schelbert, H.R., and Gambhir, S.S., *Circulation*, 106, 180, 2002. With permission.)

FIGURE 30.13 Tracking HSV infection with [¹³¹I]FIAU using autoradiography. Tracking wild-type HSV-1 infection with radionuclide-based techniques can be accomplished using the virus' native TK gene and a reporter probe such as radiolabeled [¹³¹I]FIAU. To help corroborate imaging findings with histochemistry findings, a replication conditional, oncolytic recombinant HSV-1 virus vector, hrR3, containing a *lacZ* insertional mutation within the *RR* gene locus, has been prepared. Following injection of the vector into rat gliosarcoma xenografts, tumors were processed for tissue-sectioning, autoradiography, and β-galactosidase-stained histology. Image coregistration of tumor histology, HSV-1-*tk* related radioactivity (assessed by [¹³¹I]FIAU autoradiography), and *lacZ* gene expression (assessed by β-galactosidase staining) demonstrated a characteristic pattern of gene expression around the injection sites. A narrow band of *lacZ* gene expression immediately adjacent to necrotic tumor areas is observed, and this zone is surrounded by a rim of HSV-1-*tk*-related radioactivity, primarily in viable-appearing tumor tissue. PET images (not shown) of injected tumors in the intact animal have also been performed using [¹²⁴I]FIAU as a reporter probe; the areas of PET-labeled probe uptake correlate well with the β-galactosidase-stained photomicrographs. (Reproduced from Jacobs, A., Tjuvajev, J.G., Dubrovin, M. et al., *Cancer Res.*, 61, 2983, 2001. With permission.)

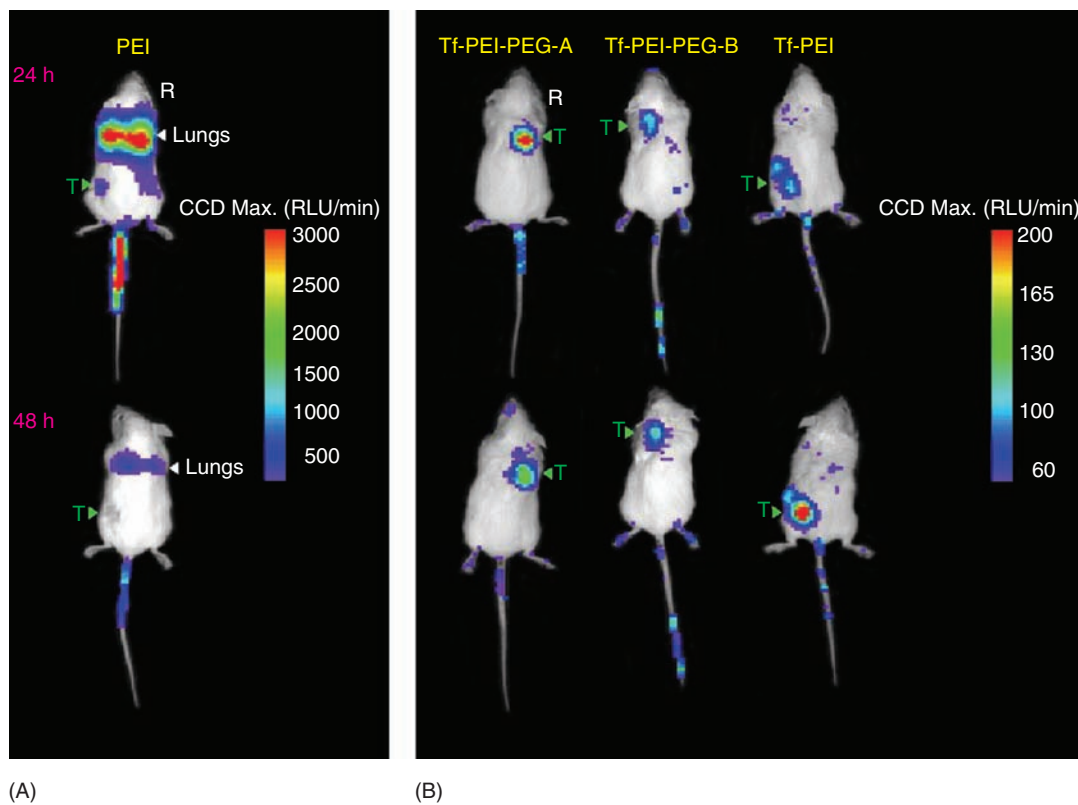

FIGURE 30.14 Tracking Tf targeted polyethylenimine (PEI)-mediated gene delivery using optical bioluminescence imaging. Delivery of the bioluminescence reporter gene, firefly luciferase (*Fluc*), by CMV-*Fluc* DNA/PEI polyplexes and subsequent *Fluc* expression can be imaged in living mice using a cooled CCD camera. Additionally, the biodistribution of modified PEI polycation complexes, altered with molecules such as Tf or polyethylene glycol (PEG), can be studied in this manner. Tf targeting has been shown to improve the transfection efficiency in certain tumor cell lines and PEG modification has been shown to improve circulation times of DNA/PEI complexes and prevent their nonspecific uptake by the reticuloendothelial system. All CCD images are of living mice carrying N2A xenograft 24 or 48 h after intravenous injection of various DNA/PEI polyplexes. Site of tumor is indicated (T). (A) PEI (positive control) treated animals show relatively high *Fluc* expression (using 1× D-Luciferin) in the lungs as compared with the tumor. The activity on the left-hind limb is from the N2A cell tumor (T). Nonspecific tail activity occurs at the DNA/PEI polyplex injection site. All *Fluc* expression decreases at 48 h. (B) Tf-PEI-PEG-A, Tf-PEI-PEG-B, and Tf-PEI treated mice show *Fluc* expression (using 2× D-luciferin) in the tumor (T) and tail regions, but no detectable signal in the lungs. For each formulation, expression in the tumor varied over 24 to 48 h. All images are quantitated as indicated by the two scales (RLU/min). (Reproduced from Hildebrandt, I.J., Iyer, M., Wagner, E., and Gambhir, S.S., *Gene Ther.*, in press. With permission.)

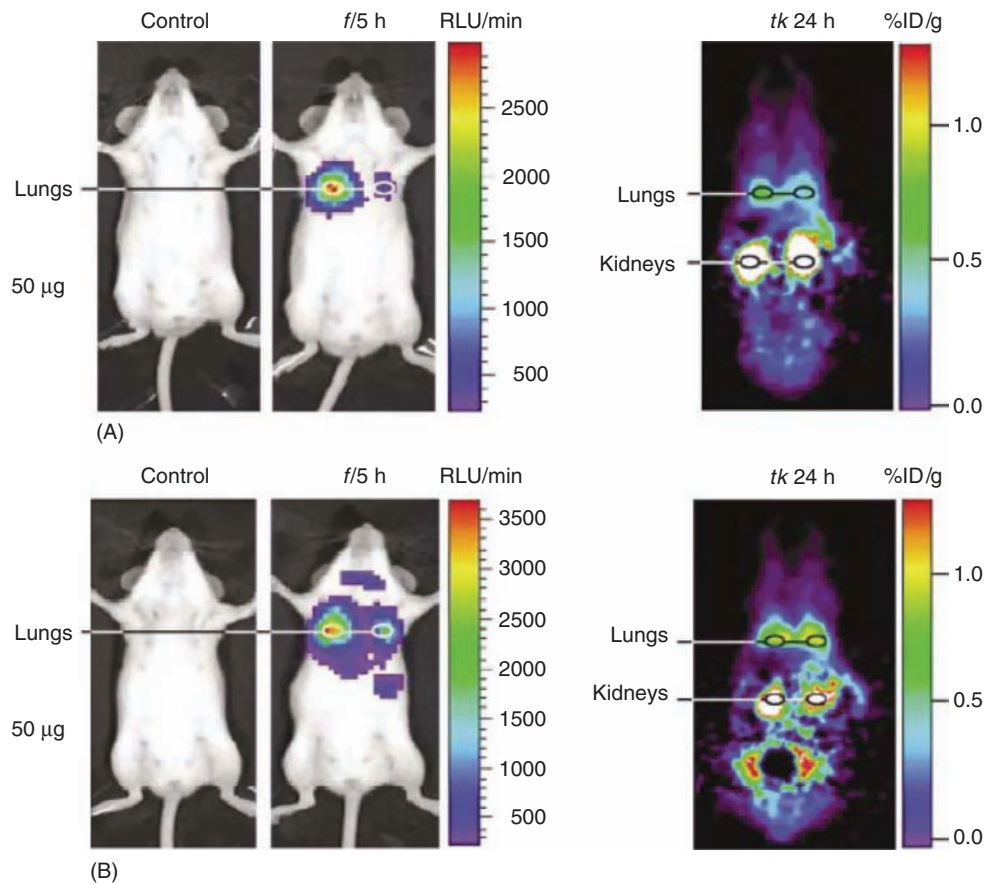

FIGURE 30.15 Tracking cationic lipid-mediated reporter gene delivery using optical (bioluminescence) and PET imaging. Cationic lipids associate with negatively charged DNA to form complexes that bind to cell surfaces by way of electrostatic interaction, thereby allowing a nonviral means of gene transfer. Distribution of systemic administration of DNA–lipid complexes in mice is demonstrated by delivering prepared DNA–lipid complexes that carry optical and PET reporter genes. CMV-*fl* plasmid DNA (CMV promoter driving expression of firefly luciferase [*fl*] gene) was mixed with cationic lipid, 1,2-dioleoyl-3-trimethylammonium-propoane (DOTAP) and cholesterol, to form *fl* DNA–lipid complexes. Similar procedure was used to prepare HSV1-sr39*tk* DNA–lipid complex (*tk* DNA–lipid complex). (A, B) show images following administration of 50 and 75 μ g of each *fl* and *tk* DNA–lipid complexes via tail vein injection into CD-1 mice, respectively. Bioluminescent images (left images) were obtained 5 h after injection of the vector and 5 min after intraperitoneal injection of D-Luciferin. MicroPET images (right images) were obtained 24 h after vector delivery and 1 h after [18 F]FHBG injection. Control mice (left) optical images obtained prior to administration of D-luciferin. Optical and PET images demonstrate that lungs are primary organs for transgene expression. Increased dose of DNA–lipid complex results in greater pulmonary transgene expression. Activity seen in the kidneys in the microPET images is the result of excreted, unsequestered reporter probe, [18 F]FHBG. (Reproduced from Iyer, M., Berenji, M., Templeton, N.S., and Gambhir, S.S., *Mol. Ther.*, 6, 555, 2002. With permission.)

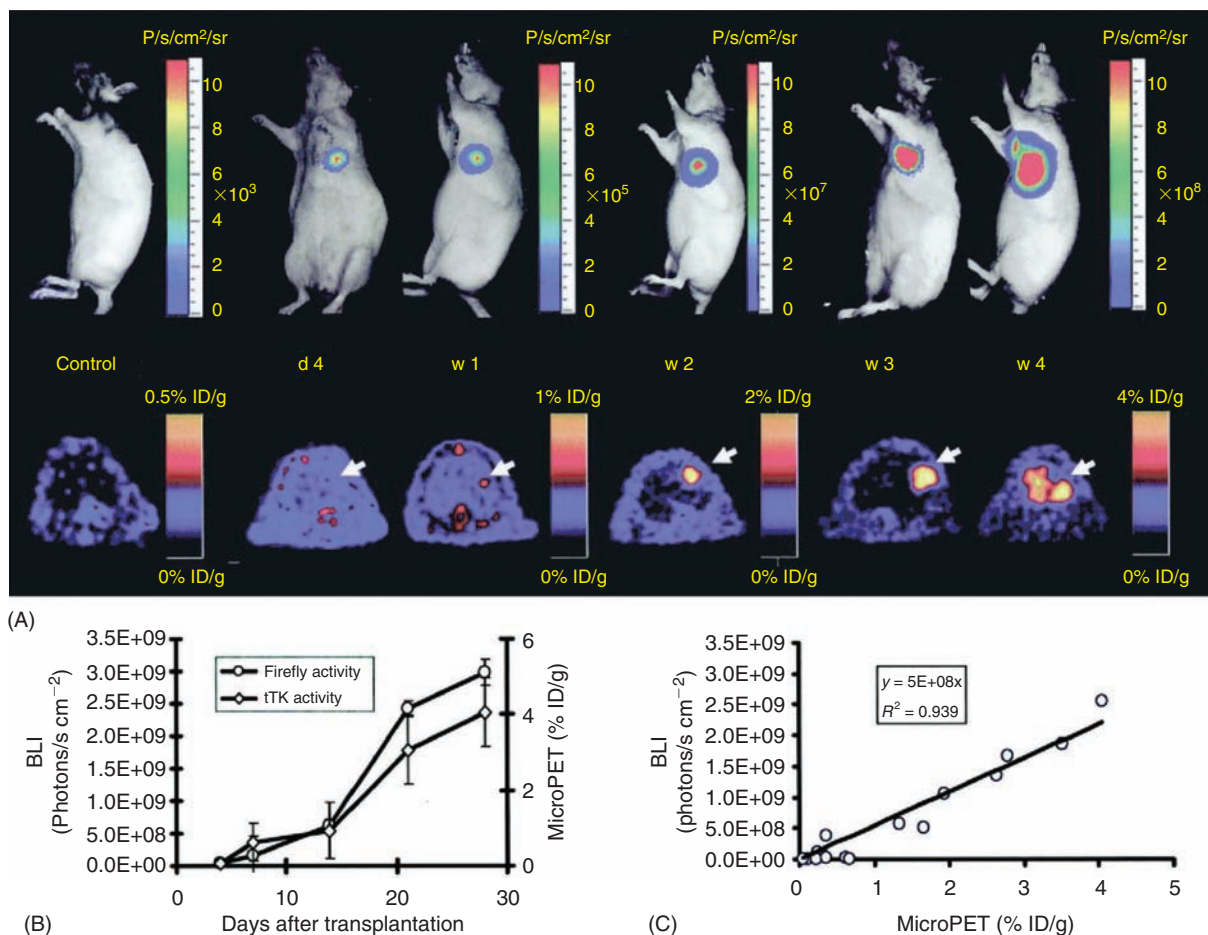

FIGURE 30.16 Molecular imaging of transplanted ES cells with bioluminescence and PET imaging. (A) Embryonic stem cells stably transduced with a triple fusion reporter gene *mrfp-fluc-ttk* were transplanted in the heart of athymic rats. Animals were subsequently imaged for 4 weeks to assess cell survival. A representative study animal is shown in the figure. Significant bioluminescence (top) and PET (bottom) signals were observed at day 4, week 1, week 2, week 3, and week 4 following transplantation. In contrast, control animals had background activities only. (B) Quantification of imaging signals showed a drastic increase of fluc and ttk activities from week 2 to week 4. Extracardiac signals were observed during subsequent weeks. (C) Quantification of cell signals showed a robust *in vivo* correlation between bioluminescence and PET imaging ($r^2 = 0.92$). BLI indicates bioluminescence. (Reproduced from Cao, F., Lin, S., Xie, X. et al., *Circulation*, 113, 1005, 2006. With permission.)

FIGURE 30.17 Noninvasive imaging of T-cell trafficking following adoptive transfer. Tumors were implanted subcutaneously on the shoulders of the mouse in the figure: A Moloney murine sarcoma virus–Moloney murine leukemia virus (M-MSV/MMuLV) tumor on its left shoulder and a control P815 tumor on its right shoulder. T-cells from an animal carrying an M-MSV/M-MuLV tumor were transfected with a retrovirus expressing both the HSV1sr39Tk and GFP reporter proteins. Transfected cells were first sorted by FACS and then injected intraperitoneally into the mouse bearing the M-MSV/M-MuLV and P815 tumor, and the animals were imaged by microPET following [¹⁸F]FHBG injection. Homing of the cells to the M-MSV/M-MuLV tumor, but not the P815 tumor, was apparent within day 13 of injection. (Reproduced from Dubey, P., Su, H., Adonai, N. et al., *Proc. Natl. Acad. Sci. USA*, 100, 1232, 2003. With permission.)

FIGURE 30.18 Indirect PET imaging using a bi-directional transcriptional approach. (A) Target (therapeutic) gene expression can be measured indirectly by imaging reporter gene expression if expression of the two genes is linked. Both genes can be simultaneously expressed from two minimal CMV promoters that are regulated by a single bidirectional TRE. The rTetR–VP16 fusion protein is produced constitutively from a CMV promoter. When the rTetR–VP16 fusion protein binds doxycycline, this complex binds to the TRE regulatory sequence and substantially enhances expression from the two minimal CMV promoters. The target gene A in one coding region and a reporter gene (for example, a reporter kinase such as HSV1-*sr39tk*) in the alternative coding region are transcribed simultaneously into two mRNA molecules. Translation of the two mRNA molecules yields two distinct proteins in amounts that are directly correlated with each other.

FIGURE 30.18 (continued) (B) Quantitative imaging of the locations and magnitude of PET reporter gene expression by trapping of a PET tracer inside the cell (for example, by phosphorylation of [¹⁸F]FHBG by the HSV1-sr39TK reporter protein) provides an indirect measure of target gene expression. Sequential microPET imaging studies of a nude mouse carrying four tumors. Four tumor cell lines, two positive controls (constitutive reporter gene expression), one negative control, and one inducible line (reporter gene expression) induced by doxycycline, were injected subcutaneously into four separate sites in a single mouse. When tumors reached a size of at least 5 mm, the mouse was imaged with 9-(4-[¹⁸F] fluoro-3-hydroxymethylbutyl)guanine ([¹⁸F]FHBG). Doxycycline was then added to the water supply for 7 days. The mouse was then scanned again with [¹⁸F]FHBG. Doxycycline was removed from the water supply for the next 7 days, and the mouse was again scanned with [¹⁸F]FHBG. The locations of the four tumors and the mouse outline are shown by the dotted regions of interest. All images are 1–2 mm coronal sections through the four tumors. The % ID/g (% injected dose per gram tissue) scale for [¹⁸F]FHBG is shown on the right. The negative control tumors show no gene expression and the positive control tumors show increased expression over the time course. The tumor on the top right, with inducible gene expression, initially does not accumulate [¹⁸F]FHBG, then at 7 days after addition of doxycycline, induction of reporter gene expression traps [¹⁸F]FHBG. Seven days after withdrawal of doxycycline, there is decreased induction and minimal trapping of [¹⁸F]FHBG. The [¹⁸F]FHBG image signal correlates well with target gene expression (not shown). (Reproduced from Gambhir, S.S., *Nat. Rev. Cancer*, 2, 683, 2002. With permission.)

FIGURE 39.1 Stereotactic delivery of an HSV amplicon vector expressing β -galactosidase into the mouse striatum. Mice were injected with 1×10^5 transduction units of HSVlac using a microprocessor-controlled pump. Animals were sacrificed and perfused 4 days post-transduction and X-gal histochemistry was performed on $40\mu\text{m}$ sections. Sections representative of the injection site (Panel A), a site anterior of the injection (Panel B), and a site posterior of the injection (Panel C). All sections were counterstained with thionin and acquired at a magnification of $2.5\times$. The photomicrographs indicate that focal delivery of a viral vector can be achieved within the brain. (From Brooks, A.I., et al., *J. Neurosci. Methods*, 80(2), 137, 1998. © 1998 Elsevier Science B.V. With permission.)

FIGURE 39.3 Immunohistochemistry of AADC in hemilesioned monkeys before and after AAV-hAADC treatment. (A) Three $[^{18}\text{F}]$ FMT PET coronal images of an AAV-hAADC-treated monkey striatum at 18 months show the strongest AADC transgene expression in targeted area (midstriatum) and correlate with AADC immunostaining. (B–D) In (B) and (C), color-coded immunostaining against TH and AADC in progressive anterior to posterior coronal slices in two representative AAV-hAADC monkeys is shown at 3 years after AAV delivery. (D) shows TH and AADC staining in a representative AAV-LacZ monkey at 2 years after AAV delivery. The pattern of TH and AADC immunoreactivity, normally colocalized in intact dopaminergic pathways, is very different in these MPTP-lesioned animals. Note the dramatic reduction of anti-TH staining in the right striatum of all animals compared to the intact left side, confirming profound loss of dopaminergic fibers and terminals on the lesioned side (B–D). Anti-AADC staining shows endogenous AADC in the nonlesioned, left striatum and almost complete restoration of the enzyme within the right striatum of AAV-hAADC animals, demonstrating widespread distribution of AADC transgene expression (B and C). No such AADC staining or $[^{18}\text{F}]$ FMT PET signal is seen on right side of control animals (D). The box in the PET image in (D) indicates the region of infusion of AAV-LacZ. (From Bankiewicz, K.S., et al., *Mol. Ther.*, 14(4), 564, 2006. © 2006 The American Society of Gene Therapy. With permission.)

FIGURE 39.4 Delivery of a lentiviral vector expressing the GDNF gene in Parkinsonian nonhuman primates. Rhesus monkeys received the dopaminergic toxin MPTP unilaterally (right side) to establish a parkinsonian state. One week later, the animals received ipsilateral infusions of lentiviral vector expressing GDNF (lenti-GDNF) or one expressing the reporter protein β -galactosidase (lenti- β Gal). Three months following treatment the animals were sacrificed and immunohistochemistry was performed. Panels A and B depict low-power dark-field photomicrographs through the right striatum of TH-immunostained sections of MPTP-treated monkeys treated with lenti- β Gal (Panel A) or lenti-GDNF (Panel B). There appeared to be a comprehensive diminution of TH immunoreactivity in the caudate and putamen of lenti- β Gal-treated animals, while a nearly normal level of TH immunoreactivity was seen in the animals receiving lenti-GDNF. Low power (Panels C and D) and medium power (Panels E and F) photomicrographs are shown of a TH-immunostained section through the substantia nigra of animals treated with lenti- β Gal (Panels C and E) and lenti-GDNF (Panels D and F). Note the loss of TH-immunoreactive neurons in the lenti- β Gal-treated animals on the side of the MPTP infusion. TH-immunoreactive sprouting fibers, as well as an above normal number of TH-positive nigral perikarya, are observed in lenti-GDNF-treated animals on the side of the MPTP injection. Panels G and H depict bright-field low-power photomicrographs of a TH-immunostained section from a lenti-GDNF-treated monkey. Note the normal TH-immunoreactive fiber density through the globus pallidus on the intact side that was not treated with lenti-GDNF (Panel G). In contrast, an enhanced network of TH-immunoreactive fibers is seen on the side treated with both MPTP and lenti-GDNF. Scale bar in (G) represents the following magnifications: Panels A, B, C, and D at 3500 μ m; Panels E, F, G, and H at 1150 μ m. (From Kordower, J.H., et al., *Science*, 290(5492), 767, 2000. © 2000 AAAS. With permission.)

FIGURE 39.5 Trophic response to NGF in the human brain. (A,B) Nissl stain of autologous, NGF-secreting cell implant in brain of individual with Alzheimer's disease 5 weeks after treatment. Graft (g) adjacent to nucleus basalis of Meynert (nbm; arrows). Inset, robust mRNA encoding NGF by in situ hybridization within graft. Scale bar in (A) 247 μ m; in (B) 24 μ m. Note proximity of graft to nbm seen in similar perspective in c at higher magnification. (C,D) Immunocytochemistry for cholinergic neurons (p75) shows graft implant on left (g) and adjacent neurons of nbm (arrows). Higher magnification (d) shows dense penetration of cholinergic axons into graft. Scale bar in (C) 82 μ m; in (D) 11 μ m. (From Tuszynski, M.H., et al., *Nat. Med.*, 11(5), 551, 2005. © 2005 Nature Publishing Group. With permission.)

FIGURE 39.10 Injection of rAAV-GDNF markedly reduces cortical infarction induced by middle cerebral arterial ligation in rats. The right middle cerebral artery and bilateral common carotid arterial were occluded for 90 min. Animals received a PBS, rAAV-lacZ (10^{10} viral particles), or rAAV-GDNF (10^{10} viral particles) unilateral infusion during arterial occlusion, were sacrificed 72 h later, and their brains were coronally sectioned (2 mm thickness) for TTC staining. White areas represent infarcted zones in the cerebral cortex. Rats receiving rAAV-GDNF exhibited a marked reduction in infarct size as compared to animals receiving the rAAV-lacZ or PBS control. (From Tsai, T.H., et al., *ExNeurol.*, 166(2), 266, 2000. © 2000 Elsevier Science B.V. With permission.)

FIGURE 39.11 Representative photographs of pyramidal neurons in the hippocampal CA1 regions after treatment (4 and 6 h after ischemia) with SeV vector following ischemic injury. Sham-operated gerbils (A), SeV/GDNF (B,E), SeV/NGF (C,F), or SeV/GFP (D,G) were administered intraventricularly 4 h (B,C,D) or 6 h (E,F,G) after ischemic insult. The sections were stained with hematoxylin and eosin. Scale bar = $50\mu\text{m}$. (From Shirakura, M., et al., *Gene Ther.*, 11(9), 784, 2004. © 2004 Nature Publishing Group. With permission.)

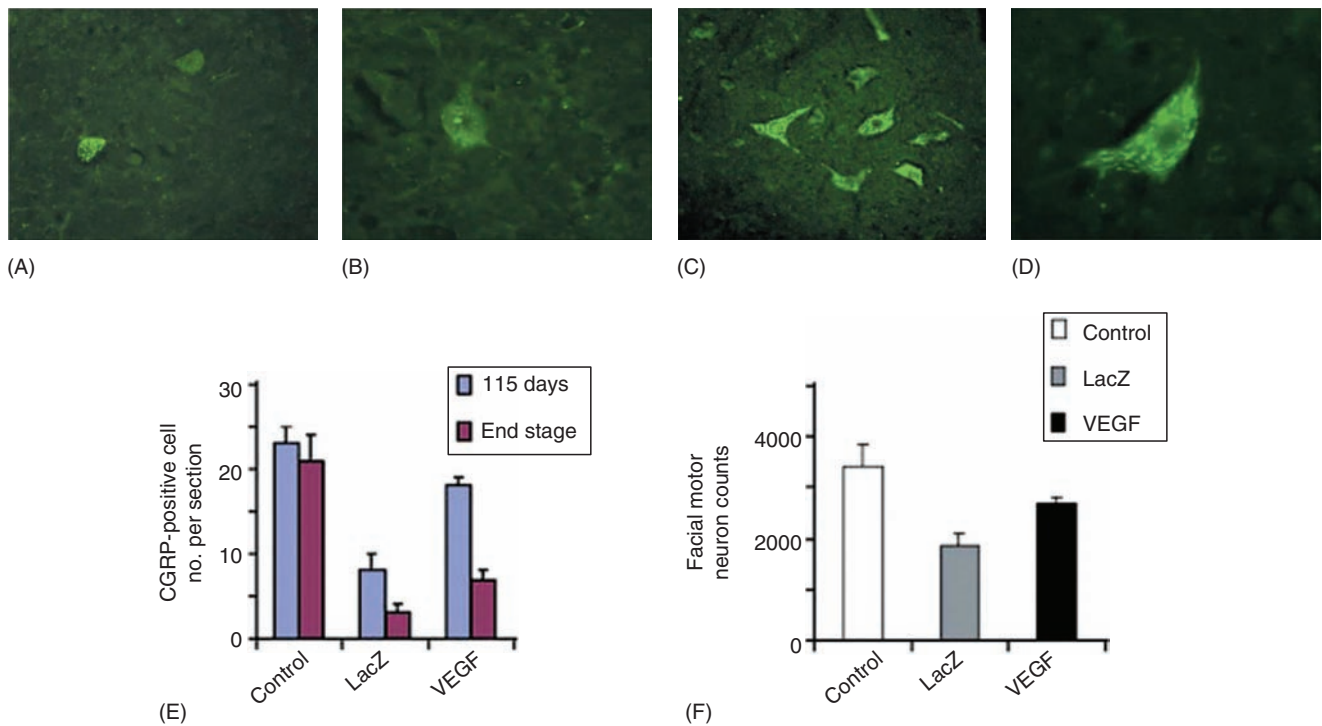

FIGURE 39.13 VEGF gene therapy protects spinal and brainstem motor neurons in $SOD1^{G93A}$ transgenic mice. (A)–(D) Immunohistochemistry showing CGRP-positive neurons in lumbar spinal cord of EIAV-LacZ (A,B) and EIAV-VEGF injected animals (C,D). (E) Cell counts of surviving lumbar spinal cord motor neurons in control (wild-type), EIAV-LacZ, and EIAV-VEGF-treated $SOD1^{G93A}$ mice at 115 days of age (blue) and at the end stage of disease (red). (F) Quantification of facial nucleus motor neurons in animals injected with EIAV-LacZ, EIAV-VEGF, and control animals at the end stage of disease. FIGURE 44.3 Effective T cell activation by APC. The interaction between antigen-MHC and T cell receptor leads to the expression of IL-2 receptor. This T cell proliferates when the second signal is provided from APC's costimulatory proteins. CD28–CD80/CD86 ligation initiates the production of IL-2 production and leads to the proliferation of activated T cell.

FIGURE 44.8 Regulation of CD8⁺ T cell expansion by adhesion molecules and chemokines in the periphery. Specific adhesion molecules and chemokines provide modulatory signals to CD8⁺ T cells in effector stage. This network of cytokine, chemokine, costimulatory molecules, and adhesion molecules represents a coordinated regulation and maintenance of effector T cells in the periphery.

Intratumoral injection of Gendicine

(A) Injection of Gendicine under ultrasonic guidance

(B) Showing a strong echo after Gendicine injection

FIGURE 49.3 Injection of Gendicine.

Before Gendicine administration

2 Months after Gendicine treatment

Male, 67 years, suffering from SCC of lower lip, T4N2aM0, was enrolled into the group and treated with Gendicine in combination with chemotherapy (CP, BLM and MTX). Ten injections of Gendicine (4×10^{12} VP/injection, one injection every 5 days) and two courses of chemotherapy. The tumor showed complete clinical recovery.

FIGURE 49.5 Efficacy of Gendicine in combination with chemotherapy for treatment of advanced squamous cell carcinoma.

Eiomyosarcoma

Before Gendicine treatment

13 Months after 6 injections of Gendicine in combination with a 50 Gy radiation therapy

Tumor showing CR

After Gendicine treatment

Gene and Cell Therapy

Therapeutic Mechanisms and Strategies

Third Edition

A Major Step Forward in the Treatment of Intractable Diseases

Praise for the Second Edition

"... this book is the most solid choice out there for sheer breadth and accessibility of information ... It's hard to imagine anyone doing a better job on content. The editors and authors should be commended."

—*Molecular Therapy*

Since the publication of the second edition of this book in 2004, gene therapy and cell therapy clinical trials have yielded some remarkable successes and some disappointing failures. Now in its third edition, *Gene and Cell Therapy: Therapeutic Mechanisms and Strategies* assembles many of the new technical advances in gene delivery, clinical applications, and new approaches to the regulation and modification of gene expression.

New Topics Covered in this Edition:

- Gene and Cell Therapies for Diabetes and Cardiovascular Diseases
- Clinical Trials
- Human Embryonic Stem Cells
- Tissue Engineering Combined with Cell Therapies
- Novel Polymers
- Relevant Nanotechnologies
- siRNA Therapeutic Strategies
- Dendrimer Technologies

Comprised of contributions from international experts, this book begins with a discussion of delivery systems and therapeutic strategies, exploring retroviral vectors and adenovirus vectors, as well as other therapeutic strategies.

The middle section focuses on gene expression and detection, followed by an examination of various therapeutic strategies for individual diseases, including hematopoietic disorders, cardiovascular conditions, cancer, diabetes, cystic fibrosis, neurological disorders, and childhood-onset blindness. The final section discusses recent clinical trials and regulatory issues surrounding the new technology.

This compendium is assembled by noted molecular biologist and biochemist Nancy Smyth Templeton. Her contributions, as well as those contained in this volume, are sure to advance the state of the art of these revolutionary life-saving technologies.
